Capacitor Cl, resistor R1, and capacitor C2 form a low-pass R-C filter network. Potentiometer (variable resistor) R2 is the diode load resistor, and also the manual volume control for the receiver. The setting of potentiometer R2 determines the amplitude of audio output signal which is coupled by capacitor C4 to succeeding amplifier stages. Resistor R3 and capacitor C3 form an R-C network to filter the dc voltage applied to the controlled stages as automatic bias.

The operation of a typical detector (demodulator) circuit is given in the circuit analysis portion of Diode Detectors, in the Detector Section of this Handbook, and may be reviewed at this time if desired. Thus, for the purpose of this discussion, it is sufficient to say that a dc voltage which varies in amplitude according to the modulation frequency is developed across

diode load resistor R2 whenever a modulated signal is applied to the input of the detector circuit. The polarity of the rectified voltage is given on the simplified schematic diagram.

The R-C network consisting of resistor R3 and capacitor C3 is connected to the junction of resistors RI and R2. The negative voltage at this point is a dc voltage with an alternating component which is the result of amplitude modulation present on the r-f signal. The purpose of resistor R3 and capacitor C3 is to remove the modulation components so that a steady dc voltage is available as a bias voltage for the controlled stages of the receiver.

Assume for the moment that a weak signal is being received. In this case the voltage developed across diode load-resistor R2 will be a small voltage, and the resulting AGC output voltage will also be small; therefore, the value of grid bias voltage applied to the controlled stages will be small, and the gain of controlled stages will be reduced only a slight amount.

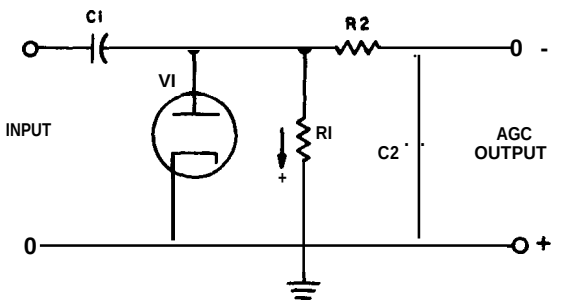
Next, assume that a moderate signal is being received. In this case the voltage developed across diode load resistor R2 will increase in value, and, as a result, the value of grid bias voltage applied to the controlled stages will also increase; thus, the gain of the controlled stages will be further reduced.

Now, assume that a strong signal is being received. In this "case the voltage developed across diode load resistor R2 will increase considerably, and, as a result, the bias voltage applied to the controlled stages will also increase; thus, the gain of the controlled stages will be still further reduced.

From the three signal input conditions just described, it can be seen that as the strength of the input signal to the receiver increases, the detector output and the value of the control voltage increase as a result, and, to offset the increase in input signal strength, the over-all gain of the receiver is reduced. Conversely, as the strength of the input signal to the receiver decreases, the detector output and the value of the control voltage decreases as a result, and, to offset the decrease in input signal strength, the over-all gain of the receiver is increased.

The effect of an automatic bias control voltage is to "level out" the response of the receiving system. Thus, the change in receiver output for a given change in input signrd is always less with an AGC circuit than it is without an AGC circuit.

A simple AGC circuit which is independent of the detector (demodulator) diode is illustrated in the accompanying schematic; this circuit is a variation of the basic diode detector circuit discussed previously in the Detector Section of this Handbook. The diode, V1, is not used to demodulate the signal; instead, it is used only as a half-wave rectifier to obtain an AGC voltage which is proportional to the input signal. The diode may be a separate electron tube, or may be included within the envelope of a multipurpose tube. Capacitor Cl is an r-f coupling capacitor, and is normally connected to a relatively high-impedance signal source, such as the plate of the detector (demodulator) diode or the plate of the last i-f amplifier tube. The dc output voltage is developed across diode load resistor R1 as a result of signal rectification by diode VI. Resistor R2 and capacitor C2 form an R-C network to filter the dc voltage applied to the controlled stages.



Simple AGC Diode Circuit

The main disadvantage of the two AGC circuits just described is that ***all*** received signals-including weak signals–will develop AGC voltage. Thus, even a very weak signal will produce a small amount of AGC voltage, causing a reduction in the over-all receiver gain at a time when maximum gain is desired.

Failure Analysis.

General. Before suspecting trouble in the AGC circuit, it must first be established that the detector (demodulator) circuit and the r-f and i-f amplifier circuits are functioning normally. Checks must be made to determine whether there are any shorted, leaky, or open components in the R-C networks of the controlled stages (either series- or parallel-fed). Defective components in these networks will affect the AGC voltage distribution, the AGC circuit time constant,

and perhaps the resonance and selectivity of the tuned coupling circuits.

No AGC Voltage. The AGC voltage no-output condition is generally caused by a failure in the detector (demodulator) circuit, and is usually accomplished by a lack of detector output. Since the AGC circuit is often a part of the detector circuit, the correct operation of the detector should be determined (as given in the Detector Section) before investigating the AGC circuit for a possible failure. An exception to this procedure is the case where a diode which is independent of the detector (demodulator) diode is used to obtain AGC voltage. The procedure for failure analysis of the independent AGC diode circuit is essentially the same as the procedure given for the detector (demodulator) diode circuit,

In either the simple AGC circuit or th independent AGC diode circuit, if the output capacitor of the R-C filter network is shorted, the AGC output voltage will be developed across the filter resistor, and, therefore, no AGC voltage will be applied to the controlled stages.

Because AGC circuits are nearly always low-voltage, high-impedance circuits, it will be necessary to use a suitable vacuum-tube voltmeter when making AGC voltage measurements.

Low AGC Voltage. Low AGC voltage will result in greater than normal over-all receiver gain, and will often cause distortion when a strong signal is received. With a known r-f or i-f signal (either modulated or unmodulated) applied to the input of the receiver or to the input of the detector circuit, a dc voltage measurement should be made across the diode lead resistor to determine the value of negative AGC voltage present. (AGC voltages should always be measured with a suitable vacuum-tube voltmeter.) A second voltage measurement should then be made at the output terminals of the AGC circuit (across the output capacitor of the R-C filter network) to determine whether the voltage at the output is the same value as the voltage measured at the input to the R-C filter network. If the output voltage measured is less than the input voltage, it is likely that a voltage-divider action is taking place, causing a current to flow in the circuit, with a consequent voltage drop across the filter resistor. In this case, the output capacitor of the R-C filter network may be leaky, or the capacitors, tuned circuits, or other impedances in the controlled stages may have leakage paths to ground (chassis). Measurements may be made throughout the voltage distribution system to determine the points at which voltage-divider action is occurring, in order to further isolate the faulty component. As an alternative, the circuit connection at the output of the R-C filter network, sometimes referred to as the AGC bus, should be disconnected to isolate the controlled stages; the components of the networks associated with these stages should then be checked by means of resistance measurements to locate the faulty component(s) in the voltage distribution system.

EMITTER-CURRENT CONTROL AGC

Application.

Emitter-current control of AGC is universally used in transistorized receivers to keep the output voltage relatively constant regardless of input signal variations.

Characteristics.

To control a PNP transistor, AGC circuit requires a positive voltage which increases as receiver input signal increases; to control an NPN transistor, it requires a negative voltage which increases as input signal increases.

For CE configuration, provides 18 dB control for first decade of emitter current variation, decreasing to half this value for successive decades (for CB configuration, the range is approximately 5 dB less).

Uses base bias voltage variation to provide dc amplification of control signal.

When transistor amplifier is directly controlled by control source (detector), the source must be capable of supplying full emitter current of transistor amplifier.

Resistive component of input impedance increases as CE emitter current decreases.

Input and output capacitance decreases as signal strength increases, and this decrease shifts center tuning frequency upward.

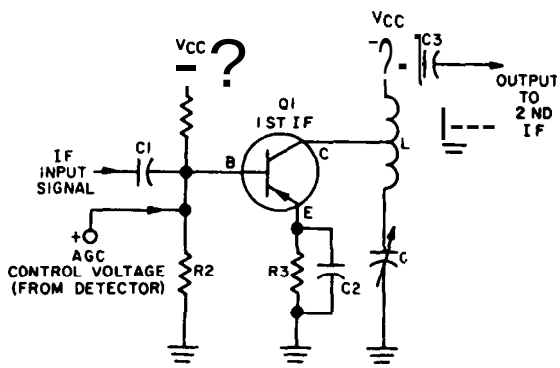
Circuit Analysis.

General. The emitter-current controlled AGC circuit operates normally with maximum gain at zero input signal. As the input (detected) signal increases in strength, the emitter current of the controlled amplifier is reduced. Hence, the gain of the transistor is also reduced. Therefore, with a large input signal the emitter-current controlled amplifier operates at a very

low level. As a general rule, currents above **500** microampere have little control over the gain; that is, the gain variation for currents over 500 microampere is so slight that the circuit provides too small a range of control to be useful. However, as the emitter current is reduced below 500 microampere, the over-all gain is greatly affected. The most effective control action is obtained over a current range of 10 to 100 microampere (as illustrated by the emitter current control curve shown above).

Since the emitter current operates over a very small current range for large input signals, distortion is produced by detector nonlinearity. Over the middle range of operation the detector is linear and little distorion is produced. At very low levels of input signal, distortion again occurs because of detector nonlinearity in the small-signal region.

Circuit Operation. The accompanying figure shows a typical emitter-current controlled amplifier.



Emitter-current Controlled Amplifier

Capacitor Cl is a dc blocking and ac coupling capacitor which prevents the low dc resistance of the input transformer from shorting the base and bias network to ground. Resistors RI and R2 provide fixed voltage-divider bias for the base circuit. Since the base is negative with respect to the emitter, forward bias is applied. The AGC control signal is also applied to the base, and consists of a positive voltage which increases as the signal at the detector increases. When the control voltage increases, the total forward (negative) bias on the base is reduced, and the emitter current is reduced accordingly. Emitter swamping is provided by R3 (by-passed by C2) to provide temperature stabilization of the amplifier (refer to the discussion of Bias Stabilization in the introduction to Amplifiers in this Handbook for a discussion of emitter swamping and voltage-divider biasing). The collector is tapped down on inductor L of the series-tuned resonant output circuit, consisting of L and C, to provide proper matching. The output circuit is tuned to provide maximum gain and selectivity at the intermediate frequency. Capacitor C3 is a dc blocking and ac coupling capacitor for the next stage (a transformer may be used in place of L, C, and C3 if desired).

Consider now the dynamic operation of the circuit. Normally Q1 is resting, with the base biased for class A operation by voltage divider R1 and R2. Emitter and collector current values are normal class A values for quiescent conditions. When an i-f signal is applied between base and ground through Cl, normal **CE** amplifier action occurs (assuming, of course, that no AGC voltage is applied from the control circuit). This, then, is the condition for no AGC where the amplifier operates at full gain with a very weak input signal. It is further assumed that the AGC control circuit is inoperative because of delayed AGC since the circuit is normally almost instantaneous in action. For this condition the emitter dc current is at its maximum value. As amplification occurs, the instantaneous emitter current varies (decreases for the positive portion of the signal and increases for the negative portion). Since both positive and negative variations of signal are equal (assuming a sine wave), there is no average change in emitter current. The instantaneous i-f variations, however, are amplifed and appear in the collector circuit (refer to the discussion of Tuned Interstage Amplifiers in the Amplifier Section of this Handbook for a complete discussion of normal amplifier action). As far as the amplifier is concerned, R3 is effective only for temperature variations, because it is by-passed by C3 for i-f signals. When the amplified signal appears in the detector, a dc voltage is developed, in addition to the demodulated signal. This dc voltage is proportional to the carrier strength and is taken at a point in the detector which provides an increasingly positive dc voltage for an input signal which is increasing (for PNP transistors). Assume that the input signal level rises to a point where the detector positive AGC control voltage exceeds the delay voltage and provides a positive dc voltage to the base of the transistor. Since the base

of the transistor is negatively biased, the positive control voltage adds algebraically to reduce the total forward bias. Consequently, hole flow through the transistor is reduced, and the emitter current is reduced accordingly. (Both base and collector currents are reduced.) Therefore, the transistor forward current gain and the effective amplification of the transistor are reduced. Under these conditions, the transistor still amplifies the i-f signal, but not as much as before the forward bias was reduced. Thus, as the input signal increases, the output of the transistor is decreased. When the input signal becomes weaker, the detector control voltage is decreased, the forward bias, in turn, is increased, and the amplifier produces a greater output signaL In this manner, the output of the amplifier is controlled by the input voltage, which automatically controls the gain of the transistor amplifier.

The over-all power gain is contingent upon matched input (and output) conditions. When the base current is reduced by AGC action, the effect is the same as though the input resistance of the transistor were increased ($R_{in} = V_{in}/I_{in}$). The output impedance also changes, but not as much as the input impedance. Thus a mismatched input and output condition results. Such a condition enhances the control action and provides more effective AGC control. Where insufficient range of control is provided by a single stage, more than one stage of control is used. However, this is the exception rather than the rule, since cutoff bias may be reached on extremely strong signals, or AM modulated signals may be compressed to the point where actual suppression of modulation occurs (FM signals are not affected by this amplitude suppression action).

Another design problem is introduced by the change of input and output capacitance with signal strength. In the CE circuit, both capacitances *decrease with strong* signals. *As a* result, the *center* frequency of the tuned output circuit is shifted upward. (In the CB circuit this effect is exactly opposite, and a downward shift is produced.) As the design of transistors improves, it is probable that types similar in action to the remote cutoff electron tube will be developed and used in AGC circuits. At present, however, the action is the same as that of a sharp cutoff tube, so that control amplifiers must be restricted to handling fractional powers to avoid blocking and distortion, and some circuit detuning must be expected.

Failure Analysis.

No Output. Usually a no-output indication is produced only by an open- or short-circuited condition in the controlled stage. Observation of the signal using an r-f probe and oscilloscope will indicate where the signal disappears. Once this is determined, a resistance or voltage analysis of that portion of the circuit should reveal the defective component.

Low Output. If excessive bias is produced, cutoff current may be reached, or the signal may be reduced so much that little range of control is offered. In such cases the increase in amplitude caused by AM modulation can cause suppression of modulation. Such a condition can be observed on an oscilloscope. If oscillations occur in the controlled stage, a preceding stage or a following stage, an excessively strong input signal to the detector will result, and the control stage may be biased off. Removal of the input signal would cause the gain to increase, as evidenced by an increased noise output with no signal present. If an output signal is still observed, the signal is being produced internally through feedback, and it will probably be necessary to temporarily disconnect each stage preceding the detector and control amplifier from its collector supply to locate the defective stage. An alternative method for an experienced technician is to quickly short-circuit the input or output of a stage to determine whether the oscillation ceases. Do ***NOT*** short-circuit the input to output to ground, or the transistor rating may be exceeded or the heavy current produced may cause the delicate i-f transformer winding to open.

Distortion. The changing of the input and output impedances and capacitances by changes in signal strength will cause a shift in the tuned frequency and the overall circuit Q. Therefore, it is to be expected that some distortion will occur, particularly on quickly varying strong signals. If the distortion is continuous, an improperly operating circuit or a defective transistor may be the cause. Use an oscilloscope, and simulate a varying input signal by means of a signrd generator connected to the input circuit. Observation of the waveform at various points in the circuit should indicate the defective portion, whereupon a resistance analysis will isolate the defective component in this portion of the circuit. If the waveforms preceding and following the controlled amplifier are identical except for amplitude, the distortion is probably occuring in later stages and is not caused by the control circuit.

AUXILIARY DIODE CONTROL CIRCUIT (SEMICONDUCTOR)

Application.

Auxiliary diode control AGC circuits are used in conjunction with the regular limited range AGC circuit, normally employed in solid-state receivers, to provide additional AGC action when extremely strong signals are encountered.

Characteristics.

Provides considerable AGC action for strong signals.

Has little or no effect on weak or medium strength signals.

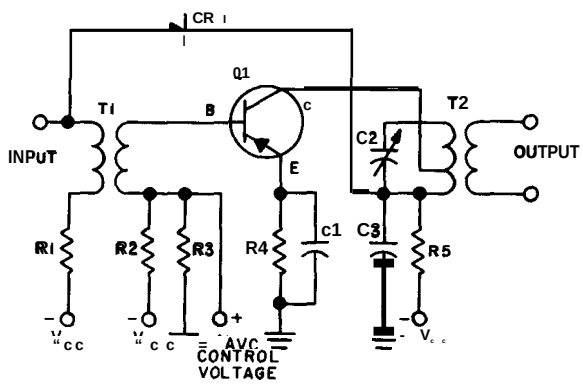
Utilizes a diode to shunt strong signals around one of the i-f amplifier stages, thereby decreasing system gain.

Auxiliary diode operation is indirectly controlled by the regular AGC circuit.

Circuit Analysis.

General. Automatic gain control circuits in the semiconductor field can be placed into two general classes. One class, referred to in this Handbook as standard AGC, uses a variation of bias on one or more of the transistor elements to control the gain of the receiver, while the other class employs a diode to shunt the input signal around the controlled stage to lower the gain of the receiver. The auxiliary diode AGC circuit operates on the latter principle, however, it is usually used in addition to a standard AGC system to obtain improved control, and to prevent the receiver from being overloaded when very strong signals are received, since the range of control of most standard AGC circuits is somewhat limited, especially at high input signal levels. In a receiver using both auxiliary and standard AGC, the auxiliary AGC circuit is controlled by the standard AGC circuit. When weak and medium strength signals are received the auxiliary AGC circuit is not operated, and the receiver output is held fairly constant through the action of the standard AGC circuit (which frequently uses emitter cm-rent control, although collector voltage control can be used, if desired). As the input signal increases beyond a predetermined point, the AGC control voltage increases to a level sufficient to forward bias the auxiliary diode AGC circuit, and the auxiliary diode conducts. The conducting diode provides a low impedance shunt around the standard AGC controlled stage, creating a great deal of additional AGC action. It is important to keep in mind that the auxiliary diode AGC circuit does not operate independently, rather it operates in conjunction with a standard AGC circuit, and its operation is controlled by the standard AGC circuit. A knowledge of standard AGC circuits, (emitter current control or collector voltage control) is helpful in the understanding of the auxiliary diode control circuit. For the interested reader, detailed information concerning these circuits is located in this section of this Handbook.

Circuit Operation. The following schematic diagram illustrates a typical emitter current controlled amplifier with auxiliary diode AGC.



Auxiliary Diode Control Circuit

Transformer T1 provides inductive coupling between the controlled amplifier and the preceding stage. Resistor RI, which is in the collector circuit of the preceding stage develops bias for the anode of auxiliary diode CR1. Resistor R2 together with resistor R3 form a base bias voltage divider between ground and the negative supply to forward bias the emitter base function of transistor Q1. Resistor R4, which is bypassed by capacitor Cl is a conventional emitter stabilization resistor which compensates for ambient temperature variation. Capacitor C2, together with the primary of transformer T2 forms a tuned output load for amplifier Ql, and the signal developed across the primary of T2 is inductively coupled to the secondary of T2 to the following

stage. Resistor R5 also develops cathode bias for auxiliary diode CR], and capacitor C3 shunts to ground any signal voltage that may be developed across R5. Resistor R5 should not be confused with the resistor used in the collector voltage control AGC circuit since the value of R5 is insufficient to achieve collector voltage control.

When there is no signal input to the receiver, there is no voltage developed. Auxiliary diode CRI is normally back biased by the voltage drop across R5 caused by the quiescent collector current of Q], and by the higher negative voltage, applied to RI and the collector of the preceding converter stage. Component values are such that the voltage across R1 exceeds the voltage drop across R5 thereby back biasing (or reverse biasing) auxiliary diode CR1, since the cathode of CR1 is less negative than the anode. When an input signal is applied to the receiver, AGC voltage is produced by the receiver detector and is coupled to the controlled stage, or stages. This AGC voltage, which is in the form of a dc voltage, is directly proportional to the average carrier power received by the receiver. However, delayed AGC is usually used and the AGC voltage must exceed a fixed "delay voltage" also called the "threshold voltage" before AGC voltage is applied to the controlled stage. In this manner the receiver gain is maintained at a maximum, since there is no AGC action when weak signals which are below a predetermined level are received. Assume that a signal is received which is of sufficient amplitude to overcome the AGC delay voltage. The positive AGC voltage (positive AGC voltage is used with PNP transistors, negative voltage is used with NPN transistors) developed in the receiver detector is applied to the junction of bias voltage divider R2, R3 and decreases the forward bias applied to the emitter base junction of Q1. The conduction of Q1 decreases, resulting in a decrease in gain of the stage. Decreased conduction of Q1 also results in a decreased voltage drop across R5 which in effect decreases the original back bias applied to diode CR1. As the strength of the input signal increases the level of the AGC voltage increases, resulting in a further decrease in conduction of Q1 and a further decrease in the voltage drop across R5. When the voltage drop across R5 no longer exceeds the voltage drop across R1 (that is the anode of CR1 becomes more positive than the cathode) auxiliary AGC diode CR1 is no longer back biased. CRI then conducts, and provides a low impedance (shunt) path around IF amplifier stage Q1. Much of the IF signal generated in the converter stage is then shunted around Q1 through CR1 and C3 to ground, providing additional AGC action (signal reduction). Component values are usually chosen so that the auxiliary diode is back biased for all but very strong signals.

Failure Analysis.

Generel. When making voltage checks use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low voltage ranges of the standard 20,000 ohm-per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No Output. No output from the auxiliary diode AGC controlled amplifer could be caused by defective power supply voltage, defective transistor or diode, or by a defective circuit component. Check the power supply voltage with a VTVM. If the transistor is not defective, a defective circuit component is more likely the cause of no output. An open emitter, base, or collector circuit, or a shorted base or collector circuit, would render Q1 inoperative and no output would result. With the power removed, check the base and collector circuits for a possible short to ground with an ohmmeter, and check R2, R3, R4, and R5 for an open. Also check the secondary of T1 and the primary of T2 for an open, and check C2 and C3 do for a possible short. A defective auxiliary diode or a change in value of circuit components is more likely to cause a low output condition, rather than a no output condition to exist.

Low Output. If oscillations occur in the controlled stage, or in a stage following the controlled stage, there could be excessive input to the detector and the resultant excessive AGC voltage produced by the detector could greatly reduce the gain of the controlled stage causing a low output condition to exist. Oscillation of this type usually result in excessive receiver noise, in addition to low output. If an output signal is present with no input applied to the receiver, oscillations are probably being produced internally through feedback and it will probably be necessary to temporarily disconnect each stage, preceding the detector, from its collector supply to locate the oscillating stage. Improper power supply voltage, a defective transistor or auxiliary diode, or a defective circuit

component which alters the bias on either the transistor or auxiliary diode could also cause a low output condition to exist. Check the power supply voltage and adjust if necessary. Check the front to back ratio of the diode. If proper operation is not restored a defective circuit component is probably the cause of of low output. A change in the value of either RI or R5 could alter the bias applied to auxiliary diode CR1, possibly causing CR1 to conduct continuously, and greatly reduce the gain of the contolled stage for all input signal levels. A change in value of either R2, R3, or R4, would alter the emitter base bias of Q1 and could also reduce the gain of the stage for all input signal levels. If Cl opens, the resulting degeneration across R4 could rdso lower the gain of the stage. If C2 or C3 become leaky low output could also result. All resistors should be checked for proper value with an ohmmeter and all capacitors with an in-circuit capacitor checker if the trouble cannot otherwise be located.

Distorted Output. Some distortion may occur in AGC controlled stages, since the input and output impedances vary as the gain of the stage is varied by the AGC circuit. The condition may be especially noticeable on quickly varying strong signrds. However, if distortion is continuous an improperly operating circuit or a defective transistor usually is the cause. A resistive analysis, with the power removed, should reveal the component at fault.

COLLECTOR VOLTAGE CONTROL CIRCUIT (SEMICONDUCTOR)

Application.

Collector voltage control AGC is one method of AGC control used in transistorized receivers to keep the output level relatively constant regardless of input signal strength variations.

Characteristics.

Automatic gain control is achieved by varying the collector voltage applied to an i-f amplifier stage.

When PNP transistors are used, the AGC voltage must be negative. For NPN transistors a postive AGC voltage is required.

Circuit Analysis.

Generel. The power gain of a common emitter amplifier may be varied by varying the dc collector voltage of the amplifier. This principle is the basis of collector voltage automatic gain control. By applying AGC voltage to the base of the controlled amplifier the dc emitter current is varied which in turn varies the dc collector current. Variation of dc collector voltage (which varies the amplifier power gain) is accomplished by passing the dc collector current through a series resistor in the collector circuit. An increase in dc collector current results in an increased voltage drop across this collector resistor, which lowers the collector voltage and the gain of the amplifier decreases. In the collector voltage control AGC system as in other AGC systems, over all receiver gain is maximum for weak signals and is decreased by AGC action when stronger signals are received, so that the receiver output remains fairly constant.

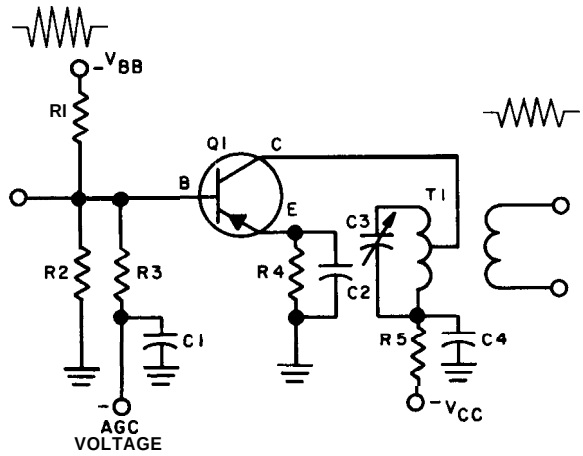
It is interesting to note the similarities and differences between emitter-current control and collector-voltage control. Circuitwise they are quite similar, the major difference betweem them is the addition of a large resistor in the collector circuit of the collector voltage control AGC circuit. In both circuits the AGC voltage is applied to the base of the transistor, however, each circuit uses a different polarity AGC voltage. The AGC voltage in the collector voltage controlled circuit is polarized so that it increases the forward bias at the emitter base junction, when a stronger signal is received (as the carrier increases), thereby increasing conduction of the transistor. Thus, an increased voltage drop occurs across the collector resistor as the forward bias increases the collector current, resulting in a decrease of voltage at the collector. This decresase of collector voltage, in turn, lowers the power gain of the amplifier.

In contrast, the AGC voltage applied to the emitter current control AGC circuit, is of such a polarity as to decrease the forward bias at the emitter base junction, when a stronger signal (carrier) is received. As the forward bias is reduced, the conduction of the transistor decreases. Since there is no large series resistor in the collector circuit of the current controlled AGC circuit, the only resistance offered to the flow of collector current is the normally low dc resistance of the output transformer; therefore, the collector voltage remains practically constant despite the change of collector current. The gain of the amplifier, however, decreases since the emitter current decreases. Hence it is seen that the current controlled AGC circuit operates near the region of

4

emitter current cutoff, while the voltage controlled AGC circuit operates near the limits of collector current saturation. As a result, transistorized AGC circuits also usually used a strong signal, shunting device such as an auxiliary diode to secure effective AGC action over large ranges.

Circuit Operation. The following schematic diagram illustrates a typical collector voltage automatic gain controlled amplifier.



Colleetor Voltage Controlled Amplifier

Resistor R1 together with resistor R2 forms a base bias voltage divider between ground and the negative supply, to furnish fixed forward bias to the emitter base junction of Q1. The negative AGC control voltage from the detector is applied to the base of Q1 through decoupling resistor R3 and both R2 and R3 are bypassed by Cl. Resistor R4, which is bypassed by capacitor C2 is a conventional emitter stabilization resistor, sometimes called a "emitter swamping" resistor, intended to prevent transistor operational characteristics from varying with changes in temperature. Collector voltage control is achieved by the addition of resistor R5 to the collector circuit of Q1. Capacitor C3 together with the primary of output transformer T1 forma tuned output load for amplifier Q1. Capacitor C4 in conjunction with collector voltage control resistor R5 also forms an i-f decoupling network to prevent if energy from feeding back into the power supply.

With no signal input the conduction of Q1 is determined by the fixed forward bias applied to the base of Q1 by base bias voltage divider R1, R2. There is no detector output and hence no AGC voltage is developed. The gain of the controlled stage is at a maximum since the voltage drop across collector voltage resistor R5 is at a minimum and the voltage applied to the collector of Q1 is, therefore, maximum. W'hen a signal of sufficient strength to produce a detector AGC output large enough to overcome the AGC delay voltage is received an AGC control voltage is applied to the base of controlled amplifier Q1. The polarity of this voltage is such as to increase the forward bias applied to the base of the transistor. In this case controlled amplifier Q1 is a PNP transistor and the AGC control voltage is, of course, negative. Conduction of Q1 is increased and the resultant collector voltage drop across R5 increases, reducing the actual voltage applied to the collector of Ql, and thereby reducing the gain of the amplifier. The receiver output remains relatively constant since a further increase in input signal strength tends to increase the AGC control voltage. This results in a further increase in conduction of Q1 and an increased voltage drop across R5. As a consequence, the collector voltage of Q1 decreases and the gain of the controlled amplifier is, again, lowered.

Collector voltage control is not frequently used because of the low vahre of collector voltage applied to the transistor. At low collector voltages the collector capacitance is increased and consequently the alpha cutoff frequency is reduced, making the transistor a poor r-for i-f amplifier.

Failure Analysis.

General. When making voltage checks, use a vacuum tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of a standard 20,000 ohms per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No **Output. No output** from the collector voltage controlled amplifier could be caused by defective power supply voltage, a defective transistor, or by a defective circuit component. Check the power supply voltage. An open emitter, base, or collector circuit, or

a shorted base or collector circuit would render Ql inoperative, and no output would result. With the power removed, check the base and collector circuits with an ohmmeter for a possible short to ground. If the collector circuit appears to be shorted to ground capacitor C4 may be shorted or the primary of TI may be shorted to its case. Check the emitter and collector circuits for a possible open, paying particular attention to R4 in the emitter circuit, and R5 and the primary of T1 in the collector circuit. Check resistors RI and R2 for proper vrdue, since an open or short of either part would alter the bias applied to Q1 and drive QI either heavily into saturation or into cutoff. This condition would probably produce little or no output from the controlled stage. If capacitor C3 becomes shorted, the output signal would be shunted around transformer T1 and there would not be any output coupled to the following stage. Improper AGC control voltage caused by a defect in the AGC deterctor circuit, could also cause a no-output condition to exist. The existence of this condition may be determined by measuring the voltage present at the base of Q1 with no signal applied to the receiver.

Low Output. A low output condition could be caused by defective power supply voltage, a defective transistor, defective circuit components, or by self oscillation. Since self oscillation would result in an excessive detector input, it would also result in the generation of excessive AGC control voltage, and therefore could cause a low output. Oscillations of this type usually also result in excessive receiver noise in addition to the low output. If an output signal is present with no signal input to the receiver, self oscillations are probably being produced internally through feedback. If self oscillations are not the cause of low output, check the power supply voltage with a high resistance voltmeter. If proper operation is still not restored, a defective circuit component is most likely the cause of low output. A change in the value of RI, R2 or R4 would alter the bias applied to the base emitter junction of Q1 and low output could result. If emitter bypass capacitor C2 opened the resulting degeneration would lower the gain of Q1 and a low output would also result. Low output would also result if R5 increased in value since the collector voltage applied to QI would be correspondingly reduced. A defect in output transformer T1 would also reduce the output by either detuning the output tank which consists of C3 and the primary of Tl, or by reducing the amount of signal coupled to the following stage.

Distorted Output. Since the input and output impedances of the amplifier vary as the gain of the amplifier is varied by AGC, some distortion is to be expected especially when strong signrds are received. However, if distortion is severe and continuous a defective transistor, power supply, or circuit component probably exists. The power supply and the transistor should be checked, and if distortion persits, voltage checks of the transistor elements should be made with a VTVM to localize the trouble. Resistance measurements with the power removed, may then be made to locate the faulty component.

AGC-CONTROLLED AUDIO AMPLIFIER (ELECTORN TUBE)

The AGC-controlled audio amplifier is used to silence (squelch) the receiver until a signal of usable level is received, and to reduce the noise output as the receiver is tuned from one signal to another. It is particularly useful in mobile and controlled net operation.

Characteristics.

It is turned off by a positive AGC delay voltage.

It is turned on by a negative AGC voltage.

It may be rendered inoperative by a separate switch.

Operating threshold is determined by a manual bias control.

It is operated by a negative AGC voltage of from O to 35 volts.

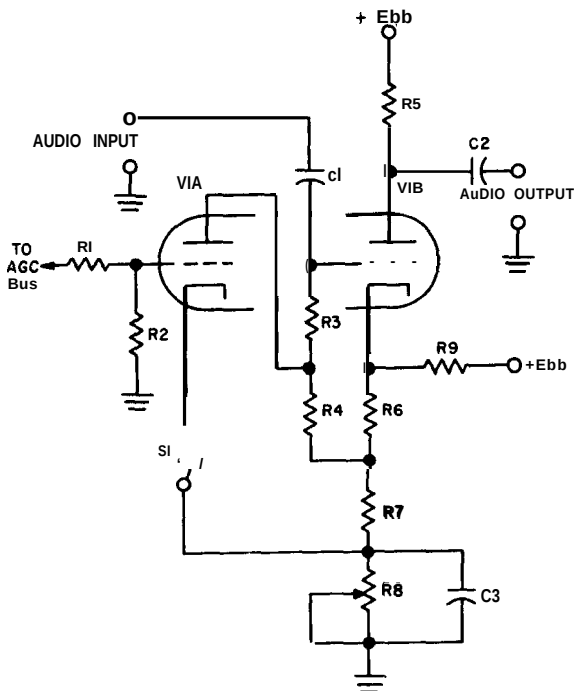
May be packaged as a self-contained accessory, or supplied as an integral part of the receiver.

Circuit Analysis.

General. To ensure that the squelch is opened by the weakest readable signal, it is necessary that a high sensitivity level be maintained. To achieve this high sensitivity without excessive background noise from various sources, the squelch circuit bias is determined by a threshold control. Thus the operator may adjust the operating threshold to suit local operating conditions. To permit operation of the reciever without squelch action, the squelch circuit is normally completed through a switch. When this switch is open the squelch circuit is inoperative. Although not necessary for circuit operation, both the threshold

control and the squelch off-on switch are usually provided for convenience in operation.

Circuit Operation. A typical audio squelch operated by receiver ACC voltage is shown schematically in the following illustration.



AGC Controlled Audio Amplifier Circuit

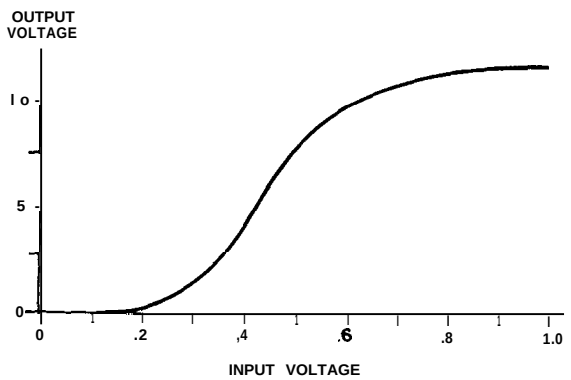
A twin-triode electron tube is used, with half-section VIA connected as a dc control amplifier, and half-section VIB operating as the bias controlled first audio stage. The grid of VI A is direct-coupled to the AGC control circuit, and is supplied with a portion of the control voltage by voltage divider Rl, and R2. Resistor R1 is also connected in series with VIA tube grid and acts as an isolation and current limiting resistor. Normally, the cathode circuit of the sequelch tube is completed through off-on switch S1. The plate of VIA is direct-connected to the grid of VIB through grid resistor R3, and the audio input to VIB is capacitively coupled through Cl. Resistor R4 is the plate resistor of VIA, which is connected to the bias voltage divider between the plate supply and ground formed by R9, R6, R7, and R8. The cathode of VIB is connected to this voltage divider at the junction of R9 and R6, while plate dropping resistor R4 is connected at the junction of R6 and R7. In this manner the cathode of VIB is always more positive than the plate of VIA, a typical direct-coupled biasing arrangement. Resistor R8 is variable and acts as the threshold control. Tube V1 B is resistance-coupled to the second audio stage, R5 is the plate load resistor, and C2 is the coupling capacitor. Cathode bypassing for VIA *is* accomplished by C3.

With no signrd applied, the receiver ACC delay voltage of approximately +1 .S volts is applied to input voltage divider RI and R2. Since the grid of VIA is connected across R2 only that voltage appearing across R2 is effective in driving the grid; approximately one-fifth is dropped and lost across R1. Because R1 is connected in series between the ACC bus and the grid of VIA, any loading of the AGC bus by grid current flow is prevented by the high resistance of R1. Cathode bias for VIA is developed across threshold control R8, which is bypassed for audio frequencies by C3. Thus the average cathode bias remains unaffected by the signal or by instantaneous changes in the plate current of VIA. Switch S1 is normally close to complete the cathode circuit; when it is open the squelch circuit is made inoperative.

As the positive input (AGC delay) voltage causes VIA to conduct, a negative voltage drop is produced by plate current flow through R4. Current flow is from the cathode of VIA to the plate, through R4, and through the voltage divider to the supply. Thus the end of R4 which is direct connected through R3 to the grid of VIB is always driven negative when plate current increases in VIA. This negative bias on the grid of VIB biases the audio stage to cutoff, silencing the receiver. The point at which cutoff occurs is determined primarily by the setting of threshold control R8. When R8 is adjusted so that heavy plate current flows in VIA, a large bias is produced and only a very small positive signal is necessary to drive the squelch sufficiently to produce cutoff control bias.

When the incoming signal produces a negative AGC voltage in the receiver it causes plate current flow through VIA to be reduced. The reduced plate current produces a smaller voltage drop across R4, thus reducing the bias applied to VIB grid, and permitting the audio stage to operate. The audio

output reaches maximum when squelch tube VIA is cut off. In a typical circuit, a AGC voltage of –0.3 volt will ungate the audio stage and the output will increase until the ACC voltage reaches 0.8 volt. At this time, the squelch tube is completely cut off, normal bias is applied to the audio stage, and full audio output is obtained. The following chart shows a typical squelch sensitivity curve.



Squelch Sensitivity Curve

Once the squelch tube is completely cut off, normal fixed bias for operation of the audio stage is supplied by the voltage divider connected to the cathode. By employing R6 and R7 as unbypassed cathode resistors, some cathode degeneration is provided to improve the linearity of the first audio amplifier. Any audio signal appearing on V1 B grid will not affect squelch operation, because squelch tube VIA is cut off when full output is obtained. During the time the squelch is biasing off VIB and partially reducing the audio output, any audio voltage coupled through R3 to the squelch plate is attenuated by the large resistance value of R3 and has no effect on circuit operation. Although there is a slight delay from application of the signal to the receiver until the circuit is completely ungated, it is only a few microseconds (which appears to be instantaneous) and has no effect on the intelligibility of the audio signal.

Failure Analysis,

Squelch Inoperative. Lack of proper input signal, an open plate or cathode circuit, or a defective tube will prevent squelch tube VIA from operating. If the receiver does not supply a positive delay voltage, or if R1 is open, or R2 is shorted, the circuit also will not operate. Measure the voltage from the grid of VIA to ground with a voltmeter, also the voltage on the AGC bus. Voltage at the bus, but not at the grid indicates either R1 is open, or R2 is shorted. Use an ohmmeter to check these resistors. If S1 is defective, the cathode circuit will be open and the squelch will not operate. Make a continwty check of the switch. If plate resistor R4 is either open or shorted, no bias will be developed to control the audio stage and the squelch will not operate. Measure the plate voltage on VIA. No plate voltage indicates R4 is open. With plate voltage on the plate of VIA and the squelch inoperative either the tube is defective, R4 is shorted, R3 is open, or threshold control R8 is set too high. Replace VIA with a known good tube and adjust the threshold control. If the squelch still will not operate, remove plate power and check the resistance of R4, and R3. If R3 is shorted, the squelch will operate but the audio will be reduced when the squelch is inoperative. On the other hand, if R3 is open there will probably be a reduced audio output and the squelch will not operate.

Squelch Operates, Audio Output Low. When the squelch operates, but the audio output is low, the receiver may be applying a weak audio signal, or the audio stage is improperly biased. Check the bias voltage divider with a volt meter to locate the defective resistor. Apply an audio signal form an audio signal generator to the grid of VI B. A larger output indicates the amplifier is operating and that the receiver is not supplying sufficient input.

PART 11-4. AFC CIRCUITS

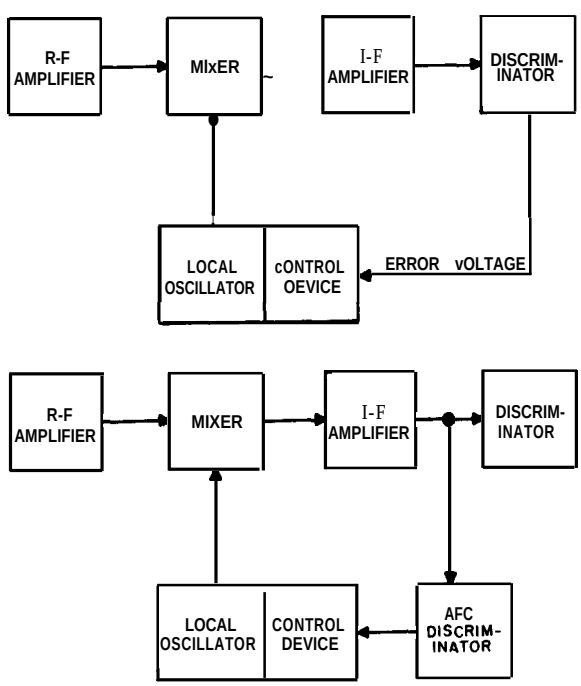
AFC CIRCUITS,

General.

Automatic Frequency Control circuits have a wide range of applications in radio, television, and radar. Their purpose is to automatically compensate for any drift in local oscillator frequency, as well as to automatically lock onto the selected frequency once the receiver is tuned to the approximate frequency. Thus, it is the function of afc to compensate for the warmup time of the receiver, during which the receiver is very susceptible to drift, as well as to compensate for any error in the mechanical tuning of the receiver.

Our discussion here will be primarily concerned with afc systems which change the frequency of the local oscillator to compensate for any frequency drift which may occur in the r-f stage of the receiver, and also counteracts any tendency towards a frequency drift in the local oscillator.

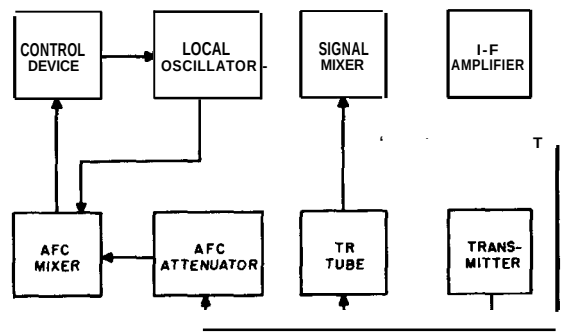
The introduction of afc to a receiver necessitates the employment of one or more additional circuits, consisting essentially of a discriminator and a control device. The function of the discriminator is to change the direction and amount of the frequency error into a corresponding correction or control voltage variation. Many discriminators or detectors employed in f-m receivers are capable in themselves of providing an afc voltage, so it may not be necessary in these cases to add a discriminator to the receiver. This type of afc system is shown in part A of the following illustration. If the receiver detector is not capable of producing an afc error voltage, the addition of an afc discriminator becomes necessary, as shown in part B of the illustration. This error voltage, regardless of how it is obtained, is now applied to the control device, whose function it is to receive the error voltage from the discriminator and change it into a frequency correction for the local oscillator.



Block Diagrams of Typical AFC Systems

If the output of the i-f amplifier is at the proper frequency, it is coupled directly through the discriminator and no error voltage is coupled back to the control device. Thus, the local oscillator frequency remains the same. If the i-f frequency is too high, the error voltage, for example, increases, and provides the necessary adjustment to the local oscillator. Conversely, if the i-f frequency is too low the error voltage, for example, decreases, and provides the necessary adjustment to the local oscillator.

A more refined method of afc contains its own separate mixer. This type of afc is used primarily in radar and thus the receiver employs two converters: one converter is used to mix the echo signal, and the other is used for the afc. A block diagram illustrating such a system is shown.



Block Diagram of Double Mixer AFC

Since the transmitted pulse is used as the frequency sample for the afc mixer in this application, it is not necessary that a TR tube preceed the afc mixer. A freed attenuator can be used instead, as a protection for the afc circuit. The remainder of the afc operation is the same as that of any other afc system, that is, the mixer discriminator produces an error voltage for application to the control device, and the control device changes the local oscillator frequency as necessary. It should be noted that the local oscillator now supplies *two* mixer circuits instead of the usual one, but this power requirement is easily attained by the use of a special oscillator tube.

Examples of circuits which maybe used as control devices are discussed in this chapter. The particular control circuit chosen is contingent upon the receiver in which the circuit is to be used. The phantastron control circuit, for example, is most commonly used

in radar receiver applications because of its sweep voltage characteristics, while for the same reason, it is not used in the standard f-m radio receiver. A control device commonly found in the f-m radio receiver is the reactance tube control device, or the thyratron control device.

PHANTASTRON AFC CIRCUIT

Application.

The phantastron afc circuit is used in radar and other electronic equipment to control the local oscillator and maintain the i-f within the receiver passband to minimize the effect of local oscillator or transmitter dirft.

Characteristics.

Uses a hard tube phantastron oscillator as a search sweep.

Search sweep operates at a rate of about one cycle per second.

Automatically controls the local oscillator repeller voltage to maintain the proper i-f difference frequency.

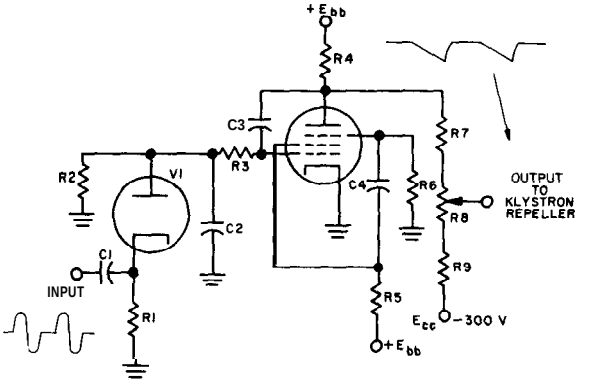
Output may be taken from the cathode, screen, or plate, and be either positive or negative.

Combines a stable multivibrator action with dc amplifier action in one tube.

Circuit Analysis.

General. The phantastron afc system provides a means of automatically controlling the frequency of a klystron local oscillator. The output of the receiver discriminator is coupled through a pulse amplifier stage to a diode search stopper stage. The phantastron search tube, in the absence of control signals from the search stopper diode, applies a one cycle per second sawtooth wave to the klystron repeller. When the sweeping klystron reaches a frequency which produces the proper output from the discriminator, the search stopper diode applies a blocking bias to the grid of the phanstastron search tube and converts it into a dc amplifier. Corrections for small frequency changes are then accomplished by the search stopper diode and the dc amplifier.

Circuit Operation. The accompanying schematic illustrates a typical phantastron-diode afc sweep circuit.



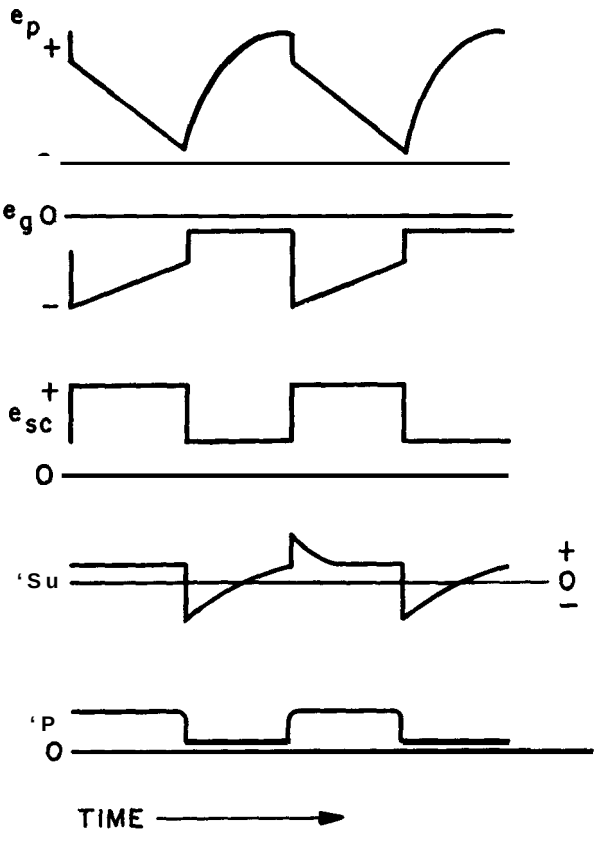
Phantestron AFC Circuit

Only the search sweep tube and the search stopper diode are shown in the schematic, since the discriminator and pulse amplifier used to furniab the afc control pulse are common basic circuits discussed in other sections of the Handbook. Capacitor Cl is the input coupling capacitor with RI operating as the input coupling resistor and cathode bias resistor for diode VI; it also offers a dc return path to ground for the diode. Resistor R2 is the diode load resistor across which the rectified afc control pulses develop a dc bias to charge filter capacitor C2. Resistor R3 couples the search stopper diode direct to the grid of phantastron sweep amplifier tube V2, and incidentally acts as a series filter resistor to eliminate any ripple frequency appearing across C2. Resistor R4 is the phantastron plate load resistor; and R5 is the screen resistor for V2. Capacitor C3 is the plate-to-grid feedback capacitor. Capacitor C4 couples the suppressor of V2 to the screen and also acts as a screen bypass to around via resistor R6. Resistor R6 serves the dual function of acting as a charging and discharging resistor for C4, and as a ground return resistor for the suppressor of tube V2. The voltage divider network consisting of R7, R8, and R9 is connected between the plate of phantastron sweep tube V2 and the -300 volt repeller supply to the

4

klystron local oscillator. Resistor R8 is a potentiometer to permit manual adjustment of the local oscillator voltage for approximately the proper frequency.

In normal operation, the application of plate voltage to phantastron tube V2 causes the plate to draw current, which decreases the plate voltage abruptly because of the high resistance of R4. This drop is applied through capacitor C3 to the control grid. The control grid voltage will not decrease far enough to cut off the plate current, since the source of voltage is in the plate circuit. The plate voltage e_p now begins to decrease gradually while the control grid voltage e_g of V2 now rises slowly as C3 discharges, causing plate voltage e_p to continue to drop and produce a negative-going output sweep voltage as shown in the accompanying waveform illustration.



Phantastron Waveforms

Since the plate current of a pentode remains nearly constant over a specific range of plate voltage, the discharge of C3 is fairly linear. When the plate voltage drops sufficiently to reach the bend or knee in the tube E_p-I_p characteristic curve the plate current no longer remains constant and decreases toweard zero. Since the cathode current of the phantastron is essentially constant, the screen grid draws the current not being drawn by the plate, and the screen voltage drops. This drop in screen voltage is applied to the suppressor grid through C4 and develops a suppressor voltage across R6 which causes an additional drop in plate current. The process is regenerative and soon cuts off the plate current. The plate current remains cut off until C4 discharges sufficiently to allow the plate to start drawing current again. During plate current cutoff C3 charges. This circuit action is repeated at a rate of about one cycle per second, developing a negative sawtooth sweep at the plate of the phantastron. As the negative sweep voltage is applied to the voltage divider consisting of R7, R8, and R9 the klystron repeller voltage becomes more negative, and the klystron frequency increases.

Normally, the discriminator stage is connected to produce negative output pulses for an intermediate frequency greater than 30 MHz. Since these pulses are inverted by the pulse amplifier stage and produce a positive pulse input to the cathode of search stopper diode V1 through Cl the diode will not conduct, and the klystron frequency is permitted to rise until the intermediate frequency becomes less than 30 megacycles, at which time the discriminator produces positive output pulses. At this point the locking action begins to take place. The positive discriminator pulses are amplified and inverted by the pulse amplifier stage. The input to the cathode of the search stopper now is a series of negative pulses which cause the diode to conduct. After a few pulses capacitor C2 is charged sufficiently by the voltage drop across R2 to hold the phantastron grid bias constant. The gradual decrease of V2 plate voltage now ceases and stops the negative sweep of repeller voltage, and the repeller voltage is held constant at this point. A small displacement of the intermediate frequency form 30 MHz will exist in order to maintain a charge on C2, and keep the phantastron plate at the desired potential.

If the klystron local oscillator frequency or the magnetron transmitter frequency now change to

produce an i-f greater than 30 MHz, positive pulses are applied to the search stopper diode to prevent it from conducting and the negative going plate voltage sweep continues until it brings the intermediate frequency back to 30 MHz. If the drift is in the opposite direction and causes the intermediate frequency to further decrease in frequency the search stopper diode conducts heavier and develops a larger bias on the grid of V2. Tube V2 now acts like an amplifier and the plate current decreases as the negative grid bias increases, developing a positive voltage swing in the output across the plate voltage divider. Thus the klystron frequency is lowered to bring the intermediate frequency back to the normal 30 MHz difference value.

Failure Analysis.

No Output. Loss of plate or screen voltage due to failure of the power supply, or if resistor R4, R7, R8, R9 and R5 are defective, or a defective tube V2 can make the circuit inoperative and produce a no-output condition. Measure the positive and negative supply voltages with a voltmeter to make certain that the supply or a blown fuse is not the fault. Check the resistance of R4, R5, R7, R8, and R9 with an ohmmeter for continuity and proper value. If the resistors are satisfactory and the voltages are normal, V2 may be at fault. Usually failure of any other components will produce an improper sweep or a constant output rather than none at all.

Low **Output. Low** supply voltage, a defective tube V2, or a change in value of resistors R4, R5, R6, R7, R8 and R9 can produce a low output. Check the supply voltage with a voltmeter, and the resistor for vahre with an ohmmeter.

Improper Sweep. Normally, with no input to search stopper tube Vl, a constant negative output sweep voltage should occur about once each second, indicating that V2 is operating normally. A faster or slower sweep indicates that V2 is not operating correctly. A faster sweep will indicate reduced time constants such as a shorted resistor or lower valued capacitor, while a slower sweep indicates an increased time constant such as a larger vahre of resistance or capacitance. Check the values of R2, R3, and R6 with an ohmmeter, and check C3 and C4 with an in-circuit capacitance checker. If circuit voltages are normal and the capacitance and resistance are satisfactory, V2 is most likely at fault. It is usually necessary that the afc circuit be adjusted so that the local oscillator frequency cannot pass through the wrong sideband, or improper locking will result.

Constant Sweep. A constant sweep with no lock-in occurring indicates either a faihrre of the search stopper circuit, diode V1, or failure of the preceding pulse amplifier or discriminator stages. Check for a pulse input from cathode to ground of V1 with an oscilloscope. If pulses exist on the input side of Cl but not across RI, capacitor Cl is open. If pulses exist across R1 and no voltage appears across R2, either C2 is shorted, or VI is defective. If the voltage at the anode of VI is low, check the values of R1 and R2 with an ohmmeter and the capacity of C2 with a capacitance checker.

THYRATRON AFC CIRCUIT

Application.

The thyratron afc circuit is used in radar or other electronic equipment to maintain the i-f frequency within the receiver pass band, and minimize the effect of local oscillator drift.

Utilizes two thyratrons, functioning as relaxation oscillators.

Changes an error voltage input into a sweep voltage output.

Sweeps continuously with no input.

Sweep speed changes for a change in error voltage.

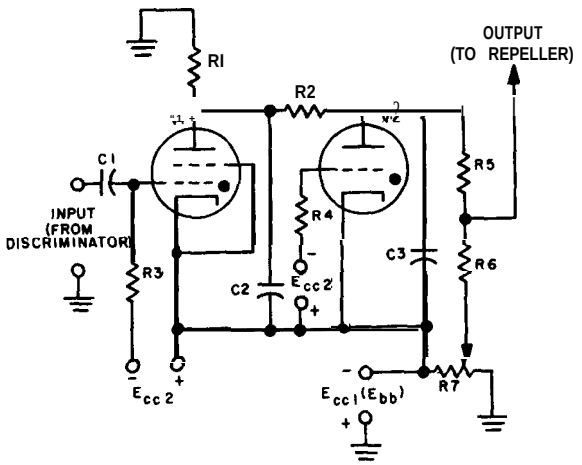
Circuit Analysis.

General. The thyratron afc system provides a means of controlling the frequency of a klystron local oscillator. The output of the receiver discriminator is coupled through a pulse amplifier stage, and is applied to the input of the first relaxation oscillator (hence-forth referred to as the search stopper). A frequency hunting afc system is necessary because of the relatively large oscillator frequency drifts encountered in high frequency radar. Two thyratrons provide a coarse and a fine tuning system, in which the sweep generator brings the i-f frequency within range of the search stopper. The search stopper, in turn, acts as the fine tune control, tuning the klystron locl oscillator so as to produce precisely the correct i-f frequency for lock-in.

System design is such that it sweeps a large band of frequencies, and locks onto the desired frequency when it reaches the discriminator cross-over point. An error voltage from the discriminator cross-over point.

An error voltage from the discriminator controls the speed of the search stopper (the first thyratron), and in the absence of an error voltage, such as when the transmitter is not operating, the sweep generator (second thyratron) hunts continuously. When the transmitter is operating, and when the i-f frequency is within the receiver bandwidth, the error voltage is supplied by the discriminator, the value of which determines the output of the search stopper.

Circuit **Oparation.** A schematic diagram of a thyratron afc circuit is illustrated in the accompanying schematic.



Thyratron AFC Circuit

Thyratron VI is the search stopper, functioning as a relaxation oscillator. Capacitor, Cl is the input coupling capacitor, and R3 is the grid resistor. Capacitor C2, connected between the plate and cathode of V1, determines the repetition rate of the search stopper. R1 and R2 form a resistive series charge path for capacitor C3, which determines the repetition rate of sweep generator V2. R4 is the grid resistor for V2, and R5 and R6 form an output voltage divider, to supply a portion of the output to the repeller of the klystron. Bias supply E_{CC_2}, applied to the grid of each tube, determines the firing point of the thyratron. Variable resistor R7 permits setting the repeller voltage to the proper value so that the sweep generator output causes the klystron local oscillator to hunt by an equal amount above and below the cross over frequency.

If the transmitter is operating, and the local oscillator and the transmitter differ by approximately the intermediate frequency, the search stopper receives a series of pulses from the discriminator (one pulse for each pulse of transmitted energy). The time constant of capacitor C2 in the plate circuit of the search stopper is such that it charges sufficiently to allow VI to fire once for every three or four discriminator pulses at the input. When the thyratron ionizes, the plate potential drops to a voltage which is very close to the cathode potential. This is due to the low conduction resistance of the tube. The capacitor begins to rapidly discharge, and as soon as it discharges sufficiently, the tube deionizes. Immediately upon deionization, the capacitor begins recharging, and the cycle repeats. The search stopper continues to ionize and deionize at the same rate, as long as the pulses from the discriminator remain at the same amplitude. These sawtooths generated by the search stopper are smoothed out to a pulsating dc voltage, by the RC network in the plate circuit, and are applied to the repeller of the klystron. Under these conditions, the klystron repeller is kept at its proper operating voltage, and the i-f frequency is correct. If there is a change in the intermediate frequency because of local oscillator drift, the amplitude of the pulses arriving at the input to the search stopper changes. For an increase in the i-f frequency, the pulses for example, decrease their amplitude. Since the amplitude of the pulses on the grid are now less positive, C2 in the plate circuit must charge to a higher voltage to ionize the tube. Thus it takes a longer period of time for the tube to reach the ionization potential, and the repetition rate is slowed down. A slower repetition rate produces a lower average plate current, so that the average plate voltage is increased in a positive direction. This voltage change appears at the repeller of the klystron, and the klystron local oscillator changes its frequency accordingly, automatically correcting the i-f frequency.

For a decrease in the i-f frequency, the opposite condition prevails. The pulses arriving from the discriminator arrive at a greater amplitude, causing V1 to ionize more frequently, and produce a higher average plate current. The higher plate current causes the average plate voltage to decrease, and this decrease (a change in the negative direction) is applied to the repeller of the klystron. The more negative repeller voltage changes the klystron local oscillator frequency accordingly, and the change in

the i-f frequency produced by oscillator drift is corrected.

During the time that VI controls the repeller voltage, sweep generator V2 remains cut-off, because its plate voltage is not positive enough to allow it to ionize. The search stopper's ability to vary the repeller voltage, however, is limited. If the i-f should drift too far off frequency, the search stopper no longer receives pulses of sufficient amplitude from the discriminator to ionize V1, and the plate voltage increases towards the value of supply voltage Ebb. It is under this condition that the sweep generator tube is activated. As the plate voltage begins rising, C3 in the plate circuit of V2 begins charging, and the output voltage to the repeller begins increasing positively. The ionization point of the tube is established by grid bias E_{CC_2}, and as soon as C3 charges sufficiently to bring the plate voltage to the proper level, the tube ionizes, rapidly discharging C3, and dropping the plate voltage (and thus the repeller voltage) to almost cathode potential. When the capacitor discharges sufficiently, the tube deionizes, and C3 again begins charging, repeating the cycle. The sweep output which is generated by this action is applied to the repeller. As the sweep voltage rises (during the time that V2 is deionized), the repeller voltage also rises and the local oscillator frequency changes accordingly.

When the sweep voltage at the repeller reaches the proper voltage to produce the correct i-f frequency, search stopper tube VI once again receives operating pulses from the discriminator, and prevents V2 from ionizing, stopping the long sweep and locking-in the local oscillator. Once again search stopper tube V2 "fine tunes" the local oscillator, until the next large oscillator frequency shift occurs, whereupon the long sweep cycle repeats.

Failure Analysis.

No Output. A defective V1 and V2, an open resistor RI, R2, R5, R6, or R77, a shorted C2 or C3, or the loss of supply voltage can cause a no-output condition to exist. Check RI, R2, R5, R6, and R7 with an ohmmeter for proper value. Check capacitors C2 and C3 for value, or possible shorts or opens with an in-circuit capacitor checker. Measure the plate supply voltage, and the bias supply voltage with a voltmeter for proper value, and correct if necessary.

Continuous Hunting. The loss of input from the discriminator, an open Cl or C2, or an open R3 can cause the failure of the afc system to lock on to the current frequency. With an oscilloscope, check for the presence of the pulses from the discriminator at the input. If not present, a defect is present in some preceding circuit, and the afc system is probably not defective. If a signal is present, thyratron V1 maybe at fault. Check R3 with an ohmmeter for proper value, and check capacitors C 1 and C2 with an in-circuit capacitor checker for proper value.

No Hunting. A defective thyratron V2, an open C3, or an open R4 are the only components which can cause the system not to hunt when the frequency drifts beyond the control of the search stopper. Check resistor R4 with an ohmmeter for proper value, and capacitor C3 for proper value with an in-circuit capacitor checker.

REACTANCE TUBE AFC CIRCUIT

Application.

The reactance tube afc circuit is used in radio receivers when it is desired to maintain the local oscillator frequency or the output of the mixer stage of the receiver at a specific frequency, which is always in the i-f pass band.

Characteristics.

Converts an input voltage change to a reactance variation at the output.

Controls the frequency of the receiver local oscillator.

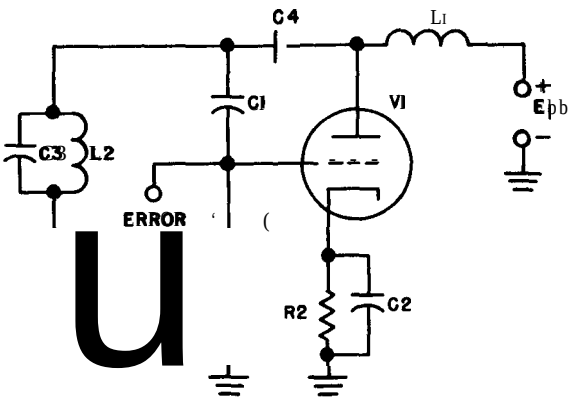
Utilizes a triode, with cathode (self,) bias.

Circuit Analysis.

General. In the basic reactance tube AFC system, a reactance tube is used to change the resonant frequency of the receiver local oscillator by an amount and direction which corresponds to the amount and direction of the frequency shift of the incoming signal. If the i-f frequency of the input changes, it causes the discriminator to produce a dc voltage at its output having an amplitude and polarity which is proportional to this change. It is this dc voltage which is applied to the grid of the reactance tube. The reactance tube circuit is connected across the tank circuit of the local oscillator, and its characteristics are such that a change in its conduction produces the same effect as a change in reactance across the oscillator tank circuit. Thus, the resonant

frequency of the local oscillator tank circuit changes, compensating for the frequency drift in the i-f stage.

Circuit Operation. A schematic diagram of a basic reactance tube AFC control circuit is illustrated.

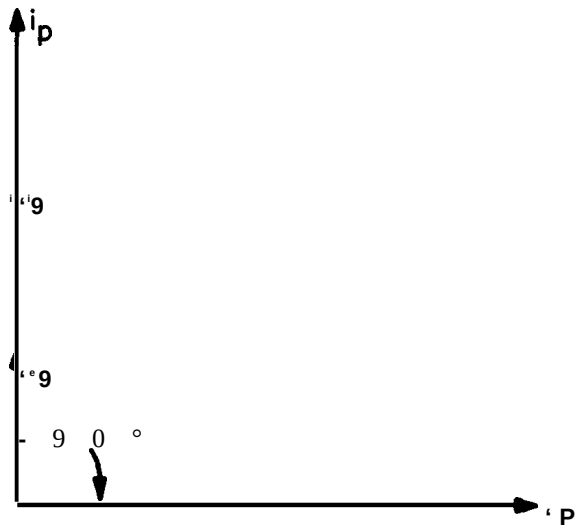


Basic Reactance Tube AFC Control Circuit

Triode VI is the reactance tube, using cathode bias, supplied by resistor R2 and capacitor C2. LI is an r-f choke which keeps the r-f out of the plate voltage supply. L2, together with C3, is the oscillator tank circuit, connected across the C1-R1 combination. Cl and R1 make up the variable capacitive reactance circuit, and capacitor C4 prevents the d-c from being applied to the oscillator tank circuit. The error voltage from the discriminator is applied between the grid of VI and ground, as shown on the illustration

With no error voltage applied to the grid of VI, the only voltage present across the C1-R1 network is the voltage across the oscillator tank circuit, L2 and C3. The values of Cl and R1 are chosen so that the reactance of Cl is large in comparison to the resistance of R1, permitting the capacitive reactance to be the current controlling component, and causing the voltage across it to lag the current through it by approximately 90 degrees. Since the same current which flows through Cl also flows through R1, and since this current leads the applied voltage by 90°, it produces a voltage drop across the resistor which leads the applied voltage by 90 degrees. The reactance tube is effectively in shunt with the oscillator tank (C3 and L2) and the phase shift network (Cl and R1). Capacitor C4 allows the ac component of current to pass through it, and at the same time, prevents the dc plate voltage from being applied to the phase-shift circuit and the tank.

The relationship of the currents and the voltages in the circuit can be best explained through the use of a vector diagram, as shown in the following illustration.



Relationship of Currents and Voltages with no Modulation Input

Voltage e_p is the alternating component of the plate to ground voltage which appears simultaneously across the reactance tube, the phase-shift network and the oscillator tank circuit. The ac grid-input voltage is applied across R1. This voltage drop across RI is in phase with the plate current i_p and the grid current, i_g, a relationship characteristic of amplifier tubes.

Since both i_p and i_g are in phase with e_g, and since e_g leads e_p by approximately 90 degrees, i_p and i_g also lead e_p by 90 degrees. both of these currents are supplied by the oscillator tank circuit, and since they lead the tank voltage, they act like the current in a capacitor. Thus the injection of these currents into the tank circuit accomplishes the same effect as placing a capacitor across the oscillator tank circuit. The frequency of the tank in this case is, therefore, decreased. With no error voltage applied at the input, this frequency is the operating frequency of the local oscillator.

If the i-f frequency drifts, the output of the mixer changes, and the discriminator produces an error voltage at its output which is proportional to the drift in i-f. This error voltage is produced as result of the input frequency to the discriminator being different than the frequency to which it is tuned. The amplitude and polarity of the error voltage is determined by the amount and direction of the frequency drift, respectively.

Consider now the application of this error voltage to the grid of the reactance tube. It is important to keep in mind that we are not speaking of actual capacitive reactance or capacitance changes. Our concern here is an *effective* capacitance produced by the leading current in the R1-C1 combination. If the voltage applied to the grid of VI increases in a positive direction, the plate current of V1 also increases, and since this current is an effective capacitance shunt across the oscillator tank circuit, the frequency of the oscillator is decreased. Conversely, when the grid signal shifts in a negative direction, V1 plate current decreases, and since this current is an effective reduction in capacitance across (shunting) the oscillator tank circuit, the frequency of the oscillator is increased.

To summarize, a positive error voltage causes an increase of frequency, while a negative signal causes a decrease in frequency. Likewise, a large amplitude error voltage causes a greater frequency change than a smaller amplitude error signal.

If resistor R1 and capacitor Cl were reversed, and their values were changed so that the resistance of R1 becomes large in comparison to the reactance of Cl, circuit operation will be reversed. The result of the change is that an inductive (lagging) current is injected into the local oscillator tank circuit instead of a capacitive (leading) current, as in the previous example. A positive error voltage will now produce a decrease in local oscillator frequency, and a negative error voltage will produce an increase in local oscillator frequency.

Failure Analysis.

No Output. An open or shorted L1, an open R2 or C4, the absence of the plate supply voltage, the absence of the input error voltage, or a defective VI may cause a no-output condition to exist. Check L1 for an open, and R2 for proper value with an ohmmeter. Check capacitor C4 for value with an in-circuit capacitance checker. Check for the presence of the plate supply voltage and the presence of the input error voltage with a voltmeter. If plate voltage is not present, either choke L1 is open or the power supply is defective. If an error voltage is not present the trouble is in the discriminator or i-f stages. If the output is still not restored with normai plate and input voltages, the tube is probably at fault.

Improperly Controlled Output. A defect in nearly any component in the circuit can produce a condition in which the afc circuit does not control the local oscillator. Check L1 for continuity, and capacitors Cl, C2, and C4 with an ohmmeter for opens or shorts, and resistors R1 and R2 for value. Check for the proper value of plate supply voltage, and the correct error voltage. If the condition still exists, check all capacitors with an in-circuit capacitor checker for their proper value. Also, do not neglect the possibility that the discriminator may be detuned from the proper frequency, causing the frequency to shift in the wrong direction.

DC AMPLIFIER AFC SYSTEM (ELECTRON TUBE)

Application.

The dc amplifier afc system is used in CW, radar, or radio applications where a slowly varying dc error voltage is used directly to produce automatic frequency control action.

Characteristics.

DC coupling is used between the discriminator and control stage.

No afc sweep is used (it is a non-hunting system).

The error voltage is generated by a discriminator.

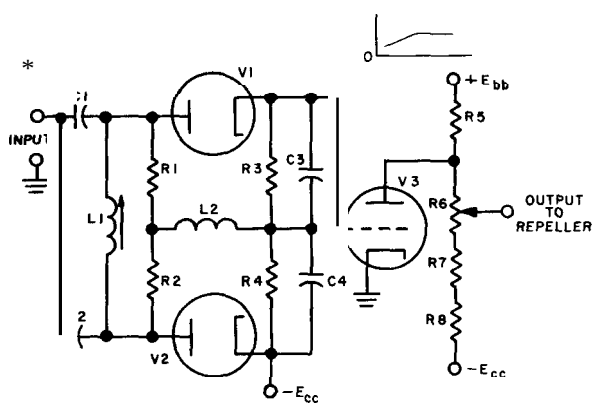
Can be used on either CW or pulsed systems.

Circuit Analysis.

General. The dc amplifier system forms a simple tracking system for a reflex klystron. It uses a discriminator to convert any deviation from the i-f amplifier center frequency into bias variations which are applied to the grid of a dc amplifier. Since the plate of the dc amplifier is connected to the repeller of the klystron local oscillator, any variation of the grid bias varies the plate voltage of the. dc amplifier and thus the repeller voltage of the klystron. This, in turn, varies the frequency of the local oscillator in such a direction as to return the local oscillator to the

proper frequency with respect to the transmitter frequency. The system requires manual adjustment of the klystron resonator and of the repeller voltage, to bring the difference-frequency signal within the bandpass of the afc discriminator, before the system can produce any tracking action. Although this system will compensate automatically for slight frequency variations of the transmitter, or of the local oscillator, it will not correct the klystron frequency if ever the difference signal falls outside the bandpass of the afc discriminator. Such a situation commonly occurs whenever the receiver is turned on after having been inoperative for a number of hours, and necessitates a manual readjustment of the repeller voltage. More complicated afc systems use a simple search sweep to obviate the necessity for initial adjustment.

Circuit Operation. A schematic diagram of a typical dc amplifier afc circuit is shown in the accompanying illustration.



DC Amplifier AFC Circuit

A Weiss discriminator is used to supply the dc afc error voltage. Capacitors Cl and C2 couple the discriminator to the last i-f stage. Inductor L1 is slug tuned to the i-f or crossover frequency. Resistors RI and R2 are diode return resistors which effectively center-tap the tuned input circuit, thus half the input voltage is impressed across each diode. L2 is an r-f choke which forms part of the dc return to the load resistors. V1 and V2 are the discriminator diodes, with R3 and R4 acting as load resistors. Capacitors C3 and C4 filter the i-f ripple from the output and furnish a practically pure d-c output from the discriminator. The grid of dc amplifier V3 is connected to the cathode of V1 and through diode load resistors R3 and R4 to a negative bias supply. This forms the quiescent or resting bias above and below which the discriminator output varies V3 grid. Resistor R5 is the plate resistor for dc amplifier and also forms a portion of a voltage divider comected between the positive and negative power supplies, consisting of R5, R6, R7, and R8. Resistors R5, and R7 and R8 limit the range over which R6 operates, and R6 is variable and used to manually adjust the klystron repeller voltage for the desired center frequency. Normally, with the local oscillator tuned so that the i-f is at the center frequency, say 30 megacycles, L] offers a maximum impedance and equal voltages are supplied to the plates of diodes V1 and V2. Thus equal load currents flow through R3 and R4 in opposite directions and develop equal and opposing voltages. Hence there is no change in bias on V3 and the klystron reflector voltage is not affected, so there is no change in frequency. Coupling capacitors Cl and C2 are unequal in value and are designed to control the peak separation of the tuned input circuit. When the transmitter frequency increases, the i-f increases and a more positive output voltage is applied to V1, and a lower output to V2. Consequently, VI conducts more heavily than V2 and a large positive output voltage is developed at the cathode. This positive increase in bias causes the plate current of dc amplifier V3 to increase, lowers the plate voltage, and consequently increases the negative repeller voltage. As a result, the local oscillator frequency increases and returns the i-f difference frequency back to its orignal value.

Conversely, when the transmitter frequency decreases, and a negative output voltage is applied to V1 while a more positive output is applied to V2. Diode V2 now conducts more heavily than V1 and a large negative voltage is developed across R4. The negative output developed across R4 is larger than the positive output across R3, so that the grid of V3 is driven in a negative direction. The increased positive output across R5 produces an effectively less negative repeller voltage and the klystron is shifted in the correct frequency direction to compensate. These changes are slowly varying dc voltages for cw operation. For pulse operation, design is such that the filter capacitors are quickly charged by the low resistance

path through the diodes, while the discharge is slow through the high resistance shunting load resistors. Thus an effective pulse stretching action is produced which provides well filtered dc for pusle control.

Failure Analysis.

No Output. Lack of klystron voltage or improper repeller voltage can cause a no-output condition. Check both the positive and negative supply voltages with a high resistance voltmeter to determine that a fuse or the supply is not at fault. Do not neglect the fact that potentiometer R7 may be misadjusted and cause the klystron to operate on a frequency out of range of the discriminator. Lack of reflector voltage on the klystron may be caused by a defective R7 or R8. Check the resistors for proper value with an ohmmeter. Resistors R5 and R6 will affect the klystron voltage also, and may be checked with an ohmmeter. If resistors R5, R6, R7, and R8 appear satisfactory and the power supplies are normal, tube V3 may be drawing abnormal current and preventing circuit action. Normally, failure of the discriminator or input circuit will show as an inability to provide proper local oscillator action rather than no output at all. If resistor R3 or R4 opened, or if the grid of V3 were shorted, lack of grid bias on the dc amplifier might cause the local oscillator to operate outside the range of the discriminator. Check the voltage from V3 grid to ground and the values of R3 and R4 with an ohmmeter.

Improper AFC Action. Usually improper afc action can be isolated to a malfunction in the discriminator. Diode VI and its associated circuit controls i-f shifts in a higher frequency direction, that is when the output of **V**I is positive. When lower i-f shifts occur they are controlled by V2 and its associated circuit. If either C 1 or C2 were shorted a continuous positive plate voltage would be applied V1 or V2 and cause the repeller frequency to increase greatly. If the capacitors were open, afc control would only occur in one direction, depending upon which capacitor is open. Use an in-circuit checker to check for the proper capacitance value. Use an ohmmeter to check L1 and L2 for continuity, and also RI, R2, R3 and R4 for proper value. Check C3 and C4 for proper value with a capacitor checker.

SECTION 12
MODULATORS

PART 12-1. AM

AMPLITUDE MODULATION (ELECTRON TUBE)

General.

Modulation is the process by which a signal (or signals) containing intelligence (modulating signal) is impressed on some other signal (usually a radio frequency, called the carrier). There are three basic methods for accomplishing modulation:

Amplitude Modulation. In this method the modulating signal and carrier signal are combined in such a manner as to cause the amplitude of the resultant waveform to vary in step with the changes in the modulating signal.

Frequency Modulation. In this method the output frequency is varied in accordance with the modulating signal.

Phase Modulation. In this method the phase of the output signal is varied in accordance with the modulating signal. Only amplitude modulation will be discussed in this paragraph.

Usually, in amplitude modulation, the modulation varies at an audio rate because the intelligence to be transmitted consists of voice, music, or other audio frequencies; the signal which is modulated is a radio-frequency signal of a constant amplitude and frequency, known as the r-f carrier. As will be seen later, once the modulation is achieved, the r-f carrier is no longer necessary and need not be transmitted, or may be transmitted at a reduced amplitude, for certain special applications.

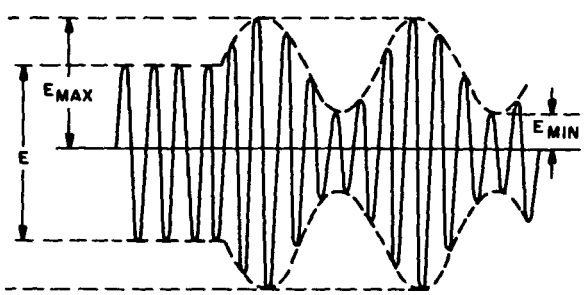
Modulation is normally achieved by varying the voltage applied to one of the elements of an electron tube, and the modulator circuits are classified accordingly. For example, varying the grid bias of a tube to obtain modulation is known as grid modulation, while varying the cathode voltage to obtain modulation (a similar process) is called cathode modulation. Modulators are further subdivided into two general classes - high level and low level. The high-level modulator usually employs plate circuit modulation; it usually modulates the final (output) stage of a transmitter, and it usually requires an audio power amplifier (modulator) capable of supplying 50 percent additional power over the normal maximum unmodulated output of the final transmitter amplifier stage for 100 percent modulation. The low-level modulator usually modulates a stage perceding the final stage of the transmitter. The exact audio power required depends upon the stage modulated. When low-level modulation is employed then the stages following the modulated stage must be operated as linear power amplifiers.

Strictly speaking, high-level modulation is defined as modulation produced at a point in the system where the power level approximates that at the output of the system. Low-level modulation is defined as modulation produced at a point in a system where the level is low as compared with the power level at the output of the system. This does not mean that high-level modulation must always be applied to the plate of the output tube or that low-level modulation is always applied to the grid of an intermediate stage. In some Navy equipment, modulation applied to the grid circuit of the power amplifier is referred to as ***low-level modulation.*** A combination of plate and screen modulation is referred to as ***high-level modulation.***

High-level modulation seems to predominate in the low- and moderate-power fields, since it gives somewhat better efficiency and less distortion for the same powers. However, in the extremely high-power field or where broad-band stages are necessary (as in television), low-level modulation seems to be preferred. Theoretically, with the same amount of sideband power, both modulation methods are equal.

The original concept of the modulated signal was that of a basic carrier frequency with an envelope which varied with the modulation impressed upon it, as shown in the following illustration. This concept is still valid, but is misleading in as much as it appears that for the signal to be reproduced, the carrier is required. Further analysis and investigation have proved that when modulation is accomplished, three signal frequencies are generated. One frequency is higher in frequency than the carrier by the frequency of the modulating signal; the second is the middle

frquency, or carrier; the third frequency is that of the lower sideband, which is lower than the carrier by the frequency of the modulated signal. The sidebands are produced by mixing the audio modulating frequency against the carrier to produce the sum and difference frequencies, At the time modulation is accomplished, and at the time of detection or demodulation, the carrier is required, but it can be either partially or entirely suppressed from the output as long as a similar signal (with same phase and polarity) is reinserted at the receiver; It must also be understood that each sideband is independent, and contains exactly the same moduating frequencies as the other sideband, being displaced in frequency above and below the carrier by this amount. Thus the carrier and one (either) sideband can be eliminated, which is done in single-sideband operation.

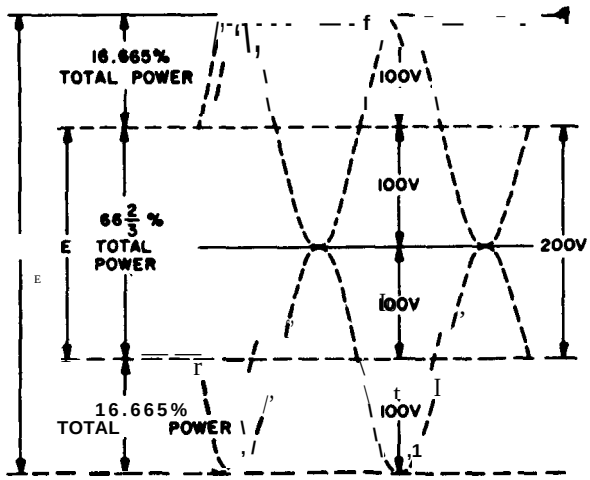


Modulation Envelope

Since the sideband frequencies are transmitted along with the carrier frequency, it is evident that the total bandwidth occupied is twice that of the modulating frequency. Therefore, the modulated signal requires more space than the unmodulated signal. Since frequencies up to 3000Hz must be reproduced for good, intelligible speech, it can be seen that a 6-kHz bandwidth is necessary for radiotelephony using AM double sideband. For single-sideband operation on a basis, with only one sideband transmitted, only 3kHz is required. To broadcast music and speech with reasonably good quality, a 10-kHz bandwidth is required when using AM double sideband.

As stated before for plate modulation, a 50% increase in power above the normal carrier power is required to achieve 100% modulation. The following figure illustrates these conditions. Thus each sideband contains one-half of the total audio power supplied (that is, 25 percent of the carrier power). For the composite signal, however, the carrier contains 66-2/3% of the total energy, with 33-1/3% of the total energy represented in the two sidebands. That is, approximately one-sixth of the total power is contained in each sideband (50 + 200 + 50, or a total of 300 divided on a 2-to-1 basis). To achieve this result, the modulator must drive the modulated amplifier plate voltage down to zero and then twice the normal plate voltage, as illustrated previously. Since the peak power varies as the square of the plate voltage, a peak power of four times normal is produced at 100% modulation. For plate modulation a Class C biased r-f amplifier is used because its output varies linearly with plate voltage. To produce low-level modulation a Class B linear amplifier is employed, in which the output varies as the square of the excitation voltage. The Class B amplifier is adjusted for maximum output and then reduced to one-quarter maximum output and driven to four times this power on peaks. Or, as is generally done with most of the efficiency types of modulation, the plate current on the output stage is adjusted (by changing the output load) for one-half maximum plate current (the output varies as the square of the plate current) and the peak power output is four times normal. In any event, plate modulation is characterized by a steady d-c plate current indication, and low-level and efficiency types by a varying d-c plate current indication. In each case the results are similar as far as amplitude variations are concerned;

however, the distortion and linearity vary from type to type.



Modulation Amplitude and Power Relationships

The amount of modulation is expressed in percentage based upon the amplitude of the carrier. When the amplitude of the modulated signal reaches twice the carrier amplitude on positive peaks and reduces to zero on negative peaks, as illustrated above, the modulation is 100% At any in-between values the modulation is less than 100Yo. Since the power in the sidebands varies as the square of the amplitude, it also varies as the square of the modulation percentage. Therefore, for a 50% modulated signal the sideband power is only one-quarter of that available at 100% modulation. It is evident, then, that the percentage of modulation must always be kept as near 100Yo modulation as possible. When the modulation exceeds 100%, the negative peaks cross the zero level and the signal is effectively chopped off, creating carrier shift, distortion, and severe adjacent-channel interference with other stations. For a sine-wave signal the amplitude variations above and below the average are even. There are other waveforms, however, which are not equally spaced or symmetrical, such as speech. Certain speech sounds contain large positive peak components and if the system is properly polarized, the negative component is of smaller amplitude. In this special case it is possible to modulate more than 100% on positive peaks without causing carrier shift. Therefore, the criterion for 100% modulation is generally considered as being the amplitude at which the negative peaks are just driven to zero, regardless of the positive peak amplitude. On the same basis, since speech is complex and not a sine wave, it can easily be seen that setting the modulation level with a tone signal for 100% will result in a loss of modulation, as only occasional peaks will reach this value. Thus the general practice of advancing the gain control so that occasional positive peaks exceed that value required for 100% modulation produces more effective speech communication with a slight amount of distortion and external interference. In the design of modern transmitters and speech equipment for voice communication, peak clippers are used to permit a greater average level of modulation without exceeding the 100% limit. For broadcast and high-fidelity transmissions, however, the modulation must be set so that the peaks never exceed 100%.

Because the intelligence which is impressed as modulation on the carrier is of prime importance, the modulator (and output stage) must be linear; that is, it must produce a minimum of distortion. Distortion

can be caused by incorrect amplitude, extraneous (spurious) frequencies injected during the modulation process, phase shift at some frequencies exceeding that at others, and other conditions. These items will be discussed as the circuits are analyzed.

Since modulation involves an increase of power in the modulated stage, it is important that the electron tubes used to supply the output signal have sufficient reserve emission to permit 100% modulation on peaks; otherwise, the signal will be clipped. Also, the tubes must be operated at reduced ratings so they will handle the excess power dissipated during modulation without exceeding the voltage and current ratings for the elements. With good design the tubes will operate without showing any sign of plate heating, and under average conditions they may show just a trace of color on modulation peaks.

AMPLITUDE MODULATION (SEMICONDUCTOR)

General.

Although the same general conditions must be fulfilled to achieve amplitude modulation with semiconductors, the semiconductor usually operates at a much lower power level that the electron tube; also since it is a low-impedance device, it operates on the principle of current gain or variation. Thus, instead of speaking of varying the voltage from zero to twice normal to achieve 100-percent modulation, the general practice is to speak of varying the ***transistor gain*** to achieve modulation. (This is similar to control grid modulation.)

Since the gain of a transitor is dependent upon the voltages applied to its electrodes, it is evident that changing the dc bias or the ac signal to any one of its three terminals will produce a corresponding change in gain. Therefore, it is possible to produce AM modulation of a transistor by any of three basic methods, namely, base injection, emitter injection, or collector injection. Each of these basic circuits are discussed later in this section.

At present, semiconductor modulators operate over a relatively low power range as compared with that of electron-tube modulators. In the majority of applications they are operated over a range of milliwatts, with the range of from 1 to 100 watts representing special and high-power applications. As high-powered r-f and audio transistors are developed, this power ***range*** will be extended so that it will be more comparable to that of the electron tube.

Although it operates at low power levels, the performance of the transistor modulator is approximately equal to that of the vacuum-tube modulator as far as fidelity and efficiency are concerned. Their small size, ruggedness, and economy of power consumption make them particularly useful as low-power modulators for small portable and mobile equipments.

CHOKE (HEISING) MODULATOR (ELECTRON TUBE)

Application.

The choke (Heising or constant current) modulator circuit is used to produce 100% high-level plate modulation of the transmitter output stage. In the early days of radio it was the most popular modulator circuit because of its simplicity and economy of parts, plus good performance.

Characteristics.

Uses a single choke in an impedance-coupled arrangement to match the modulator to the output stage.

Operates at a higher voltage level than the transmitter output stage.

Can be adjusted to obtain 100% modulation or more.

It is the most economical modulator from a cost standpoint.

It is not as efficient as the transformer-coupled circuit.

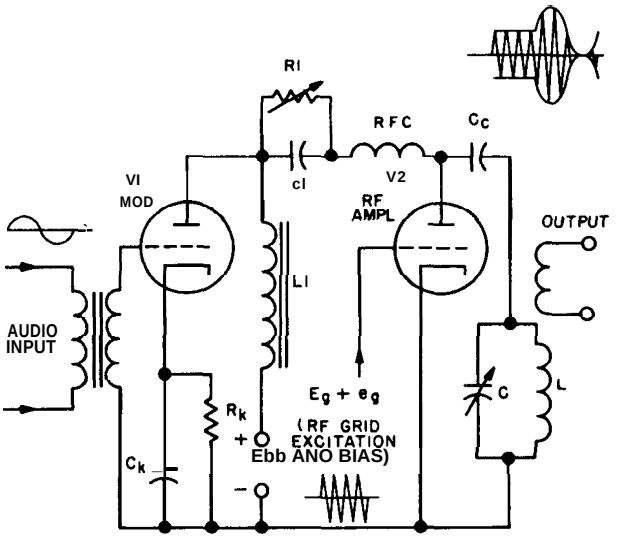
Circuit Analysis.

General. There are three versions of this type of circuit two of which will not be discussed further than to indicate their form and the reasons for omitting the discussion. One version uses a tapped choke, which is usually connected as an autotransformer. Basically, then, the tapped-choke type is equivalent to the transformer-coupled type except for the transformer's isolation of the primary and secondary windings and the effects incidental thereto. Also, it is practically as expensive to build the tapped-choke circuit as the transformer-coupled circuit, so little is gained by its use. In the second version the transmitter plate voltage dropping resistor is not used, so that 10070 modulation cannot be obtained; therefore, it is considered a less desirable circuit. The remaining circuit to be described is the basic Heising circuit, which is also known as a "constant current"

modulator. This latter name is derived from the use of a common choke in the power supply lead, which tends to keep a constant current flowing; thus when the transmitter current reduces because of modulation, the modulator current increases a like amount, and vice versa. A simpler and more easily understood analogy is to consider that the modulator output voltage is equal to the plate voltage applied to the transmitter, and that on positive peaks they add, making the instantaneous total plate voltage equal to 2Eb; on negative peaks they subtract and drive the voltage to zero. Thus the instantaneous voltage varies from zero to two times maximum, and the current does likewise. For this type of circuit the modulator is simply a Class A power amplifier capable of supplying 33-1 /3% of the total transmitter output power (50% of rated carrier power, neglecting losses). Since a Class A amplifier is normally linear, the instantaneous signal varies equally for positive and negative signals (assuming equal drive, equal signals, and no distortion); thus the average plate current remains steady (for 100% or less modulation) and does not vary as indicated by a plate meter. The instantaneous signals, however, are constantly varying in accordance with the modulation impressed.

The Heising circuit has not been very popular up to now because of its lack of plate efficiency, and because advances in the art have developed other more efficient modulator circuits requiring much less audio power. However, the Heising circuit once again is gaining in popularity because of its simplicity, and does serve as a basic circuit for studying and understanding basic modulator principles, thus leading to an understanding of other types of modulator circuits.

Circuit Operation. A typical choke modulator circuit is shown schematically in the following figure. For simplicity and ease of discussion, only the pertinent circuit parts are shown, as the basic modulator may be applied to any transmitter amplifier or oscillator stage. Functionally, V1 is a Class A audio power amplifier, which is impedance-coupled through choke L1 to r-f power amplifier V2 operating Class C. See the Amplifier Section of this Handbook for a discussion of a-f and r-f power amplifier circuits.



Typical Choke (Heising) Modulator Circuit

From an inspection of the illustration, it is evident that V2 is a conventional r-f amplifier, with the output tank circuit shunt-fed. The RFC keeps the rf out of the modulator and the dc power supply, which in this circuit is connected through choke V1 and dropping resistor R1. Resistor RI is adjusted to keep the applied d-c plate voltage of V2 at a value less than that at the plate of modulator tube V1. Capacitor Cl is selected to offer minimum reactance at the lowest usable frequency so as to pass the lower audio frequencies around R1 without attenuation. Since the higher frequencies are offered much less attenuation, Cl effectively bypasses R1 completely for the audio frequencies (assuming that the modulation is audio). The grid drive of V2 is considered to be more than that necessary to drive the tube to saturation, with a dc bias voltage of twice the amount needed for cutoff operation. Therefore, V2 is operating as a Class C amplifier and is assumed to be linear. That is, the plate current and r-f tank current of V2 vary linearly with a change in plate voltage. Thus, as the instantaneous plate voltage of V2 is varied, the instantaneous

491-044 0 73 67

plate current and r-f tank current vary likewise. In this mode of operation, V2 appears as if it were a pure resistance connected between R1 and ground, and the value of this resistance is:

$$R_p = \frac{E_p}{I_p}$$

The output of V2 is designed to produce the proper plate current at full load for the plate voltage set by Rl, to produce the desired plate load resistance for modulator V1.

Tube V1 is operated as a Class A audio amplifier, with cathode bias supplied by R_k bypassed by C_k. In this case the method of supplying bias is immaterial; it can be any of the methods applicable to a power amplifier. The modulator input to the grid of V1 is shown transformer-coupled, but can be by any method that will supply sufficient drive. Since the tube is operating Class A, no grid current is drawn, and only sufficient voltage need be supplied to operate the tube over the linear portion of the tube grid-plate transfer characteristic. When the input (modulation) signal goes positive, the plate current of V1 increases and produces a voltage drop across choke L1 in a negative direction; for a negative input the plate current of V1 decreases, reducing the drop across L1, so that effectively the voltage at the plate of V1 increases (goes positive). Since tube V1 normally operates at a quiescent value of current and voltage (Class A biased), the result of an input signal is to instantaneously increase or decrease the plate voltage and current in accordance with the grid modulation. When the plate voltage of V1 goes positive, the polarity is such that it adds to the source voltage E_{bb} obtained from the power supply; when it goes negative, the source voltage is reduced. It can be seen then, that at the peak of the negative modulator swing, the maximum positive instantaneous plate voltage applied to V2 is the sum of the dc power supply voltage, set by R1 and the audio component on the plate of V1 coupled through Cl. If properly adjusted, the audio voltage developed by V1 will just equal the dc voltage supplied V2, and the instantaneous plate voltage supplied to V2 will be zero, while on the positive modulator swing it will be twice that of the normal applied d-c plate voltage. Without resistor RI in the circuit, the plate voltage of V1 would have to be driven to zero to reduce the instantaneous plate voltage of V2 to zero. When reduced to zero no plate current would flow in V1, the tube would no longer operate Class A, and distortion would be produced. Likewise, on the positive swing, the d-c voltage drop through L1 would be subtracted from the V2 plate voltage, and the instantaneous plate voltage would never reach the two-times-normal value. With R1 correctly adjusted, the d-c plate voltage of V2 is always less than that of V1, and the positive and negative swings of V1 are sufficient to drive the plate voltage of V2 from zero to two times normal, thus producing 100% modulation. It is evident that, since the output of V2 is varying linearly in accordance with the plate voltage swings produced by the modulating signal, V2 is amplitude-modulated. When the plate voltage of V2 is increased, the plate current is increased also. To increase the plate voltage of V2 instantaneously, it is necessary for the plate current of V1 to be reduced during that instant. Choke L1 supplies the energy for this power change through its collapsing field as the plate current of V1 reduces. Thus the power supply current drain remains substantially constant, even though the instantaneous variations of current and voltage in this circuit are from zero to twice the normal value; hence the derivation of the term ***constant current modulation,*** as applied to the average dc drain.

The modulated tube (r-f amplifier) must be operated at below maximum ratings of tube current and voltage during modulation because of the possibility that the instantaneous variations of voltage and current will exceed the safe ratings during sustained peaks of modulation when the peak power is four times maximum. Conversely, the modulator tube (which supplies half the power taken by the r-f amplifier) is at best only 30% efficient as compared with 70 to 8070 for the r-f amplifier, and is subject to the same range of instantaneous voltages and currents (or peak power). Therefore, this type of modulator usually uses a tube of equivalent or greater power rating than the r-f amplifier being modulated. Like the Class A amplifier, the modulator just discussed produces the least amount of distortion; however, because of its low efficiency, it has become practically obsolete in favor of other more efficient types.

Vacuum Tube Considerations. While the preceding circuit discussion was based upon triodes, this modulator may be used with other types of electron tubes if the proper electrode voltages and currents are applied. For screen-grid tubes of the tetrode, beam, or pentode type, it is important that the modulation be applied to the screen grid as well as to the plate.

This is usually accomplished by using a series voltage-dropping resistor from the plate to screen, for screen voltage supply, so that both electrodes have the same modulation impressed upon them. Thus, as the screen controls the plate current, it permits full swing on positive peaks and reduced swing on negative peaks, effectively aiding the modulation process. The reduced swing on the negative peaks prevents the plate voltage from falling below that of the screen and creating a virtual cathode. Since the series screen resistor does not permit plate current cutoff, bias is chosen on the basis of projected cutoff for a fixed screen voltage under quiescent conditions. ***In*** addition, the power from the modulator must be sufficient to supply the screen modulation power, or about 10Yo additional. In circuits using a fixed screen voltage supply, 100% modulation is achieved by inserting a series choke of about 5 henries between the screen and the screen supply. The electrical inertia of the choke produces on effect similar to the constant current action. When the plate current is greatest and tends to increase beyond the limits fixed by the screen voltage, the plate robs the screen of electrons and decreases the screen current. Whereupon, the reduction of current through the choke produces an induced voltage because of the collapsing lines of force in the choke field. This voltage is in the direction which continues current flow (that is, an increase in screen voltage), and the effect is similar to that caused by the modulation superimposed on the series screen comection. Likewise, on the negative peaks of the modulating signal, the screen current tends to increase, because less plate current is drawn and the screen tends to become the plate. The increased screen-current flow through the screen choke produces an opposing voltage, which tends to decrease the screen voltage and the total current Wrmissible, and reduces plate swing. Thus the raising and lowering of screen voltage with modulation is simulated by the choke, permitting practically 1007o modulation. Without the choke the modulation is limited to about 90 to 95%.

Failure Analysis.

No Output. Lack of output should first be isolated to either the transmitter r-f amplifier or the modulator circuit. Even though the modulator is operative, an open RFC or tank circuit, a shorted or gassy electron tube, or a lack of grid excitation in the amplifier will produce a no-carrier indication. Checking the r-f amplifier plate meter will indicate whether the circuit is complete and whether a resonant dip can be obtained; also, a check on the grid drive meter will determine whether excitation exists. Lack of grid drive indicates trouble in the transmitter, while lack of plate current places the trouble in either the transmitter or the modulator. Where the modulator plate meter indicates but the transmitter does not, the probability is an open dropping resistor, open RFC, or poor transmitter tube; the trouble can be isolated with a high-voltage voltmeter (turn off the high voltage and use a shorting bar before connecting the meter). If both the modulator and transmitter meters are not indicating, either the power supply is defective or modulator choke L1 is open. With both meters indicating but with no modulation, either a shorted modulation choke, a bad modulator tube, or lack of modulator drive may be suspected. High plate current usually indicates short-circuited components or lack of bias, while low plate current indicates excessive bias, high-resistance joints, or poor tube emission. Voltage checks on the grid and plate elements will indicate continuity as well as terminal voltages. No output generally indicates lack of voltage, lack of continuity, or short-circuit conditions. A resistance check to ground will be helpful, but is normally unnecessary. With the voltages and currents usually involved in high-power transmitters and modulator, breakdowns are usually obvious from external symptoms such as arcing, charring, and burning; on low-power equipment additional test equipment may have to be used. But remember, DANGEROUS voltages are involved; take all safety precautions before connecting or disconnecting any test equipment.

Low Output. It must first be determined whether the low output is lack of audio power or reduction in percentage of modulation. While low modulation is normally due to lack of sufficient audio power, this can occur from a reduced setting of the audio driver gain control, or from trouble in the speech amplifier stages which drive the modulator. An oscilloscope is very useful in determining the cause of malfunctioning since the waveform may be directly observed. For simple, quick tests of modulation percentage, the trapezoidal pattern is useful. The waveform check, however, can show both percentage of modulation and distortion, and is more useful. Too high a grid bias will cause a reduction of output (with the same

drive). A short-circuited coupling capacitor will eliminate the dropping resistor for the r-f amplifier, so that the percentage modulation will be reduced, and even with increased drive the 10070 level will not be reached. But, since the capacitor is shunted by the dropping resistor, such trouble is rather infrequent. On the other hand, since the dropping resistor is constantly carrying the current of the r-f amplifier, it will most likely change in value with age. If it increases in value sufficiently, over-modulation will occur, even though the stage can be loaded by antenna coupling adjustments to the operating value of current. While the modulator load will be correct, the reduced voltage will permit less swing; thus the same audio output will overdrive and cause carrier shift, as indicated by a varying plate meter with modulation. Note that normally with modulation, if the power supply regulation is insufficient in either the transmitter or the primary a-c supply line, there will be some movement of the plate current meter. Overmodulation will be indicated by more than normal movement. Where the power supply regulation is satisfactory, the normal meter indication will be rock-steady, and any meter movement will indicate overmodulation or a distorted condition.

A modulation choke that has partially shorted turns may not be easy to locate from external appearance, but will probably show up as low power output, as well as insufficient and usually distorted modulation. Ordinarily, this condition can be located only by substitution of a new choke after the other parts have been eliminated by systematic analysis.

Lack of fdament emission in the r-f amplifier or modulator tube will cause peak clipping and inability to obtain 100% undistorted modulation.

Distorted Output. Distortion is usually obvious when monitoring audio modulation. It may occur from a number of causes. For example, overmodulation will cause carrier shift, severe interference with other stations, and distortion. Changing of the modulator load impedance, by adjusting the r-f amplifier output loading for different currents than normal, will change the modulator load line; depending upon the magnitude of the change, this condition may be easily detected, or a special check may be required to determine the amount of distortion. Any change of grid bias will shift the operating point and require a change of drive. With low bias the input will be clipped and distorted, and with high bias a larger input signal will be required; thus speech amplifier distortion will most likely be increased. Should the bias reach the Class B point, actual plate current cutoff will cause distortion, while with Class AB operation there is the possibility that grid current being drawn on peaks may cause some distortion. Thus the region of operation between Class A and Class B becomes somewhat of a problem. With proper drive and with symmetrical modulation, little or no distortion will occur; on the other hand, with improper drive and with large unsymmetrical or sustained peaks of modulation, excessive distortion can result.

Lack of sufficient plate voltage will cause a reduction of plate swing, and thus cause distortion by plate clipping. Shorted modulator turns can cause an insufficient inductive effect to produce the amount of modulation required, and thereby result in distortion. A change in the value of the coupling capacitor will result in different attenuation for different frequencies, so that attenuation of these frequencies (usually the low frequencies) will cause another form of distortion,

Lack of sufficient fdament emission in the r-f amplifier (and modulator) tubes will cause peak clipping, produce distortion, and make it impossible to obtain 100% modulation.

PLATE MODULATOR

Application.

The transformer-coupled plate modulator circuit is used to produce high-level modulation of the transmitter r-f output stage. It is used for both low- and high-power applications, particularly where it is desired to use a triode as a high-level modulator.

Characteristics.

Uses a transformer to match the modulator stage to the transmitter output stage.

Supplies an audio (modulator) output equivalent to one-half the dc input power of the r-f output stage.

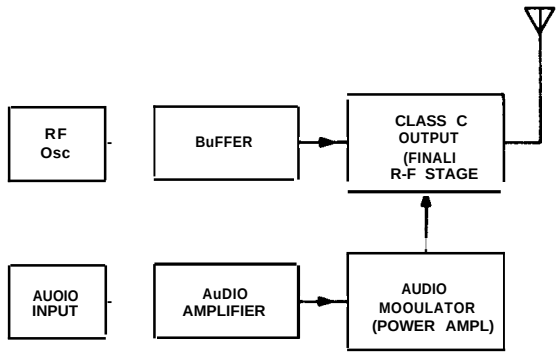
Operated class A for a minimum of distortion with low efficiency and low output, or class B for highest efficiency with some distortion. When operated between the two classes (Class AB or AB), intermediate values of efficiency and distortion are produced.

Uses triode type electron tubes only (see Transformer-Coupled Plate and screen Modulator circuit for tetrodes).

Circuit Analysis.

General. Before reading this discussion, read the introduction to this section covering Amplitude Modulation for background. A better understanding of the various voltage and current relationships in class C amplifiers will also be obtained by reviewing RF Power Amplifier Circuits (Class B or C) for both single-ended and push-pull applications, in the Amplifier Section of this Handbook.

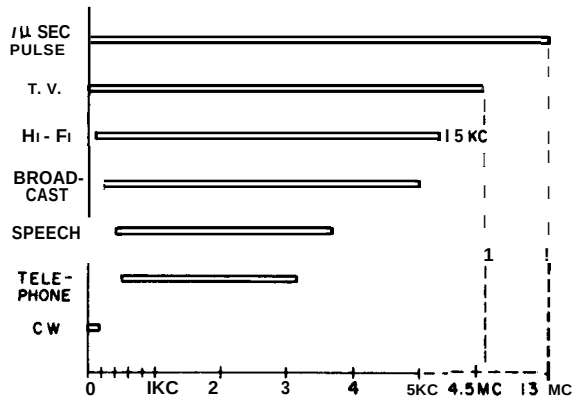
The ***high-level plate modulator*** uses the audio output of a conventional ***a-f power amplifier*** (the modulator) to produce a modulated r-f output signal in the ***plate*** circuit of the transmitter r-f amplifier connected to the antenna. A typical high-level system is shown in the accompanying block diagram. The ***transformer-coupled plate and screen*** modulator which is used with screen-grid tetrodes and pentodes employed as the final RF power amplifier is a variation of this type of modulator circuit; it is discussed separately later in this section of the handbook.



High-Level Modulation System

High-1evel modulation is defined as modulation produced at a point in the system where the power level approximates that at the output of the system. Therefore, plate modulation always involves considerable power output from the modulator. For 100-percent modulation, the plate modulator must produce an output equivalent to 50 percent of the dc input power to the final r-f power amplifier. For an r-f power amplifier having an efficiency of 80 percent and an r-f carrier output power of 100 watts, the total dc input power would be 125 watts. The power required from the modulator would be one half of this, or 62.5 watts, and the resulting output to the antenna would be 100 watts of carrier power and 50 watts of audio (sideband) power. For high-power operation the circuit must incorporate design considerations to prevent corona loss, arcing and flashover, and damage or destruction of parts. On the other hand, for low-power applications as in mobile operations, the audio power is relatively small (for example, 50 percent of 5 watts is only 2.5 watts) and may be handled by receiving type audio amplifier output stages. Regardless of power output, however, the basic principles of operation are the same.

Modulation involves frequencies other than audio, such as video (television) or pulses (control systems, or telemetry); however, since modulators are conventionally associated with audio frequencies, other types of signals which may affect modulator circuit operation are discussed only as required to bring out the manner in which they differ from audio use. The accompanying chart illustrates some typical ranges of frequencies involved for various forms of modulating signals.



Frequency Ranges Required

The maximum power from a particular transmitter with a given type of electron tube operating at its maximum ratings can be obtained when operating the transmitter in the Al (CW) mode of emission. When

using the A3 (AM) mode of emission, the power output for plate modulation is about 20 percent less than for CW operation. The reason for this is that during plate modulation, at the peak of the modulation cycle (at 100% modulation), the plate voltage is doubled and the input power is increased by a factor of four. In order that the maximum tube ratings will not be exceeded, the tube must be operated below its normal operating point as a class C amplifier. Other factors that affect the power output from a plate-modulated stage are the loading of the antenna (the amount of antenna coupling) and the value of the load impedance that the r-f amplifier presents to the modulator. The power output of the modulator and the amount of distortion it develops are directly dependent upon the loaded value of plate current and voltage applied to the r-f stage.

The plate efficiency of the high-level, modulated r-f stage is constant at about 70 percent, and does not change with modulation. Therefore, the r-f output (carrier) produced by a given type of electron tube with no modulation is at a maximum value in the plate-modulated high-level transmitter (although not as large as can be produced for CW operation). Low-level modulation, using the same type of electron tube, produces a carrier output of half this value. The reason for this is that during low-level modulation the tube efficiency varies with the percentage of modulation. At no modulation the efficiency is approximately 33 percent, and represents the condition of greatest tube loading (maximum plate dissipation because of low efficiency). At the peak of modulation the highest efficiency (about 66 percent) is obtained. Although the plate voltage and current are doubted to produce a four-time power increase at the peak of modulation .(which is necessary for all AM modulators), the low-level modulator must obtain this increase from the transmitter power supply. In the high-level modulator, the additional power required for modulation is obtained from the modulator.

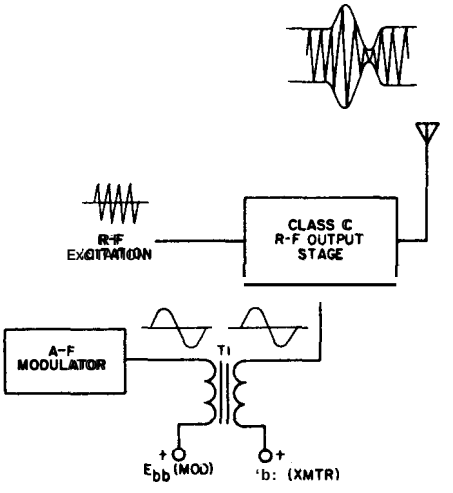
Since in high-level plate modulation the modulation occurs in the final stage of the transmitter, the r-f driver stages can be operated more efficiently (they need not be linear as in the low-level transmitter); therefore, they can be operated without considering distortion to produce maximum r-f output. Hence, the r-f section of the high-level plate-modulated transmitter is most efficient for r-f production, and its power supply need only be large enough to supply the power required to produce the r-f carrier. When fully modulated, the audio output (modulator) stage of the high-level modulator supplies an additional 50 percent of the power required to produce the carrier. The additional power supplied by the modulator represents the output power in the sidebands, which is equal to 50 percent of the carrier (25 percent in each sideband). Therefore, the total average power output of the high-level plate-modulated stage at full modulation is 1.5 times the unmodulated (carrier) power.

Since the low-level modulator must be operated at a carrier level which is one-quarter of the maximum power obtainable from the same type of electron tube in high-level operation, it is adjusted to operate at one-half the maximum plate current. Thus it is clear why, for a given type of electron tube, the high-level modulated stage produces a greater power output. To do this, the audio (modulator) stage must also produce considerable power (to supply the 50 percent additional (sideband) power necessary for 100 percent modulation). For high-power transmitters such a powerful modulator is costly and involves special component design to operate at the high voltages and currents required.

The various power relationships and differences between high- and low-level modulation methods will become clearer and will be more fully explained as the various modulator circuits involving these methods are discussed. It should be borne in mind, however, that regardless of whether operation is at a ***high level*** or at a low ***level,*** the ***equivalent ratings are the same.*** For example, a 1000-watt 100-percent modulated transmitter produces the same output whether or not the modulation is accomplished by high-level or low-level methods.

Circuit **Oparation. A** simplified diagram of the basic transformer-coupled plate modulator is shown in the accompanying figure. The a-f modulator stage is represented as a block since it may be any one of a number of audio amplifier combinations as long as the proper audio power output is obtained. Likewise, the r-f output stage is also represented as a block since it may consist of any arrangement of tube(s) to produce the desired carrier output to the antenna. The r-f output stage is always biased so that it operates as a class C amplifier. Since class C operation requires a bias of two times the cutoff value, a separate bias supply is used to provide fixed bias. Since the r-f excitation to

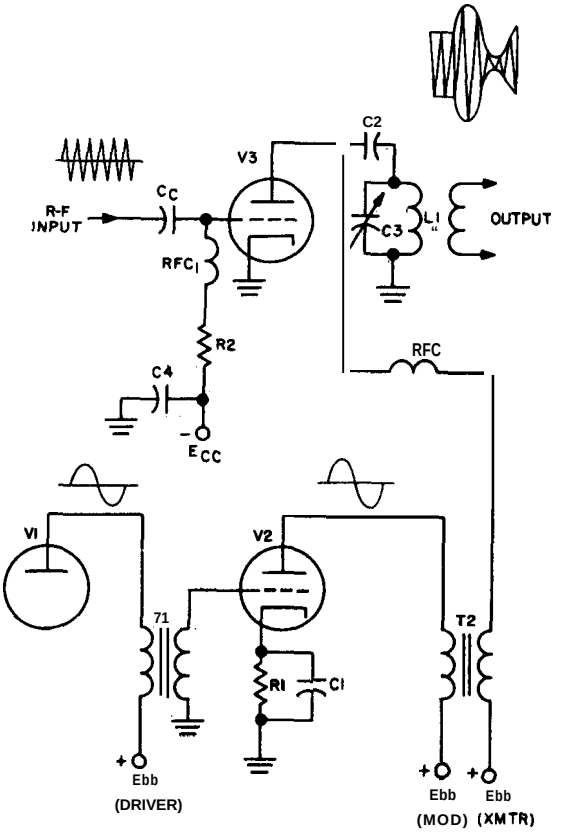
the r-f- stage is relatively constant, grid leak bias (produced by grid drive) is also used, with the total bias being the combination of the fixed and grid-leak (grid-drive) bias. In case of failure of the grid drive, the fixed bias provides a protective bias to prevent the final bias provides a protective bias to prevent the final-stage tube ratings from being exceeded.



Basic Transformer-Coupled Modulator

With no modulation applied, the carrier r-f output is developed by the application of the normal dc plate voltage to the plate of the class C stage, with sufficient r-f grid drive and antenna loading to produce the desired r-f carrier. When modulation is applied, the audio output of the modulator is applied through the secondary of T1 in series with the dc plate voltage, and adds to or subtracts from this voltage to produce an instantaneous plate voltage which increases the r-f output to 1.5 times the rated carrier power at 100 percent modulation. To do this, the plate voltage of the r-f stage is varied from two times the normal plate voltage at the positive audio peak down to zero on the negative peak, both varying in accordance with the modulating frequency.

Class A Modulator. The schematic diagram of a simple triode modulator which operates to modulate a triode r-f output stage is shown in the accompanying figure.



Triode Plate Modulator

This single-tube triode modulator can be operated class A, Al, or A2, depending upon the fidelity desired and the amount of distortion that can be permitted. Class A operation provides the best fidelity with the least amount of distortion, but uses a large power input to obtain a small power output (highest efficiency), with usable fidelity for the amount of distortion allowed. Class Al operation is intermediate between these two levels.

Although the modulator driver may be r-c coupled, if the modulator is operated class A2, grid current is drawn. Therefore to minimize grid-voltage drop and the development of a reverse bias which will seriously affect the operating point and produce excessive distortion, it is necessary to provide a low-impedance grid circuit. Thus the illustration shows

transformer coupling to the modulator. Through the use of a transformer with taps, the driver stage can be made to operate at the desired load point to produce maximum audio output with minimum distortion by selecting the taps that provide the required turns ratio for matching impedances (output to input). Thus the input and output impedances of the transformer can be selected for sufficient distortiordess voltage drive at all times, including the time during which the modulator grid draws grid current (when the positive drive peak voltage exceeds the modulator grid bias). Modulator bias is produced by cathode resistor RI, which is bypassed to prevent degeneration (see the introduction to the Amplifier Section of this Handbook for a discussion of degeneration effects). Since cathode bias is used, current must flow throughout the cycle to produce the bias; therefore, this circuit is limited to class A operation (a class B modulator will be described later). Since transformer coupling is used, T1 in the input and T2 in the output, the frequency response is somewhat limited (see introduction to amplifier section for explanation of transformer coupling response limitations). Because of a loss of low and high frequencies causing a nonuniform audio response, the modulation signal is similarly affected. In practice, this condition is overcome by opeating the modulator at less than the maximum output over the mid-range of frequencies, and by providing bass and high frequency boost to provide reasonably linear response over the audio frequency range when necessary. Actually, for ordinary speech transmissions the desired frequency response is usually easily obtained with transformers of good design, but for the higher audio frequencies and for video applications special design is required, including both high and low boost compensating circuits.

Since the output of the modulator is developed across transformer T2, the transformer must be provided with the proper load impedance to produce the desired output (both voltage and power) from V2. This is achieved by employing the transmitter output tube (a class C r-f stage) as the load across the secondary of T2. The r-f stage can be used as the audio load because radio-frequency choke RFC presents a high r-f impedance to the r-f signal developed by tube V3 and prevents it from feeding back into, and being shorted out by, the power supply filter capacitor. Thus T2 remains unaffected by the rf and sees only a resistive dc path from the plate to the cathode of V3 and gound. This dc path is the effective resistance placed across the secondary of T2 (the modulator load), and is equal to the dc plate voltage applied to V3 divided by the dc plate current a simple Ohm's law relationship:

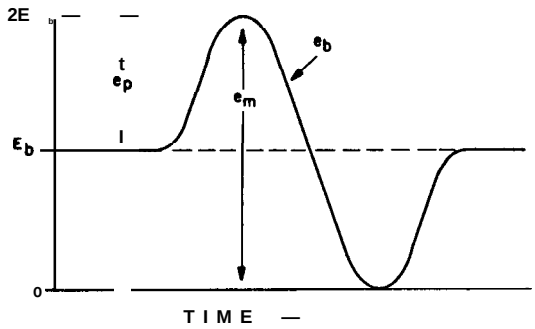
$$R = E/I$$

Since the transformer has the inherent property of transforming impedance in accordance with the square of the turns ratio of primary to secondary, with a multi-tapped transformer it is possible to select the proper turns ratio to make the dc plate resistance of V3 properly match V2 for maximum output. (Taps are not necessary if the proper ratio is used, but they do provide a convenient and easy method for load matching.) Final adjustment of the load is achieved, once the proper turns ratio is obtained, by setting the output coupling of V3 for the exact plate current at the rated plate voltage.

Transmitter output amplifier V3 operates as a conventional shunt-fed r-f amplifier, with combination freed and grid-leak bias being supplied by R2, which is bypassed by C4. The plate voltage is applied in series with the secondary of transformer T2, and C2 is the conventional shunt-feed coupling and dc blocking capacitor which connects tank L1, C3 to the plate of V3. In addition to the bias supplied by R2, fixed bias is applied through RFC_1 to the grid of V3 from a separate "C" supply. Thus the final bias applied to V3 is the sum of the fixed and grid-leak bias voltages, with the fixed bias providing protection in case of failure of the grid-drive (r-f excitation). The r-f output of the transmitter driver stage is capacitively coupled to the grid of V3 by Cc. When the grid of V3 is driven above its bias level by the r-f grid drive from the buffer amplifier, plate current flows and develops an r-f voltage across the parallel resonant tank circuit consisting of L1 and C3, which is isolated from the modulator by the RFC. An r-f output is thus produced in the inductively coupled antenna circuit. When the modulator is operated at static values of plate current and voltage, the output is the r-f carrier signal, with no modulation applied.

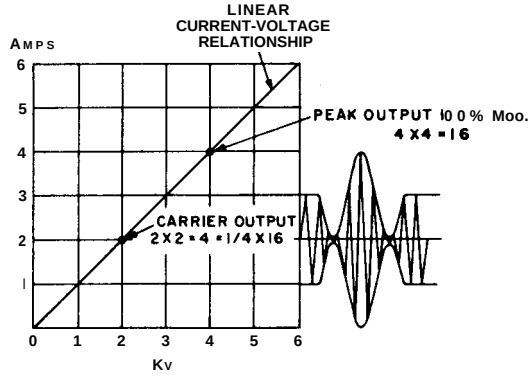
Assume that a sine-wave input is applied to Vl, the modulator driver stage. On the positive excursion of the input signal (with proper phasing of transformer connections) modulator tube V2 produces a positive output voltage at the secondary of T2. Since T2 is connected in series with the transmitter plate

supply, the plate voltage of transmitter output tube V3 is effectively increased and made more positive, so that the output of V3 also increases. Thus a positive modulation signal produces an increase of r-f voltage and output power in the transmitter output stage. At the peak of the sine-wave modulating signal (100% modulation), T2 supplies an instantaneous positive voltage equal to the dc voltage supplied by the transmitter power supply. These two voltages add, so that the plate of V3 operates at twice normal voltage, as shown in the following figure.



Equivalent Plate Voltage at 100-Percent Modulation

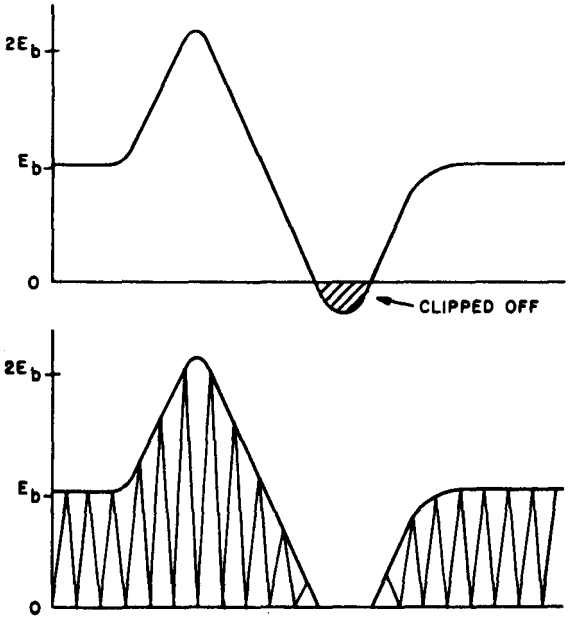
The dc applied voltage is E_b, and the instantaneous ac plate voltage component is e_p; when added, they produce the maximum instantaneous voltage, em, which varies throughout the cycle as shown by the heavy line; this is the effective plate voltage, e_b. When e_m equals $2E_b$, the instantaneous plate voltage is twice the normal dc value, thus producing a plate current which is also twice the normal value. As a result, the instantaneous (peak) power output is four times the normal (carrier) value. As the sine-wave modulation signal decreases, it reaches the zero (no modulation) level or starting value, and the r-f amplifier plate voltage consists of the dc supply voltage alone, which produces normal carrier output, completing the positive half cycle of modulation. In a similar manner, as the modulating since wave goes through its negative alternation, it produces a negative voltage in the secondary of transformer T2. At the peak of the negative half-cycle, the voltage at the secondary of T2 exactly equals that of the dc power supply feeding V3, but it is not opposite polarity. Thus both voltages cancel (instantaneously), and the instantaneous voltage applied to the plate of V3 is zero. At this time the r-f output is zero. The r-f output rises to the normal carrier value as the negative halfcycle of the modulating sine wave goes positive, and returns to zero at no modulation. Thus, by varying the instantaneous plate voltage, the sine-wave modulating signal produces a similar and amplified sine wave of r-f voltage at the plate of V3, which is coupled to the tank and thence to the antenna, where the modulation envelope is radiated. It is an amplified replica of the original sine-wave modulating signal. Thus, it can be seen that during modulation by a sine wave, the instantaneous r-f output power of the transmitter varies as follows: it is increased from its normal carrier value to four times normal, it is reduced to zero, and it is returned to the original carrier level. Therefore, in a plate-modulated amplifier, during modulation the instantaneous power varies from zero to four times normal, and the instantaneous plate voltage and current vary from zero to twice normal to produce 100 percent modulation, as shown in the following illustration.



Modulation Power Relationships

Actually, only the instantaneous values of current and voltage change, and these vary at the rate of the modulating signal. For a sine wave applied over a complete cycle, the positive and negative variations are equal and opposite; since the plate meter cannot follow the audio variations at the carrier frequency (and the average value is unchanged), the dc plate current appears to remain steady at the normal input value without modulation. Therefore, as long as the positive and negative alternations average out to zero,

the plate meter remains steady. In practice, however, this is true only if there is perfect regulation of both modulator and r-f amplifier plate supplies. Since the plate current is instantaneously varying in both tubes and since the voltage regulation is usually not perfect, there is a slight amount of meter movement with modulation. On the other hand, when the negative alternation exceeds the normal carrier level, the plate current is cut off for the time that the zero voltage line is exceeded, as shown in the following figure.



A-634
Effect of Excessive Negative Drive

Such interruption of the carrier appears as a noticeable jump in the plate meter indication each time the negative peak is exceeded. In actual practice, the r-f amplifier (transmitter) tube is not driven to zero plate voltage, because at zero plate voltage the current would become zero and the carrier would be interrupted in the same manner as when the negative peak is exceeded. To prevent such undesirable action, the modulator is adjusted to swing the r-f amplifier plate voltage between predetermined minimum and maximum values. Such adjustment prevents cutoff of the carrier (provided these values are not exceeded). It also prevents excessive interference, known as **splatter,** from being produced by the chopped-up carrier. When the carrier is interrupted, it acts as if it were a highly damped wave instead of a continuous wave. This type of emission is a form of ICW (interrupted continuous wave), and is similar to that produced by spark transmitters and some types of noise generators. Instead of a single frequency, a number of harmonics and spurious frequencies are produced in bursts each time the carrier is interrupted. Thus the radiation is spread over a spectrum of a few hundred kilohertz about the carrier frequency, and causes interference to other signals since the receiver cannot tune it out. The actual plate voltage relationships in the transmitter tube plate circuit are shown in the following figure, together with the actual instantaneous plate cathode voltage. Since the transmitter stage is operating class C, current flows for less than a half-cycle, usually somewhere between 120 and 150 degrees. Therefore, the illustration shows operation on only one side of the zero line during the conducting period. The smooth envelope which varies above and below the zero level, as shown by the plate-cathode **voltage,** is the result of tank 'circuit action. Although pulses are supplied to the tank, since the tank circuit charges and discharges sinusoidally, any output taken from the tank, directly or indirectly, will also be sinusoidal. Thus, the upper and lower portions of the plate voltage (E_b + em) effectively add and subtract from the tank current. The result is the production of the modulation envelope shown, since the tank provides the impedance across which the rf is generated, and sees no zero level. In addition to supplying what might be considered as the missing half of the modulation waveform, the tank is also the frequency-selecting device, permitting only those frequencies within its pass band to be amplified. If the tank is too selective (has a high Q), some of the sideband frequencies may be cut off, in which case distortion is produced because of the missing frequencies. For radiotelephony the Q is usually 10 to 15 to prevent excessive selectivity. For CW (unmodulated) signals it can be much higher. For very wide band transmissions, as in television, it must be much lower. The highest sideband frequencies to be transmitted determine the allowable Q of the tank circuit.

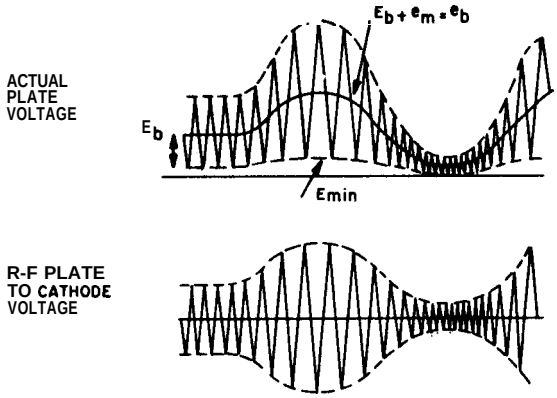


Plate Voltage and R-F Voltage Relationship

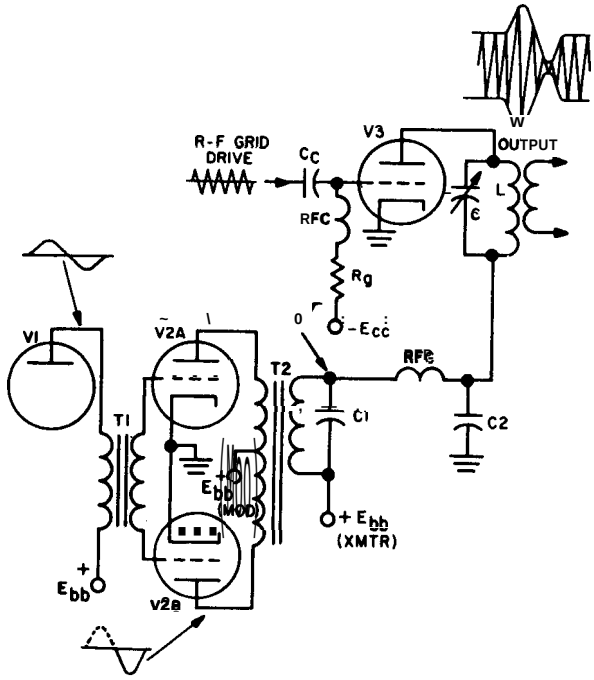
The transmitter output amplifier is always operated class C to produce linear modulation with high efficiency. In class C operation, the power output of an r-f amplifier varies as the square of the plate voltage while the plate current varies directly with the plate voltage. Therefore, a high-level plate modulator can be used to vary the effective plate voltage in accordance with the modulating signal and produce an output which varies exactly as the modulating signal. The r-f amplifier acts as a resistive load on the modulator because the plate tank is tuned to the same frequency as the r-f grid-driving signal. Since the tank appears as a resistive load, the plate voltage and plate current are in phase. Therefore, the current flow is limited only by the effective resistance in the plate circuit, which can be determined by the simple Ohm's law relationship of E/I. Although the r-f amplifier could be operated class B and modulated with the plate modulator, serious distortion would be produced because the r-f class B amplifier output varies as the square of the input voltage and not linearly with plate voltage. For full efficiency and minimum distortion, the class B r-f stage would be better modulated by applying the modulation to its grid circuit. In this case it would be operated as a linear r-f amplifier with low-level modulation.

The modulator can be operated class B (instead of class A) provided that two tubes are employed (one for each half of the audio cycle).

Class B Modulator. Since class B audio amplifiers provide a more efficient modulator and are in popular use, a schematic of a typical class B driven plate modulator is shown in the accompanying illustration.



Class B Audio Driven Plate Modulator

The actual operation of the class C modulated stage is exactly as just described for the class A modulator. The difference between them is in the manner in which the audio modulation is obtained. When the output of preamplifier V1 is applied to Tl, the grids of V2A and V2B are simultaneously driven in opposite directions. These tubes are class B zero-bias tubes, which are normally inoperative without grid drive (although with some tube types a small plate current may flow). When tube A is driven positive, the grid of tube B is driven further negative. On the opposite half-cycle, tube B is driven positive and tube A is driven below cutoff. The current pulses produced in the plates of each tube flow through the primary of modulator transformer T2 in opposite directions, and are added together in the secondary to produce the complete and amplified replica of the signal applied to the primary of driver transformer T1. The output of the secondary of T2 is connected in series with the plate voltage of the r-f stage, V3. On the positive alternation, the plate of V3 is driven to twice the normal plate voltage; on the negative alternation, the audio output voltage is of opposite

polarity and reduces the instantaneous plate voltage of V3 to almost zero. Thus, the circuit operates as previously described. For a more detailed and complete story on the operation of class B audio amplifiers, see the discussion of the Push-Pull (Class A, AB, and B) Audio Amplifier, in the Amplifier Section of this Handbook.

Capacitor Cl, across the secondary of T2, is a simple high-pass filter, which attenuates any high frequencies produced on modulation peaks to prevent splatter. Capacitor Cl is not necessary for operation of the modulator, but it does minimize distortion products produced by overmodulation on voice peaks.

The plate of r-f stage V3 is shown with series plate feed, rather than shunt-feed as is used in the class A modulator previously discussed, to illustrate that there is no essential difference between the two. In either case, the secondary of modulator transformer T2 is connected so that the audio output is in series with the dc plate voltage applied to V3, and the rf is isolated from the power supply and modulator by an rfc. To avoid loss of frequency response, C2 is limited to a size which will not bypass any of the audio modulation. Otherwise, the operation is identical with the operation of the class A modulator just discussed. In practice, the use of a class B modulator results in some problems with power supply regulation and audio distortion products. These effects, however, are all a part of the audio power amplifier design, and do not change the modulation action previously described.

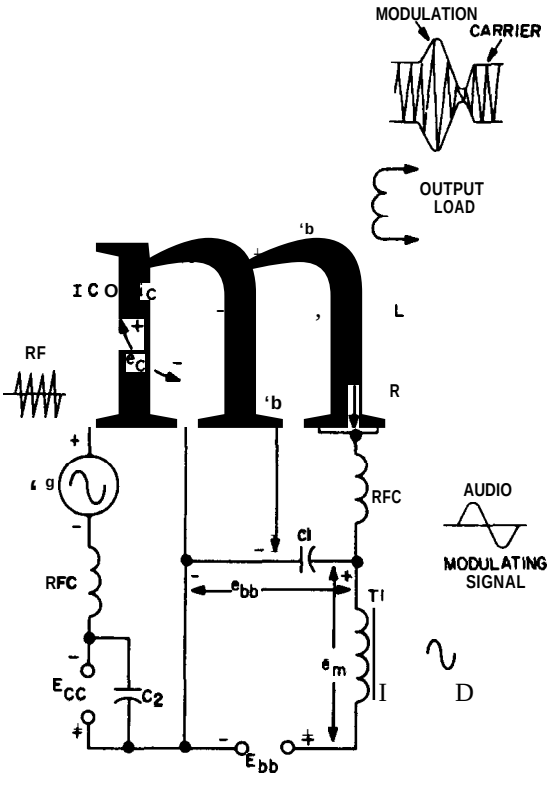


Plate Modulator Equivalent Circuit

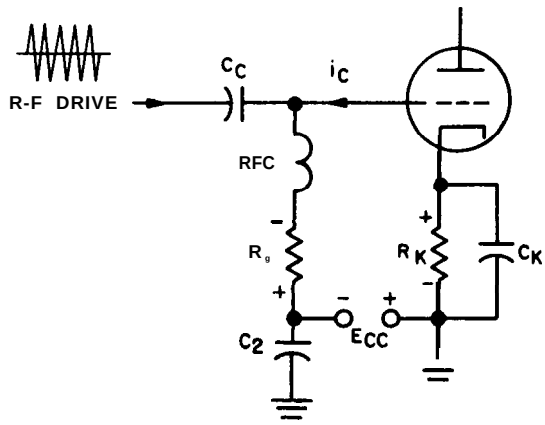
Detailed Analysis. In the high-level plate modulator, the modulator consists of an audio power amplifier whose output is applied to a class C r-f amplifier which operates as both a mixer and a frequency and power converter to superimpose the modulation signal on the r-f carrier. A simplified equivalent circuit is shown in the foIlowing figure. The audio modulator stage is represented as a sine wave generator coupled by T1 to the plate circuit of the r-f stage, V1. The modulator functions exactly as any class A, AB, or B audio power amplifier capable of producing an audio output equal to one-half the carrier power of the r-f stage, with the desired fidelity. The instantaneous a-c output of the modulator at the secondary of T1 is represented by the instantaneous voltage em. Under conditions of no modulation, e_m is zero and the power for the carrier is supplied by the transmitter power supply, represented by the voltage Ebb connected in series with e_m and the plate of V1. Under modulation conditions, the additional power needed for 100 percent modulation is obtained from the modulator stage, which at 100-percent modulation must supply exactly one-half of the dc input power to V1 at zero modulation. The rfc isolates both modulator and power supply from the class C r-f stage, with C_1 acting as a bypass to ground for any rf which might leak through the rfc. For the circuit to operate properly, the rfc must offer a very high impedance to the rf and little or no opposition to the audio modulation frequency, since it is desired to vary the plate voltage at the audio frequency. Although capacitor C_1 must have a low enough reactance to

bypass the carrier frequency and a small range of sidebands around this frequency, it must not be low enough to bypass any of the audio output from the modulator. Otherwise, there will be a progressive loss of high frequencies and consequent lack of fidelity with a predominantly bass response. Since the plate current of V1 flows through the secondary of Tl, the effects of core saturation produced by the flow of 1_p must be taken into account by the use of a heavier core than would normally be required for an ordinary a-f power output transformer. In addition, the transformer windings must have the proper power handling capacity (proper wire size) so as to handle the maximum current taken by VI. In this respect, the design of the output transformer of the audio modulator represents a slight difference from that of a conventional audio amplifier. Since the modulator output must produce considerable undistorted audio output power, it must be properly matched to the load. This is achieved by providing a transformer (preferably multi-tapped), which through the impedance transformation produced by the difference in turns ratio between primary and secondary provides the desired load impedance for maximum output with minimum distortion. The modulator load is essentially resistive, being the quotient of the dc plate voltage applied to V1 and the loaded dc plate current to which VI is adjusted. In the equivalent schematic, e_{bb} represents the instantaneous applied plate voltage, which is $E_{bb} + e_m$. The voltage between plate and cathode is represented by $e_b = e_{bb} - e_L$, where e_L represents the voltage drop across the r-f load offered by the tank circuit impedance. This load is represented by resistor R, which is the effective dc load presented to the modulator, and is equal to the applied dc plate voltage, Ebb, divided by the dc plate current, I_p, neglecting the small dc resistance in tank coil L. Since the tank circuit is resonant, X_C equals XL, and the tank appears solely as a resistive load to VI. Because the tank circuit is resonant to a single -frequency (the carrier) which is much higher than the relatively low modulating-signal frequencies, no audio voltage is developed across the tank. The instantaneous plate current is represented by ib, and the plate-to-cathode resistance, which is equal to E_p/I_p, is transformed by T1 to the proper value to load the modulator for maximum undistorted output. Although the instantaneous values of plate voltage and current change during modulation, the average values remain unchanged so that tube VI could be replaced by a resistor as far as modulator loading is concerned.

Consider now the grid bias applied by E_{cc}. This represents a freed negative bias, but actually may be a combination of protective cathode bias, fixed bias from a separate supply, and bias developed across a series resistor as a result of grid current flow produced by the r-f driver. The driver signal (r-f grid excitation) is represented by a-c generator voltage e_g, which on the positive half-cycle is polarized in opposition to the freed bias, as shown in the plate modulator equivalent circuit above. The effective grid voltage is the instantaneous value from grid to cathode, represented by e_c. The dc value of grid current is represented by I_c, and the instantaneous value, by i_c. The grid rfc isolates the bias supply from the driving source and prevents shorting the input to ground, and C2 acts as a conventional r-f bypass shunting the bias supply. An illustration o,f a typical bias circuit is shown in the following figure.

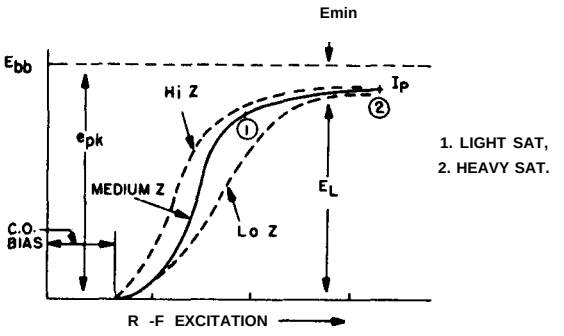


Typical Bias Circuit

When used, the cathode bias produced by cathode resistor R_K offers protection from excessive plate current when either the drive or freed bias fails. The cathode resistor is conventionally bypassed by C_K. Usually cathode bias is used only when the freed bias supply is not employed, since double protection is unnecessary. For high-voltage transmitter tubes, it is also desirable to keep the cathode at ground potential, so cathode bias is used only in low-power applications. The freed bias is obtained from a separate bias supply and is usually set for about 1.5 times

cutoff, with the remaining bias (that developed by the r-f drive) being developed across grid leak R_g. Placing R_g after the rfc helps attenuate any rf which may leak through the rfc, and C2 bypasses any r-f residue to ground. Note that i_c flows in a direction which adds to the polarity of E_{c} so that the total effective bias value is fixed by the amount of grid drive from the preceding r-f amplifier. Normally, tube V1 operates in a lightly saturated condition, that is, where an increase of grid excitation will not increase the plate current very much, if at all, but an increase of plate voltage will, as explained below.

The following figure illustrates how the output voltage varies with an increase of excitation before and after saturation is obtained. Since fixed bias is used the output is zero for values of excitation lower than the cutoff-bias voltage with a corresponding high plate to cathode voltage. As the cutoff-bias voltage is exceeded plate current flows and the drop across the load, EL, becomes greater while the plate-to-cathode voltage is reduced. When the drive reaches the value at point 1 on the curve, the tube is just starting to saturate (light saturation), and it takes much more drive to increase the current sufficiently to develop an appreciably greater output voltage. At this point the effective plate voltage reaches its minimum vahre (approximately), which is the applied value less the drop across the load (Ebb – E_L = E_{mm}). At this point the tube is operating most efficiently and produces an output voltage almost as great as the applied voltage. At point 2 heavy saturation is obtained, and it takes almost twice as much drive to obtain a slightly greater output. If the applied Vohage, E_{bb}, is increased, a greater drive is required to reach saturation, and a greater output voltage results.

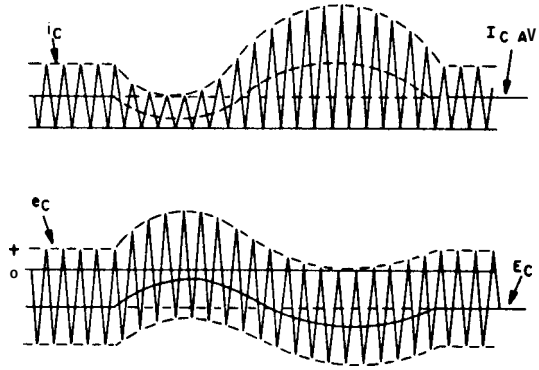


saturation Characteristics

It can be seen, then, that when the excitation is adjusted for saturation at the peaks of modulation, during the resting or carrier condition the drive will be much more than is required. Thus it is evident that while the r-f drive voltage is essentirdly constant, it will tend to vary somewhat in accordance with modulation and loading. Under resting conditions, the grid current is about the rated tube value, and produces the remaining bias needed (plus the fixed bias) to attain twice the plate current cutoff value. When an input is applied to the modulator grid, the output at the plate of the modulator adds to the plate voltage, and more plate current flows. At the same time, if the grid excitation is obtained from a source which is barely able to supply the required drive at modulation peaks, the effect of poor regulation is obtained and the grid current tends to decrease (the source cannot supply more excitation). At the peak of the modulation cycle, the r-f grid excitation is made just sufficient to drive the tube to twice normal

plate current (assuming perfect linearity). The tendency of the grid current to decrease during modulation peaks lowers the effective bias (since it is partially produced by grid drive) and permits a greater plate current to flow, producing the same effect as though the drive were increased at the peak of the cycle, just when the most drive is needed to handle the increased plate voltage. Since the grid current is at a minimum at this time, it represents the lowest drive power during the operating cycle and the grid dissipation is also the lowest. Conversely, as the modulation decreases and reaches the trough of the signal, the effective voltage applied to the plate ($E_m i_n$ in the preceding figure) is the lowest, since the modulation and dc plate voltage are canceling each other; and the drop across the load is at its lowest with an output voltage just greater than zero. For best efficiency, E_{min} is made just equal to e_c; hence, the grid becomes more effective than the plate (since it is closer to the cathode), and more electrons are attracted to the grid, increasing i_c. As i_C increases, the grid dissipation becomes greater since the tube is also overdriven, having much more drive than is needed to swing the small plate current at the minimum plate voltage. The result is excessive heating of the grid.

By using grid-leak resistor R_g (together with the fixed bias), the effect of poor regulation in the grid circuit is achieved. Thus the excessive grid dissipation caused by the low plate voltage at the trough of modulation (discussed above) is reduced. The waveforms in the following figure illustrate the use of the grid leak in providing poorer grid regulation and improved operation. At the peak of the modulation, the reduction of grid current caused by poor regulation from the source produces less voltage drop in the grid leak, and the bias is reduced as before (but to a larger extent). On the other hand, as the modulation trough is reached, the increase of grid current (because of the increased drive, since the plate voltage is now low) produces greater grid bias, which is the same as reducing the drive, just at the time it is needed least. Thus, the addition of the grid leak helps reduce grid heating, and helps the plate reach its maximum and minimum swings so that full 100-percent modulation is achieved. Although the circuit operates satisfactorily without the grid leak, use of the grid leak results in less distortion and cooler tube operation.



Grid-Leak and Fixad Bias Relationships

Note that, while the instantaneous grid current and grid voltage change, their meter indications appear as an average steady dc value since a sinusoidal symmetrical modulating signal is being applied. Therefore, as in the constant-current system, proper operation is indicated by steady grid and plate current indications (assuming perfect power supply regulation and neutralization of the r-f output stage).

Assuming no modulation and a steady input to the plate of the r-f amplifier, with the proper load coupling a steady r-f carrier is produced. As the modulating signal is applied, the power in the plate circuit and in the tank of the r-f stage is increased to a peak value of four times normal (output power varies as the square of the plate voltage). Since the tank circuit cannot absorb all the additional power (the load does not change), the additional power mostly appears as an increase in output (except for the amount replacing the losses in the circuit and a small percentage wasted in extra plate dissipation). Because the modulator furnishes this power increase, it is clear that the r-f power supply furnishes only the carrier power, while the modulator provides the audio or sideband power. Hence, the reason for requiring the large amount of power needed for plate modulation. Although a peak power of four times normal exists, the average output over the entire cycle is only 1.5 times normal at full 100 percent modulation. That is, for a 100-watt radiated carrier modulated 100 percent by a continuous tone, the radiated power would be 150 watts total. For this condition, 25 watts

resides in each of the two sidebands developed by the modulation.

Other Considerations. Because of the requirement that the r-f amplifier tube handle peak powers of four times normal, the tube is operated 20 percent below the ratings for class C operation. Although the efficiency does not change during modulation, the plate dissipation is greater because more power is developed and applied. Therefore, the tube cannot be operated at maximum rating during periods of no modulation. As a result, the normal carrier output is less than the maximum output possible using the same tube unmodulated.

Since the tank circuit must pass both the carrier frequency and the sideband frequencies, the tank circuit Q is important. The half-power bandwidth of the tuned tank must be sufficient to pass the carrier frequency plus the sidebands which extend on each side to a frequency equivalent to plus or minus the highest modulation frequency. For example, if the modulation is 5 kHz and the carrier is 5 MHz, the half-power points must cover a range of 4.995 to 5.005 MHz; otherwise the sidebands will be clipped, causing loss of the bigher frequencies.

While too great a drive results in excessive grid dissipation, the r-f grid excitation to the class C stage must be great enough to drive the tube at twice normal plate voltage. Otherwise, on the peaks of modulation lack of sufficient drive will cause peak flattening with distortion. There must also be sufficient reserve electron emission to supply the peak power requirements, or peak flattening will also occur.

For efficient operation, the grid signal should never exceed the minimum plate voltage, or excessive grid current will flow. Excessive grid current will cause grid heating and a loss of efficiency.

Failure Analysis.

No Output. Lack of output should first be isolated to either the transmitter r-f amplifier or the modulator stage. Even though the modulator is operative, an open rfc or tank circuit, a defective electron tube, or a lack of r-f grid excitation in the transmitter r-f amplifier will produce a no-carrier indication, and thus no output. Checking the r-f amplifier plate meter for current will reveal whether the circuit is complete, and whether a resonant dip can be obtained. A check on the drive meter (dc grid current) indication will also determine whether r-f excitation is present. Lack of grid drive indicates trouble in the driver stages or transmitter power supply, and lack of plate current indicates trouble in the transmitter or in the modulation transformer. If the plate meter indicates at all, the trouble is probably in the r-f stages; if no indication is observed, the modulation transformer is open, the transmitter power supply is defective, or the plate circuit in the transmitter is open.

A no-output condition is generally indicative of lack of voltage, lack of continuity in the circuit, or a short-circuited condition. A resistance check to ground will be helpful, but is usually unnecessary. With the voltages and currents commonly involved in high-powered transmitters and modulators, breakdowns are usually obvious from external symptoms, such as arcing, charring, and burning. On low-power equipment, additional test equipment may have to be used. But remember, DANGEROUS VOLTAGES are involved; be certain to take all safety precautions before connecting or disconnecting any test equipment.

A no-plate-current indication is usually indicative of an open circuit, or lack of continuity, which can be determined by a resistance check or a voltage check. Voltage checks on the grid and plate elements will indicate continuity as well as terminal voltages. A low-plate-current indication usually indicates lack of sufficient r-f drive, high-resistance joints (poorly soldered connections), low tube emission, or an excessively high grid bias. A high-plate current indication usually indicates short-circuited components or insulation breakdown, or a lack of sufficient grid bias. In the last two cases, check for proper grid voltage before making any other checks.

Low Output. It must first be determined whether the low output is due to lack of audio power or a reduction in the percentage of modulation. Although low modulation is normally due to lack of sufficient audio power, it can also be caused by a reduced setting of the audio drive gain control or by trouble in the speech amplifier stages which drive the modulator. An oscilloscope is very useful in determining the cause of malfunctioning since it permits direct observation of the waveform. For a simple quick test of the modulation percentage, the trapezoidrd pattern is helpful. The envelope waveform check, however, can show both percentage of modulation and waveform distortion, and is more useful in trouble analysis. Too high a grid bias (with the same drive) will cause a reduction of output. Insufficient r-f drive on

the peaks of modulation will also cause flattening of the waveform peaks and prevent full 100-percent modulation. A similar effect is also obtained when the r-f amplifier plate voltage is too high for the amount of audio voltage supplied (indicating loss of modulator output), and when the modulator output exceeds the r-f plate voltage. In the latter case the negative peaks are clipped and carrier shift results, with accompanying distortion, reduced output, splattering, and a shifting plate current indication (this immediately pinpoints the trouble as overmodulation). Refer to the Basic Measurements section of NAVSHIPS 0967-000-0130, Test Methods and Practices, for specific modulation tests, oscilloscope connections, and waveforms.

Normally, with modulation, if the power supply regulation is inadequate in either the transmitter or the primary ac supply line, there will be a slight movement, or flicker, of the plate current meter during the process of modulation. Overmodulation will be indicated by a sharp noticeable movement each time the peak exceeds the maximum value, If the power supply regulation is satisfactory, the normal meter indication will be rock-steady, and any meter movement will indicate either overmodulation or the presence of distortion products.

A modulation transformer which has partially shorted turns or which is partially shorted to ground may not be easy to locate from external appearances. If the short is to ground, there may be a noticeable arcing or an audible indication. If the short is between turns, however, it will probably result in an unusually low or distorted output. If the short circuit is severe, the output voltage will be too low to provide 100-percent modulation; a less severe short circuit will probably indicate itself by distortion and a mismatched type of presentation on the oscilloscope. Failure of the modulation transformer that is not visible by external symptoms is difficult to determine, and usually can be remedied only by replacement of the transformer with a good one after all other components have been checked and found satisfactory.

Lack of sufficient electron tube emission to develop the extreme peaks of modulation in the r-f amplifier can cause peak clipping, more than usual distortion, and inability to obtain 100 percent modulation. Such a condition is usually progressive and can be observed by noticing that the output indicator (r-f ammeter) fluctuations become less for modulating signals known to produce large indications. (At 100-percent modulation the output indication on an r-f ammeter will increase approximately 22 percent above the normal indication without modulation.)

Distorted Output. Any distortion in the output is usually obvious when the audio modulation is monitored. R may occur from a number of causes. For example, overmodulation will cause carrier shift, severe interference with other stations because of spurious signals, and audio distortion. Changing the modulator load impedance, by adjusting the r-f amplifier loading (r-f output) for a value of plate current which is different from the normal value, will change the modulator load line; depending upon the magnitude of the change, this condition may be easily detected, or a special check may be necessary to determine the amount of distortion. Any change of modulator grid bias will shift the operating point and require a corresponding change in the r-f drive. With low bias (for a given drive voltage) the input will be clipped and distorted, and with high bias a larger input signal (drive) will be required; thus speech amplifier distortion will most likely be increased. If the audio gain control is advanced too far in the speech amplifier, the modulator can be overdnven, regardless of whether it operates class A, AB, or B. This can cause peak distortion in both the modulator and the r-f amplifier. With proper drive and symmetrical modulation, little or no distortion will occur. On the other hand, with improper drive and with large unsymmetrical or sustained peaks of modulation, excessive distortion can result. Use of a modulation indicator to indicate the percentage of modulation is a help in determining whether distortion is caused by overmodulation. Only, a waveform check can positively determine whether distortion is present. An oscilloscope arranged to check waveforms at key points is most helpful in isolating trouble.

Lack of sufficient plate voltage in either the modulator or the r-f amplifier can cause a reduction in plate-voltage swing with a consequent loss of the peaks in the output. In the modulator, this is evidenced by a rounding off of the peaks and an inability to reach 100-percent modulation with a further increase in the audio drive. In the r-f amplifier, it is shown by peak clipping caused by overdrive from the modulator. In either case, distortion components can be heard in a monitor, as well as seen on the oscilloscope.

491-044 0 73 68

Operating at a higher than rated load can also cause core saturation effects in the modulation transformer and thus produce a flattening off of the peaks. Such a condition will return to normal when the load is readjusted for the proper current. Poor frequency response in the transformer can also cause distortion by loss of low or high frequencies, but this is an inherent design problem and will not occur unless the modulation transformer is defective or is replaced with an inferior part. Poor connections or internal dc leakage will most likely be shown by the presence of noise components in the modulation. Use of a harmonic analyzer will usually indicate the source of the distortion.

Iack of sufficient filament (cathode) emission in the r-f amplifier and modulator tubes can cause distortion due to peak clipping and make it possible to obtain 100-percent modulation.

COLLECTOR-INJECTION MODULATOR

Application.

The collector-injection modulator is used to produce modulation at either low or relatively high levels, and up to a maximum of 100 per cent for semiconductor transmitting equipment.

Characteristic.

Is operable under either small signal or large signal conditions.

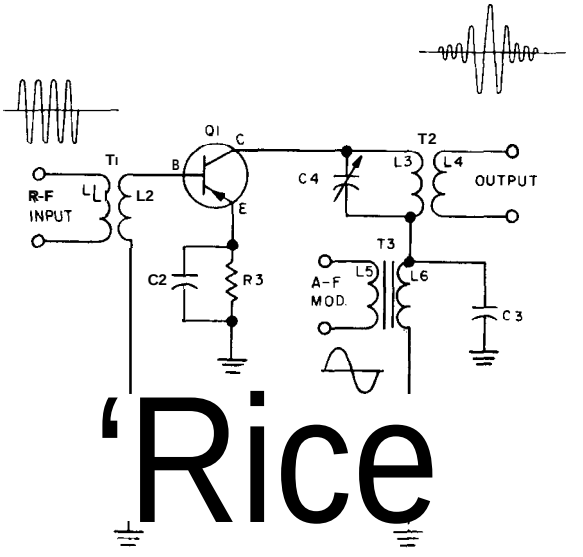
Uses fixed bias.

Is capable of full 100 per cent modulation.

Circuit Analysis.

General. Collector-injection is the semiconductor counterpart of electron tube plate modulation. While plate modulation is usually always at a high level, collector-injection can be at very low levels. In fact, at the present state of the art, linear modulation for high frequency transistors is limited to a maximum change of one tenth of a volt or less which is a very low level of operation. In addition, the transistor ratings must be such that normal dc collector voltage does not exceed one half of the collector breakdown rating, otherwise the peak swing on large signal operation may cause breakdown. When inputs larger than the emitter bias are applied, rectification occurs in the base circuit and causes an increase of bias. However, this slight bias shift does not create as much distortion when collector-injection is used as it would if either base-or-emitter injection were used.

Circuit Operation. The accompanying illustration is a schematic of a typical collector-injection modulator circuit.



Collector-Injection Modulator

The r-f drive voltage is applied to the base of Q1, through r-f transformer T1, inductively from primary L1 to secondary L2. The base is held at a fixed forward bias by bias voltage divider R1 and R2. Cl is the r-f bypass for R1, preventing feedback of r-f into the bias supply and possible regeneration. Emitter resistor R3 provides thermal compensation and is bypassed by C2 to prevent degeneration. With the emitter at ground potential, only slowly varying d-c current changes caused by a temperature change will bias off the emitter and counteract the tendency of increased current flow with increasing temperature. The audio modulation is inserted in series with the collector of Q1 through audio transformer T3 by connecting secondary L6 between the collector supply and the output tank. The secondary of T3 is also bypassed for r-f by C3 to prevent r-f squeal in the audio circuits caused by feedback. Output transformer T2 has its primary tuned, with L3 and C4 forming the tank, which is inductively coupled to secondary L4 providing a modulated output.

The freed negative base bias causes heavy forward conduction in Q1, and base current flows from the supply through R2, L2 secondary, and through Q1 emitter-base junction back to ground through emitter swamping resistor R3. Thus the base is held near cutoff for large signal operation (and is Class A biased for small signal operation). With only the r-f drive signal applied, collector current is decreased during the positive half-cycles and increased during the negative half-cycle. This is conventional r-f amplifier operation and provides the normal r-f carrier.

Assume now, that modulation is applied to the input of L5. The signal is transformer coupled into the secondary. Thus during the positive hrdf-cycles of modulation (assuming an in-phase connection) the collector voltage is opposed decreasing the effective collector voltage. On the negative half-cycle the polarity of the modulation adds to the collector voltage, increasing it. Thus the transistor gain is alternately decreased or increased in accordance with the modulation swing. When the gain is increased a peak of modulation occurs, when decreased a trough in the modulation occurs. If the transistor gain varies linearly, 100 percent modulation is achieved when the collector voltage is doubled on the negative half-cycle. Although secondary L6 of T3 is bypassed by C3, the bypassing is effective for rf only and the af signal remains effective in changing the instantaneous collector voltage. The output tank circuit varies in accordance with the modulation and inductively couples the output to L4 secondary of T2. In smrdl-signal, Class A operation the tank circuit determines the output frequency. In large-signal, Class B or C operation, the tank supplies the missing half cycle which is lost during cutoff, and also determines the output frequency. Thus distortion is kept to a minimum for either small- or large-signal operation.

Failure Analysis

General. When making voltage checks use a vacuum tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges of conventional voltmeters. Be careful, also, to observe proper polarity when checking continuity with the ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A defective transistor, open base, emitter, or collector circuit, or a loss of bias will prevent operation. An open base circuit can be caused by lack of continuity in the windings of T1. Check L1 and L2 for continuity with an ohmmeter. Likewise, an open bias circuit may be caused by either R1 or R2 open. If R2 is open the operation is certain to cease, but with only R1 open some bias will be produced through R2 and the transistor, so complete output should not be lost. Check the values of R1 and R2 with an ohmmeter. An open circuited emitter, possibly caused by a defective swamping resistor R3, will also stop operation. Check the value of R3 using an ohmmeter. An open circuited collector will also stop operation; this can be caused by an open tank coil L3, a high resistance soldered joint, or by shorting of tank capacitor C4. An open modulation transformer will also prevent collector voltage from appearing if it is in the secondary of T3, as well as a short on C3. Use an ohmmeter to check the winding for continuity and an ohmmeter to check C3 for a short. If all the circuits thus far are found to have continuity and correct value there are still two possibilities. Transistor Q1 may be defective or output winding L4 of T2 may be open. Check L6 and IA for continuity with an ohmmeter. Improper supply polarity will reverse the bias, stop operation, and most likely ruin the transistor. In most cases a continuity check combined with a voltage analysis, using a high impedance voltmeter, will locate any of the no-output troubles.

Low Output. Improper bias can result in a low output with distortion. Check R1 for proper value with an ohmmeter. Low output can also be caused by low collector voltage. First check the unmodulated value to be certain it is normal, and then check the instantaneous value with modulation using an oscilloscope. The modulation should be able to drive the collector from zero to twice normal voltage, less than this will produce less than 100 per cent modulation. Check the waveform with an oscilloscope. Lack of sufficient r-f drive will also produce a low-output condition, since the af merely functions to modulate the carrier. A defective or mistuned tank circuit can also cause a low-output condition, since the maximum output is developed on the same frequency as that of the input (carrier). With no a-f applied and low drive, the carrier amplitude will show on an oscilloscope as being less than normal or less than one-half the maximum possible amplitude at peak modulation. To determine if the tuning is correct adjust the tank for maximum r-f output (minimum current) if there is no sharp dip in current or

pronounced peak output as the tuning capacitor is rotated, check the tuning capacitor for an open or short.

Distortion or Incorrect Output. Distortion will be caused by improper bias or collector voltage, and by excessive input signals. The r-f signal must not exceed the dc bias; otherwise, rectification of the r-f will occur and change the bias, and, as a result, produce a slight modulation shift on peaks. This will not be as pronounced a distortion as if the injection were of base or emitter type, since only a small fraction of the signal is affected in collector modulation. Too great a modulation signal will cause peak clipping and distortion since the negative peaks will enter saturation and be lost. Use of an oscilloscope will permit this type of waveform distortion to be observed and located. It is also possible that excessive modulation peaks can exceed the maximum inverse voltage, and likewise cause peak clipping effects and possibly damage the transistor.

CONTROL GRID MODULATOR

Application.

The control grid modulator is employed as a low-level modulator in applications where it is desired to use a minimum of audio (modulator) power. It is widely used in portable and mobile equipments to reduce size and power consumption, It is also used in extremely high-power, wide-band equipment such as television transmitters, where plate modulation is more difficult and costly to achieve, and grid modulation is considered standard.

Characteristics.

Varies effective grid bias of transmitter r-f stage to achieve modulation.

Operates as a basic low-level modulator, with mixing process occurring in grid circuit.

Requires very little audio power (on the order of 1 percent of carrier power).

Is more critical in adjustment than plate-modulated class C amplifier.

Produces very little distortion up to 75-percent modulation limit, with greatest distortion occurring between levels of 75 and 100 percent.

Has lowest efficiency for unmodulated (carrier) condition, and highest efficiency at 100-percent modulation.

Has greater bandwidth capabilities than plate modulator when full 100-percent distortionless modulation is not required.

Usually uses triodes, rdthough tetrodes and beam power tubes may also be employed to provide greater power gain and to utilize their inherently low-grid-to-plate capacitance, thus avoiding necessity of neutralization.

Circuit Analysis.

General. Before starting this circuit analysis, the reader should review the discussion on RF Power Amplifiers, in Section 6 of this Handbook, for background on class C amplifiers.

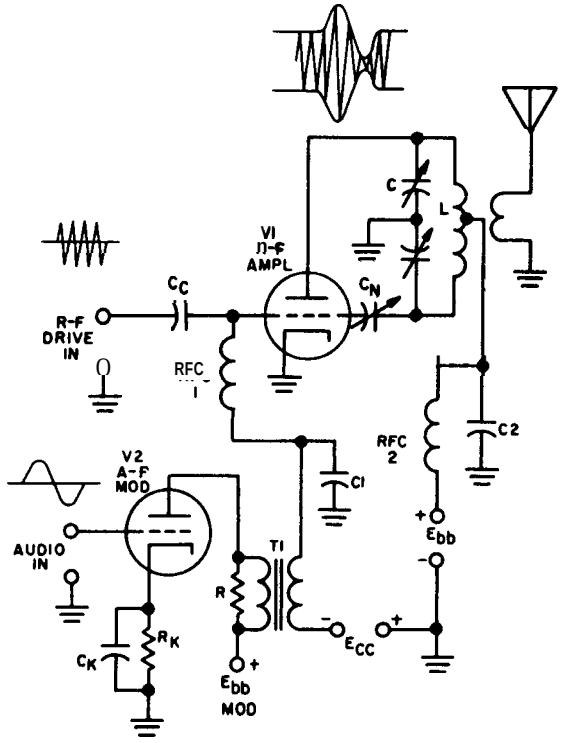
The grid modulator utilizes the variation of grid bias (at the frequency of the modulating signal) to vary the instantaneous plate current and voltage, and thus achieve modulation. The modulating signal is introduced into the grid circuit in series with the fixed bias, so that on each half-cycle the modulating signal alternately aids and opposes the bias. Although the modulation actually takes place in the plate circuit, the modulating signal is applied to the grid circuit, where the power is at a relatively low level (as compared with the plate circuit); thus, the modulator power requirement is low. For this reason, the grid modulator is also classified as a low-level modulator.

Under ideal conditions, only a voltage amplifier would be necessary to produce grid bias modulation. However, in actual practice, the grid w-ill draw current at the positive crest of the signal, and extra power is dissipated in the grid circuit. Therefore, grid modulation does require a modulator capable of supplying a few watts of power (on the order of 2 to 5 watts for moderate power applications). This condition also requires that the r-f driver stage be capable of supplying suftlcient drive power to prevent peak flattening on the modulation peaks.

Unlike the plate modulator, the sideband power and the carrier power are both developed from the same power source. Since this power supply must furnish all of the power on the peaks of modulation, it is necessary to operate the electron tube so that it produces a carrier power which is only one-fourth of that available from the same tube operating as an ordinary class C amplifier. (The plate modulator operates at approximately two-thirds of the rated class C amplifier output.)

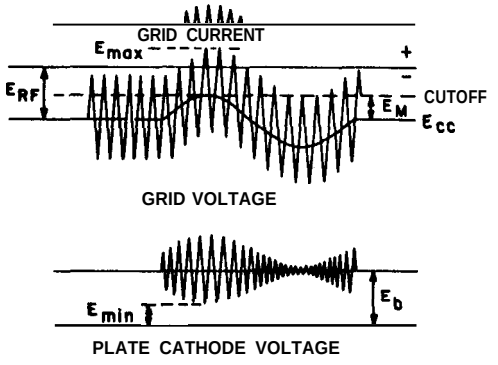
Circuit Operation. The schematic of a typical triode modulator is shown in the accompanying

illustration. The r-f excitation (drive), which is at the same frequency as the output, is coupled capacitively



Triocle Modulator

through C_c to the grid of VI, and a freed negative bias is supplied through RFC1. The modulating (audio) signal is coupled in series with the bias through TI. Capacitor Cl, a decoupling and bypass capacitor, prevents any rf that leaks through RFC1 from entering the audio circuits or the bias supply. Capacitor Cl has a value high enough to bypass the rf, but not high enough to bypass any of the modulation and cause a loss of high frequencies. Since the r-f output is at the same frequency as the r-f input, capacitor C_n, together with a portion of tank coil L, provides a neutralizing arrangement to prevent self-oscillations from being produced as a result of feedback from plate to grid through the grid-plate interelectrode capacitance. To provide a tank comection for neutralizing the modulator and also to provide a low Q, a split-stator capacitor is used to tune tapped coil L. Since the plate end of coil L is 180 degrees out of phase with the neutralizing end, a signal of the proper phase can be fed back to the grid (through C_n) to prevent self-oscillations. RFC2 and C2 form a conventional series plate-feed decoupling arrangement (shunt plate feed may also be employed, if desired). The r-f drive voltage, the modulation voltage, and the fixed bias are selected so that, on the positive peaks of the modulation signal, the tube operates as a lightly saturated class C amplifier. As shown in the following waveforms, the freed bias is slightly greater than 1.5 times the cutoff voltage for the tube, and the modulation signal (Em) varies the effective bias about E_{cc}, with the positive peaks of E_m approximating cutoff. With the effective bias varying in this manner, the r-f drive voltage (E_{rf}) is of such an amplitude that: (1) on the positive swing of E_m, the r-f signal drives the grid positive, grid current flows, and the plate draws current for approximately 120 to 150 degrees of the r-f cycle; (2) on the negative swing of the modulation cycle, the r-f signal drives the grid just barely above cutoff, and plate current flows for just a few degrees of the r-f cycle; (3) with no modulation present, the plate current and voltage are approximately half their maximum values, and the output carrier produced is one-fourth the power of the same tube operating as an ordinary class C amplifier. The most positive swing of the instantaneous grid voltage is E_{max}, and is equal to $-E_{cc} + E_m + E_{rf}$. E_{min} is the minimum instantaneous plate voltage, and must never be less than the instantaneous grid voltage, E_{max}. That is, the grid must never go more positive than the plate. (This is explained fully in Section 6 under Class C Amplifiers.) Since the plate current consists of pulses of current, it may appear that the plate-to-cathode voltage would be in the shape of pulses extending downward from E_b. However, the other half of the sine wave is supplied by the flywheel effect of the tuned tank circuit, and the output is as shown in the diagram. The pulses of plate current in effect reinforce the oscillations of the tank circuit, and thereby make up for any losses in the tank.

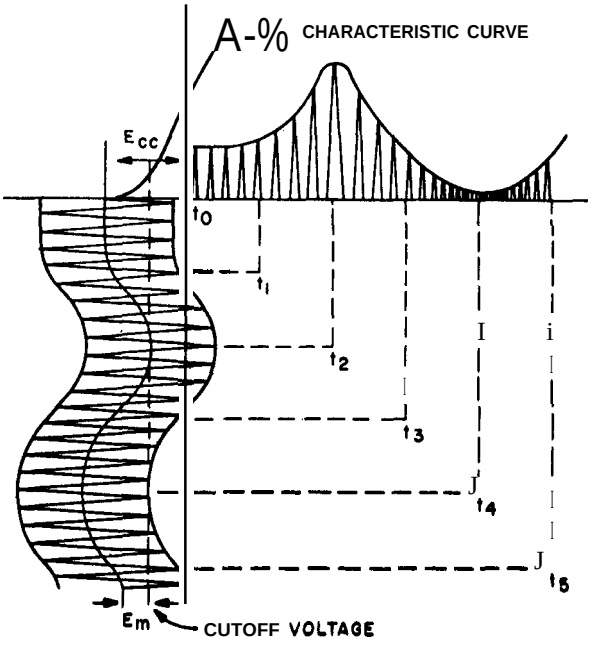


Grid and Plate Waveforms

To accomplish modulation, the varying grid bias drives the plate current from zero to twice normal, and the plate voltage from approximately half the applied dc potential to the full value. This is the same as driving the plate voltage (and current) to two times normal, as in the plate modulator.

Grid bias modulation uses the linear variation of plate tank current with bias voltage variations to produce the modulated envelope, as shown in the following illustration. The grid voltage versus plate current transfer curve is essentially linear over the operating portion, but drops off nonlinearly at the begirming and end. The operating bias is selected so that the resting value (E_{cc}) is at the center of the linear portion of the curve.

With no modulation (time t. to t_1), the bias is E_{cc}, the r-f signal drives the grid above cutoff, with the positive peaks just below O volts. Plate current flows for the portion of the r-f cycle that is above cutoff, with an amplitude approximately half that for the modulation peaks. The plate voltage is one-half the applied voltage, and the power output is one-fourth the maximum power available. As the modulation signal swings in the positive direction (time t_1 to t_2), the grid bias is now $-E_{cc} + E_m$, the r-f signal now drives the grid positive, and grid current begins to flow. Because of the reduced bias, the plate current increases and the instantaneous plate voltage is reduced. At the most positive peak of the modulation signal (time t_2), i_p is maximum and e_p is minimum, E_{min} in the diagram (previously shown). At time t_2 the operation is much the same as for an ordinary class C amplifier (with full r-f drive and fixed grid bias). At time t_3, the grid bias is once again E_{cc}. As the modulation cycle continues in the negative direction, the bias becomes $-E_{cc} - E_m$, this increased bias reduces the plate current to its minimum value, and the plate voltage increases toward the applied voltage. At time t_4, the negative peak of the modulation cycle, the r-f drive voltage is just able to bring the tube out of cutoff (assuming slightly less than 100 percent modulation), and plate current flows for just a few degrees of the r-f cycle. At this time i_p is minimum and e_p is almost equal to the applied voltage. The power output varies between 4 times the unmodulated carrier on the positive modulation peaks and zero power on the negative troughs, resulting in an average power of 1.5 times the unmodulated carrier. Thus, 100-percent modulation is attained.



Grid Voltage Versus Plate Current Relationships

The dc plate current during the time of no modulation is one-half of that supplied during the peaks of modulation. However, the power output during this time is only one-fourth of that supplied during the peaks of modulation. Thus, the efficiency during unmodulated times is only half of that for 100

percent modulation. Typical values of efficiency are 33 percent for no modulation, and 66 percent for 100-percent modulation.

The linearity of the output depends on the linearity of the $i_p - e_g$ characteristic curve. In the preceding discussion it was assumed that the curve was linear from the maximum value of grid bias ($-E_{cc}$ -Em). However, the curve is actually nonlinear in the region near cutoff (and near saturation); thus, some distortion occurs on the negative peaks of the modulation cycle. Distortion also occurs on the positive peaks of the modulation cycle. This is true because of nonlinearity of the curve at saturation, and for the following reason. When the grid is driven positive, grid current is drawn, which places a load on the modulator, the r-f source, and the bias supply. This load is not present during the remainder of the modulation cycle. Because of this varying load, good regulation is required for these circuits. Distortion-free operation may be realized by decreasing the modulation voltage. However, this decreases the percentage of modulation, the power output, and the efficiency of the circuit.

To improve the regulation of the modulator circuit, the primary of the modulation transformer is usually shunted with a load resistor equal to the rated dc modulator load, and the audio output stage is usually designed to have a power output of two to three times the output actually required. In addition, some form of inverse feedback is used. in the audio output stage to keep load variations and distortion to a minimum.

Various combinations of bias supplies are used. Good regulation is achieved by providing a bias supply capable of supplying two or three times the required load. Since the dc (average) power to the plate is constant throughout the modulation cycle, a convenient means of obtaining bias is the use of a cathode resistor. The cathode resistor must be bypassed for the modulating frequencies as well as for the r-f frequencies.

Good regulation in the r-f driver stage is usually accomplished by designing the driver stage to be able to supply more power than is actually required.

The total result is that, because of these interacting requirements, the full theoretical advantages of grid bias modulation are not obtained practically, and the basic distortion is always greater than that obtained with plate modulation. Although extra r-f and audio drive power is needed to minimize distortion, the small amount of modulator power needed for full modulation makes it economical to use grid modulation where the increased distortion can be tolerated.

Failure Analysis.

No Output. Lack of output should first be isolated to failure of the r-f amplifier stage or the modulating signal circuit(s). Even though the modulator is operative, an open rfc or tank circuit, a shorted or defective electron tube, or a lack of grid excitation to the r-f amplifier will produce a no-carrier condition. Check the r-f plate current meter for an indication to determine whether the plate circuit has continuity, and check the griddrive meter for an indication to determine whether grid excitation is present. With both indications normal, and with the tank tumble for a minimum dip of plate current, a lack of coupling or continuity in the output circuit of the r-f amplifier is indicated.

Lack of grid drive places the trouble in the exciter stages of the transmitter or the input circuit to the r-f output stage, whereas lack of plate current indicates possible power supply trouble or an open circuit in the r-f stage.

With an r-f carrier existing, the trouble is definitely in the audio circuits or modulation transformer. An open transformer secondary would remove the grid bias to the r-f stage and cause excessive plate current; a shorted transformer would allow the r-f stage to operate normally and produce a carrier, but no modulation could occur.

High transmitter plate current usually indicates short-circuited components or lack of bias; low plate current indicates excessive bias, high-resistance joints, low tube emission, or a possible lack of coupling to the load. With open-circuited or short-circuited conditions indicated on the equipment meters, a simple resistance analysis made with the power OFF, and with the high-voltage supply grounded for safety, will reveal the defective components.

Low Output. It must first be determined whether the low output is from lack of sufficient audio drive or from an actual reduction in percentage of modulation. Although low modulation is usually due to lack of sufficient audio drive, it can also be caused by a reduced setting of the audio gain control, by trouble in the speech stages, or by lack of sufficient r-f drive. An oscilloscope is very useful in determining the

cause of malfunctioning, since the waveform may be directly observed. For simple, quick tests of modulation percentage a trapezoidal pattern is helpfuL'A waveform check, however, can show both percentage of modulation and waveform distortion, and is more useful. Too high a grid bias will cause a reduction of output and an inability to reach 100-percent modulation with the same drive.

Loading too heavily will increase the r-f carrier output, but it will also result in inability to obtain 100-percent modulation; on the other hand, loading too lightly will produce a reduced carrier, overmodulation on the peaks, and a greater amount of distortion as indicated by a flickering plate meter reading. In the plate modulator, a flickering plate meter reading always indicates distortion and carrier shift, but this is not always true of the grid modulator. Because of the use of a changing efficiency to obtain the modulation, and since the power is obtained from the same source, distortion and lack of full modulation (and even overmodulation) can exist sometimes without greatly disturbing the normal meter indications. Therefore, it is important that the grid modulator be adjusted for. proper results, using an oscilloscope.

A partially shorted modulation transformer will not indicate its condition externally by arcing or burnt. spots since it operates at a very low level; instead, it w-ill probably cause a loss of output combined with distorted modulation. Such a condition can be determined by substitution of a new transformer known to be good after the other parts have been eliminated by a systematic analysis.

Lack of sufficient filament emission in the r-f amplifier or modulator tube will produce peak clipping and a lower output because of inability to obtain 100-percent undistorted modulation at the peaks.

Distorted Output. Distortion is usually obvious when the audio modulation is monitored. It can result from a number of causes. For example, overmodulation will cause carrier shift, severe interference with other stations, and distortion. Since the grid modulator is inherently subject to more distortion than the plate modulator, any slight change in load conditions or misadjustment will usually be indicated by an increase in distortion.

Since the grid modulator essentially supplies voltage, it is necessary for the primary of the modulation transformer to be damped with a stabilizing resistor in order to maintain a substantially constant load. With a varying load caused by an open stabilizing resistor, the distortion will be excessive. In those stages that must be neutralized, it is important that the neutralization be correct; otherwise, during the peaks of modulation, self-oscillations either will occur continuously or will start to occur on the voice peaks. In either case, the distortion produced by poor neutralization is excessive and noticeable. This condition is easily identified on the oscilloscope by a fuzzy and blurred pattern, which is indicative of oscillation (See the Basic Measurements section of NAVSHIPS 0967-000-0130, Test Methods and Practices, for typical modulation tests and waveforms.)

Distortion in the preamplifier stages can easily be detected by supplying an undistorted signal to the input and checking the output waveform of the modulator transformer with an oscilloscope. If low power and low voltages are involved, a quick but less accurate check can be made by using a speaker or set of headphones instead of an oscilloscope.

BASE-INJECTION MODULATOR

Application.

The base-injection modulator is used to produce low-level modulation in equipment operating at very low power levels. It is particularly well suited for small portable transmitters, such as walkie-talkies, and for test equipment.

Characteristics.

Operates by varying the base bias at the modulating frequency.

Is restricted to low-level, small-signal operation.

Uses common emitter configuration.

Modulating signal amplitude is limited to less than that of the base bias voltage.

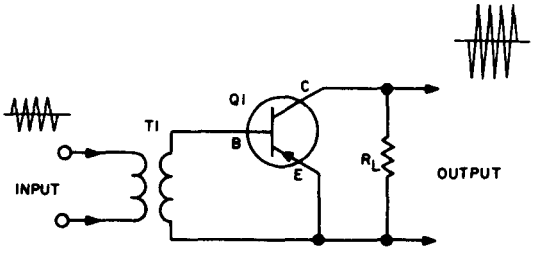
Circuit Analysis.

General. The base-injection semiconductor modulator is analogous to the control-grid modulator in electron-tube circuits. The operating conditions, however, are entirely different. For example, since the semiconductor operates as a true low-level device under small-signal conditions, the voltage required to produce the modulation is also very small. This means that very little modulator power is required, much

less than for comparable vacuum-tube operation. Likewise, since the transistor is operating under small-signal conditions, the r-f input (drive) is also small. Under these conditions, operation is usually class A or class AB. If operation is extended into the class B or C regions, it becomes large-signal operation. When operated large-signal fashion, the rectified r-f drive signal determines the operating bias and considerable distortion is produced by the non-linear transistor response characteristic for large signals. Because of these conditions such operation is seldom used, except for special applications; therefore, it will not be further discussed in this technical manual.

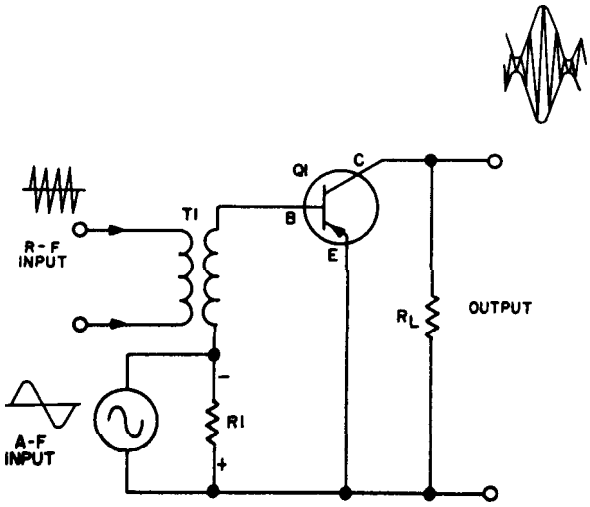
Base injection can be accomplished by a number of different methods. For example, it may be accomplished by feeding the signal either in series with the base-emitter circuit or in parallel with it, and can be accomplished by capacitive coupling or through means of transformers. Each of these methods will be considered in the following discussion.

Circuit Operation. Amplitude modulation by base injection (or emitter injection) depends upon a widely separated r-f frequency and modulation (audio) frequency. There are two basic circuits involved, namely, the r-f amplifier circuit and the gain control (bias) circuit. A simplified schematic of the basic r-f amplifier is shown in the accompanying figure. For simplicity, the r-f amplifier circuit is shown without bias supplies, and with a resistive load in place of the tank circuit. It is assumed that normal forward bias is applied to the base+ mitter junction, and that a reverse bias is applied to the collector junction. The secondary of T1 is effectively connected across the base-emitter junction, and the load is connected between emitter and collector as shown. With normal class A bias applied, the r-f signal will vary the base voltage equally above and below the operating point (assuming a sine-wave signal), and a corresponding base current will flow. A similar but larger (amplified) collector current will flow through the load resistor, developing an oppositely polarized output voltage. This is the action of a conventional r-f amplifier circuit.



Simplified R-F Amplifier Circuit

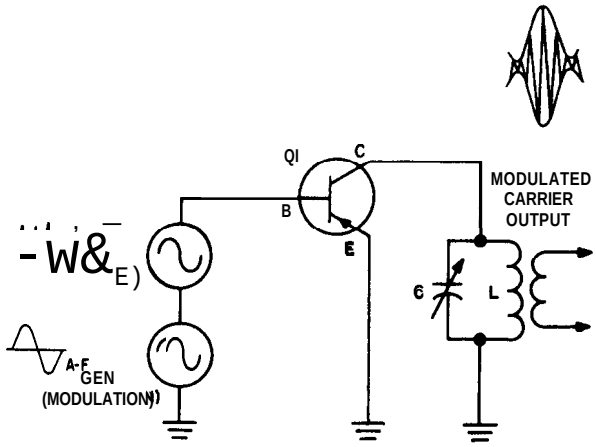
Consider now the method by which modulation is accomplished in the bias circuit, using the accompanying simplified schematic. For simplicity this circuit is also shown without bias supplies and with a load resistor in place of the tank circuit. It is assumed that normal forward bias is supplied to the base-emitter junction, and that a reverse bias is applied to the collector junction. The modulation is injected across R1, which is also the bias resistor, having a freed dc forward bias placed across it. Since the modulation signal is effectively connected in series with the base-emitter circuit, it adds to the bias when of the same polarity. When these voltages are of opposite polarity they cancel and reduce the total effective bias. Thus' tie bias on the transistor is made to vary instantaneously above and below the fixed dc bias level in accordance with the modulation signal.



Simplified Modulator Circuit

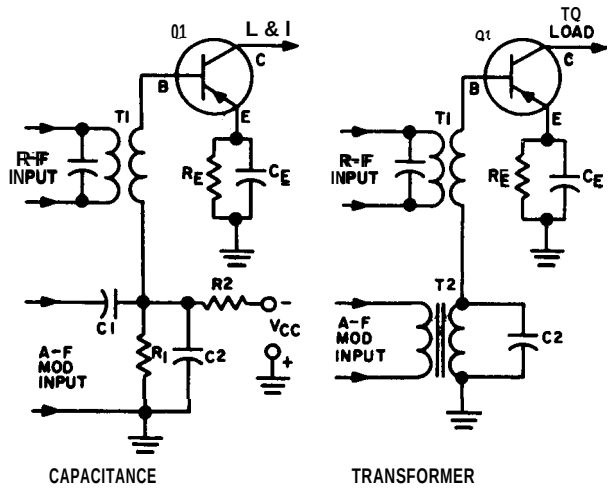
Assuming a sinusoidal modulating signal, it is evident that the instantaneous bias will also vary sinusoidally. Since a change in bias will produce a change in gain, the instantaneous gain will also vary similarly. Consequently, the instantaneous amplification of the r-f carrier signal will vary in accordance with the modulation, but in an opposite direction. (The common-emitter output polarity is opposite the input polarity.) For maximum modulation the a-f signal must be slightly greater than the r-f carrier input signal. To prevent distortion produced by driving the transistor to cutoff or into saturation, the modulation signal amplitude must never exceed the dc bias value.

A simplified schematic of the series-feed method of base injection is shown in the following figure. For simplicity, the inputs are shown as r-f and a-f generators, and biasing voltages are not shown. As can be seen, the r-f driver signal is connected in series with the a-f modulating signal between base and ground. The dc bias (not shown) is such as to bias the transistor for class A operation. The bias value is chosen so that the quiescent collector current is set for half the maximum value. When the r-f input is applied, it adds to the base bias on the negative excursions and reduces the base bias on the positive excursions. The collector current follows these sinusoidal variations of bias, producing a voltage drop across the tuned tank (LC) in series with the collector. The tank is tuned to the driver frequency and is inductively coupled to the next r-f amplifier (or output circuit). Because of the gain through the transistor, the r-f drive signal is amplified. When the a-f modulating signal is applied, it alternately adds to and subtracts from the r-f drive signal applied to the base circuit (both r-f and a-f generators are series comected). The result of combining the r-f signal with the audio modulation signal has the total effect of increasing and decreasing the bias in accordance with the modulation signal amplitude. The changing bias varies the transistor gain in accordance with the modulation signal, and an amplified and modulated r-f output signal is obtained. This signal appears in the output as an r-f carrier with an envelope which is a replica of the original modulation signal.

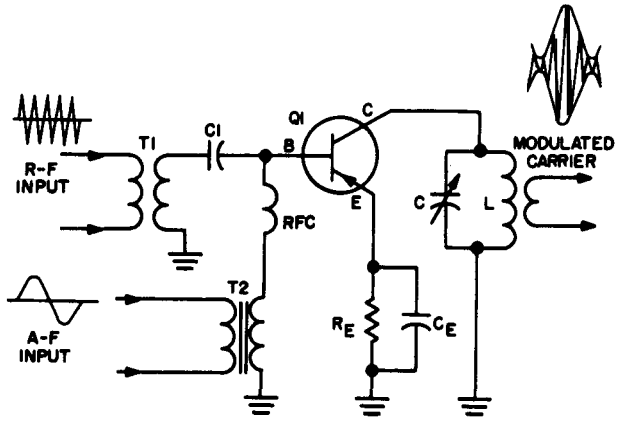


Series Injection

While either capacitance coupling or transformer coupling may be used to inject the modulation signal, there is essentially no difference between them in the manner in which this base injection circuit operates. In the capacitance-coupling method the modulator is isolated by the capacitor (Cl) from the d-c biasing circuit as shown in the following figure, and the modulation is applied across the base bias resistor (Rl) which also acts as the modulator load. RI is bypassed for r-f by C2. With transformer coupling either internal (contact) or emitter bias, or a combination of both are used. Whereas with capacitive



Coupling Methods



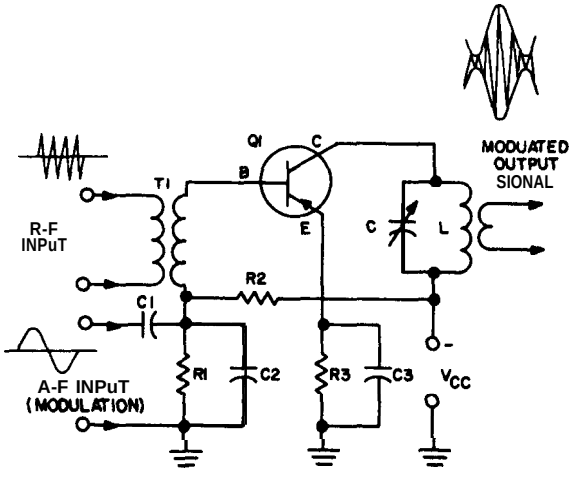
Parallel (Shunt) Injection

coupling **fixed** (voltage divider) bias is usually used. In either case **C2** bypasses the r-f around the audio, completing the emitter-base circuit for r-f. The two methods of coupling are illustrated in the preceding figure. Although not very prevalent, the parallel (shunt)-feed method of base injection may also be used; it is shown in simplified form in the following illustration. Blocking capacitor Cl is used to prevent r-f transformer T1 secondary from shorting the base bias and modulation signal to ground, through its very low secondary resistance. Likewise, the RFC is used to prevent the low-impedance secondary of modulation **transformer** T2 from shunting the r-f carrier signal to ground. Emitter bias and swamping are employed, using R_E and C_E. The collector circuit is identical with the series injection circuit; it contains the tank and output coupling circuit.

In the parallel-feed circuit, the bias is also caused to vary at the modulation rate. The difference is that since the two inputs are in parallel with each other, more modulation signal is required for full modulation. At low percentages of modulation (very small modulator inputs), a larger signal is also required in the parallel-feed circuit to produce the same effect as in the series-feed circuit. The addition of the r-f choke also presents an additional problem, that is, avoiding unwanted resonances in equipment operating over a large range of frequencies. Therefore, shunt injection is not very popular with designers.

The circuit of a typical capacitance-coupled series-feed base-injection modulator is shown in the following illustration. The r-f input is applied to the base of Q1 through r-f transformer Tl, which is shown untuned for simplicity. Assuming normal bias and operation as a conventional class A amplifier, the r-f drive signal is amplified by Q1, and appears as a larger-amplitude r-f output in r-f transformer T2.

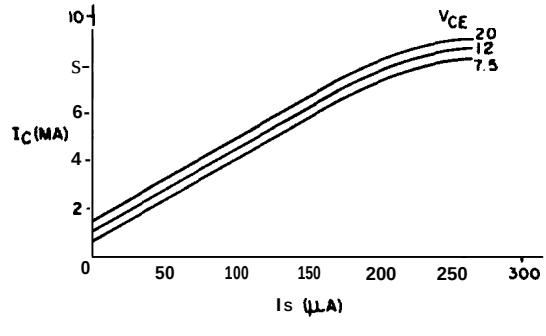
Transformer T2 has a tuned primary with L and C acting as the conventional tank circuit across which the output signal is developed. The secondary of T2 is connected to the next amplifier stage or to a load (an antenna in special cases). Conventional emitter swamping is employed, with resistor R3 serving as the swamping resistor, bypassed by capacitor C3. Capacitor C3 is large enough to offer a low reactance to the lowest modulation frequency employed. Thus, both rf and af are bypassed around R3, so that no degeneration is produced. Only very slowly varying temperature changes produce a voltage change across R3. (See the discussion of Bias Stabilization in the Introduction to the Amplifier Section of this Handbook for an explanation of the function of R3 and C3.)



Base-Injeetion Modulator

Consider now the bias circuit consisting of RI and R2. This is fixed bias with the resistors forming a voltage divider across the supply. (See the explanation of Bias Circuits in the Introduction to the Amplifier Section of this Handbook.) The voltage appearing across RI is the effective bias applied to the base of Q1 through the secondary of r-f transformer T1. Thus, the r-f input is applied in series with the dc bias provided by RI. However, capacitor C2 bypasses RI to ground for rf and, together with C3, effectively comects the secondary of TI from base to emitter. As the r-f signal vanes between positive and negative alternations, the emitter current varies similarly but oppositely (decreases on positive part of cycle and increases on negative part of cycle). The pulses of emitter current applied across the tank load (LC) produce an amplified sine wave of rf at the same frequency as the input.

Consider now the effect of the modulating signal. Since the modulating signal is coupled through capacitor Cl, it appears as a varying a-f voltage across R1. While C2 bypasses R1 for rf, it is not large enough to bypass the a-f modulation. Therefore, since the a-f voltage is applied across R1, between the bottom of the T1 secondary and ground, it is also effectively in series with the d-c bias voltage, and the bias is caused to vary at the modulation rate. As the bias changes under control of the modulating signal, the gain of the transistor is varied likewise. Since the transistor is not exactly linear in its base-collector relationship, the carrier envelope will not be a linear replica of the modulation. It will be similar in shape, with the peaks and troughs occurring at the same time, but somewhat distorted. A typical forward-transfer characteristic curve for the common-emitter circuit is shown in the following figure. Because of the rounding off at the higher currents, the effective limits of modulation are for values between zero and about 92-percent modulation. Above this range the distortion tends to become excessive. Therefore, applications requiring full 100-percent modulation generally employ the collector-injection circuit, which will be discussed later in this section.



Typical Forward-Transfer Characteristic

While a resistive collector load has been assumed for ease of explanation in the simplified circuit discussions, in practice a tuned (L-C) tank circuit is necessary to select the proper output frequency. In every modulator there are sum and difference frequencies, and spurious frequencies are generated by the nonlinearity of the modulator (even in so-called linear modulators). Therefore, it is necessary to select the desired output frequency. In this case it is the frequency of the r-f carrier plus the sidebands generated in the modulation process.

Failure Analysis.

No Output. A defective transistor or open base circuit caused by a defective transformer or an open bias resistor, will prevent operation. Also, an open bias capacitor can produce cutoff bias through degeneration if the r-f drive and the resistance in the circuit are sufficient to block operation. Either of these conditions can be detected by means of a resistance or continuity check with an ohmmeter. An open-circuited emitter, possibly caused by a defective swamping resistor, (RE) will stop operation. An open-circuited collector will also stop operation; this condition can result from an open tank coil or a defective soldered joint, causing an extremely high resistance. Checking the collector voltage to ground will determine whether this circuit is open. Improper supply polarity will reverse the bias, stop operation, and most likely ruin the transistor. In most cases a simple resistance and continuity check combined with a voltage analysis, using a high-impedance volt-ohmmeter, will locate any of the no-output troubles.

Low Output. Too low or too high a bias will cause clipping of the output signal, resulting in low output and distortion. For maximum modulation, the a-f signal must be slightly greater than the r-f carrier input signal. Therefore, lack of audio gain, a defective coupling capacitor (Cl), or shorting of the a-f signal to ground through a shorted bypass capacitor (C2) can cause loss of or low audio, and produce a low-output indication. The use of an oscilloscope to check the waveform will indicate the point in the circuit where the waveform amplitude changes or is lost. Lack of sufficient r-f drive will also produce a low-output condition since the a-f functions merely to modulate the r-f carrier. A defective or mistuned ***tank*** circuit can cause a low-output condition since the maximum output is developed at the same frequency as that of the input (carrier).

Where the modulation is present but r-f drive is lacking, no output will appear with normal a-f drive, since the collector load impedance (tank circuit) is too low to develop any audio voltage across it as it is tuned to the r-f signal.

Distorted or Incorrect Output. Distortion will be caused by improper bias and collector voltage, or by excessive input signals. Collector voltage and bias can be checked with a high resistance voltmeter. The r-f signal must not exceed the d-c bias; otherwise, rectification of the rf will occur and change the bias, and, as a result, clipping will occur on the peaks of modulation. If the a-f modulation is not of sufficient amplitude, the peaks of modulation will also be lost and distortion will occur. In a similar manner, too great an a-f drive will send the collector current into the saturation region, the troughs (negative peaks) will be cut off, and distortion will result. The use of an oscilloscope will permit waveform distortion to be observed and located. In the case of failure of the a-f modulation, an unmodulated r-f output will be obtained. Under special circumstances with high a-f drive and no r-f drive, it is possible that the audio waveform may be observed on an oscilloscope (because of capacitive leakage across the transistor); however, this is a rather remote possibility. In any event, the proper method of determining whether distortion exists and of locating the origin of distortion are to use an oscilloscope to observe the waveform, to make a resistance and voltage analysis to check the components, and to determine that the values of the element voltages are correct for normal operation.

If the tank circuit is too sharp (that is, has too high a Q), sideband clipping will result and the higher modulation frequencies will be lost. However, this is only of academic interest since such a condition could result only from an unauthorized modification of Navy equipment.

CATHODE MODULATOR

Application.

The cathode modulator is generally employed for low-level operation where the audio power is limited and the inherent distortion of the grid-modulated circuit cannot be tolerated.

Characteristics.

Varies the cathode voltage to achieve modulation.

Operates as a combination plate and grid modulator, and can be designed to function either way.

Requires an audio output of 5 to 50 percent of the r-f plate input, depending on design.

Requires only half the normal r-f drive for class C conditions.

Provides a higher efficiency than the grid-modulated types and lower efficiency than the plate-modulated types, depending on the design. (For the 50 percent grid and 50 percent plate modulation condition, the efficiency is 62 percent.)

Provides better linearity than the grid-modulated types, and can be made equal to the plate-modulated type of circuit.

Can be used equally well with triodes, tetrodes, or pentodes.

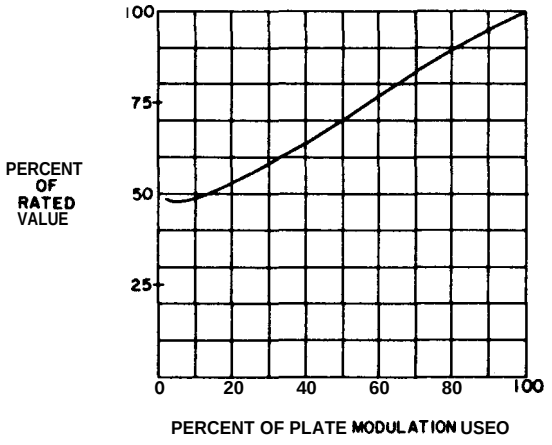
Circuit Analysis.

General. The cathode modulator vanes the voltage of the cathode to produce the modulation envelope. Since the cathode is in series with the grid and plate circuits (and the screen circuit for tetrodes), it can be seen that changing the cathode voltage will effectively change the voltage of the other tube elements. By proper proportioning of the voltages, the injected cathode voltage can be caused to operate the tube in a form of grid modulation with relatively low efficiency, or to operate it in a form of plate modulation with high efficiency. Usually, the cathode modulator is made to perform about midway between these two classes, utilizing the advantages of each type, Thus, generalizing, it can be said that the cathode modulator normally operates at efficiencies on the order of 55 to 62 percent, and requires modulator (audio) power of about 20 to 25 percent of the rated carrier power.

As a result, more linear operation is achieved than in other types of grid modulators, with only a slight audio power increase being required to obtain it. As in all forms of AM modulation, the plate voltage and plate current vary from zero to twice normal with a peak power of four times normal at 100 percent modulation. Whereas the grid modulators vary the grid bias to produce a varying efficiency which develops the required power increase from the regular transmitter supply, and operate at half the tube capability with carrier alone, the cathode modulator operates somewhat like the plate modulator. That is, the additional power required for modulation comes mainly from the audio modulator, with the transmitter stage supplying the remaining power by a variation of efficiency. Since the cathode modulator is basically a half grid and half plate modulator, it forms a unique type of circuit. When operated mainly as a grid modulator it offers little if any advantage over other types of grid modulation, and when operated mainly as a plate modulator it offers practically no advantage over straight plate modulation for a triode; however, with a pentode or tetrode it helps achieve 100 percent modulation. When operated between the two levels it does provide a more linear output with moderate efficiency and a modest audio power requirement.

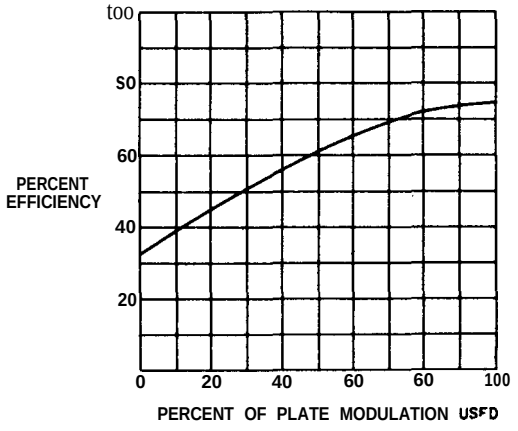
The r-f excitation requirements for the cathode-modulated amplifier are midway between those for plate modulation and for control-grid modulation. More excitation is required as the percentage of plate modulation is increased. Grid bias is always considerably beyond cutoff. Fixed bias from a supply having good voltage regulation is preferable, especially when the percentage of plate modulation is small and the amplifier is operated more nearly like a grid-bias-modulated stage. At the higher percentages of plate modulation, a combination of fixed bias and grid-leak bias can be used, since the variation in rectified grid current is smaller. The grid leak must be bypassed for audio frequencies. The cathode circuit of the modulated stage must be independent of other stages in the transmitter. When directly heated tubes are used, their filaments must be supplied from a separate transformer. The filament bypass capacitors should not be larger than about $0.002\mu f$ to avoid bypassing the audio modulation.

The cathode modulator performs differently for each ratio of grid-to-plate modulation selected. The accompanying graph illustrates the manner in which



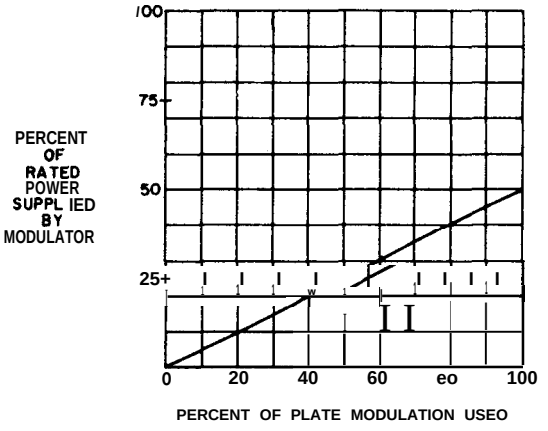
Input Power Variation

the input power requirement varies. As can be seen, with grid modulation alone the input power is about 48 percent of the normal plate power for plate modulation. At the halfway point, where equal amounts of grid and plate modulation are employed, the input power is just slightly more than 70 percent of the power for a similar plate modulator. This represents an efficiency of approximately 62 percent, as shown in the following graph which illustrates how the efficiency varies.



Efficiency Variation

Note that neither of the above graphs varies linearly, but that the following graph, showing the audio power requirements, does vary linearly. At the 50-percent plate modulation point, it requires only about 25 percent audio power from the modulator, as compared with 50 percent for full plate modulation. Thus, it can be seen that while higher efficiency is obtained from the cathode modulator, one must pay for this directly in terms of audio power supplied by the modulator.

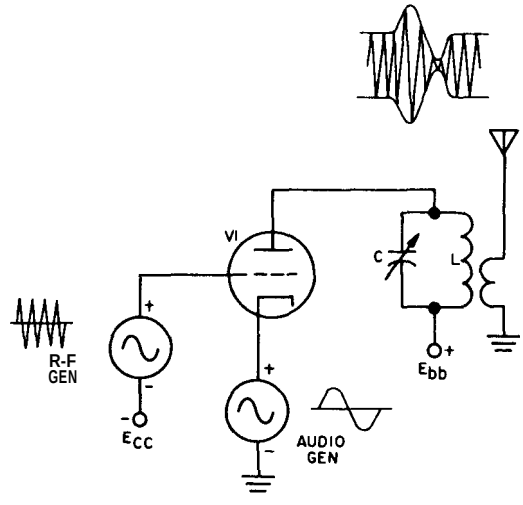


Audio Powar Variation

Since the cathode modulator uses only a 15 percent change of efficiency as compared with a 50 percent change for the grid modulator, it is evident that the power supply regulation and current hanclling capacity need not be as stringent or as large as is required for grid modulation. Likewise, a reduction of distortion due to lack of these effects is realized. By similar reasoning it can be understood that since the plate modulator is rdways more linear than the grid modulator, and a 5050 ratio of grid-plate modulation is employed, a 50-percent reduction in distortion is immediately realized with cathode modulators.

When tubes with indirectly heated cathodes are used, the heater-cathode breakdown voltage limita the maximum instantaneous voltage which may be applied during modulation. in this case the power employed is low and less plate modulation with more grid modulation is used. For high-powered equipment and large voltage swings, tubes with directly heated cathodes (filaments) are used.

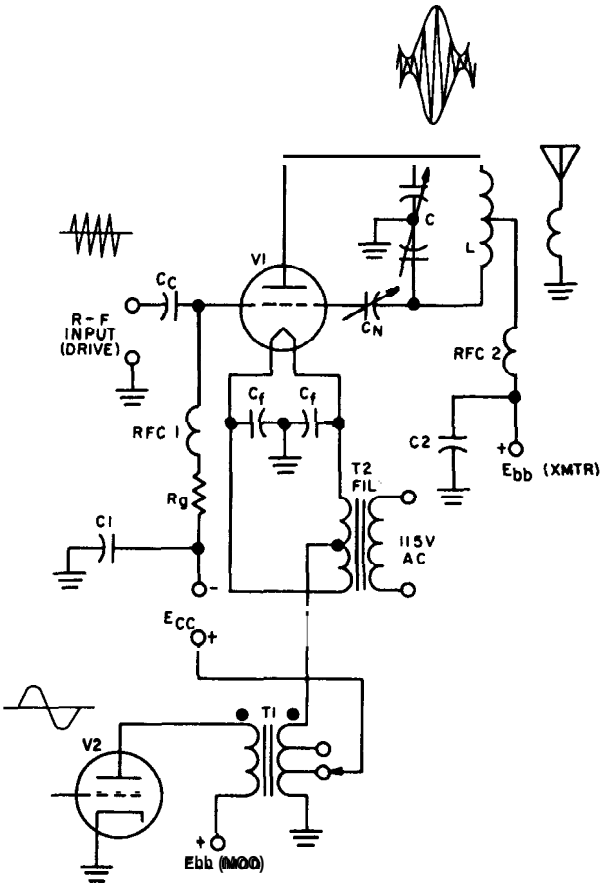
Circuit Operation. The basic cathode modulator in the accompanying illustration is shown using sine-wave generators for audio and r-f power for simplicity. In the illustration the complete biasing and neutralizing arrangements have also been omitted for ease of presentation. As shown, a freed negative bias of more than cutoff is always employed, and the r-f drive is such that the stage operates as a lightly saturated class C amplifier. (If fully saturated, it would require large grid voltage swings to obtain the desired amount of grid modulation.) The plate circuit employs a conventional LC tank circuit inductively coupled to the load. The output of the audio modulator is transformer-coupled to the cathode circuit, and is represented by the audio generator. As the modulation occurs, assuming a sine wave polarized by transformer connections so that on the positive peak the cathode voltage is positive, the effective grid-cathode bias is increased, thus reducing the plate current flow. At the same time this cathode polarity opposes the plate voltage so that the plate-cathode voltage is also effectively reduced by a like amount. As the modulation is reduced to zero and goes negative, the opposite effect occurs. The cathode bias is now reduced and plate current is increased, while simultaneously the polarity of the cathode voltage. is such as to add to the plate voltage. Thus, both the instantaneous plate current and plate voltage are increased. At the 100 percent modulation level, the instantaneous (peak) plate voltage is just twice normal, and so is the peak plate current, representing a peak power of four times normal and a maximum efficiency of 77 percent, which is equivalent to plate modulation alone. At zero modulation (carrier condition), with the circuit operating halfway between grid and plate modulation conditions, the efficiency is about 62 percent. This represents almost the maximum efficiency obtainable from grid modulation at the peak of the modulation; thus, it can be seen that cathode modulation does provide fuller use of a given transmitting tube's capabilities.



Basic Cathode Modulator

The modulating impedance of a cathode-modulated amplifier is approximately equal to: m x E_b/I_b (where m is the percentage of plate modulation expressed as a decimal, and E_b and I_b are the plate voltage and current of the modulated amplifier, respectively). This modulating impedance is the load into which the modulator must work, just as in the case of pure plate modulation, and is matched by proper choice of the transformer turns ratio. The schematic of a typical cathode modulator is shown in the following figure. A triode using a directly heated (or filament-type) cathode is shown in the illustration; this circuit is sometimes known as a center-tapped modulator because the modulation voltage is injected into the filament center tap. Otherwise, the circuit is that of a conventional r-f amplifier, being biased to beyond cutoff by the fixed negative supply and by the bias developed across R_g from the drive current. RFC1 prevents the r-f drive from being shunted to ground, and Cl provides the conventional

bypass around the bias supply for any r-f that might leak through the r-f choke. The percentage of grid modulation may be regulated by choice of a suitable tap on the modulation transformer, as shown in the illustration (or by changing the dc value of the grid bias). Capacitors C_f form the conventional center-tap arrangement of directly heated (filamentary) cathodes to provide an electrical center tap which prevents hum modulation due to unequal voltages across the sides of the filament. The plate tank uses a split-stator capacitor to tune a center-tapped coil, which provides out-of-phase voltages at the ends of the coil, Thus, a neutralizing voltage which is 180 degrees out of phase with the normal plate-to-grid feedback within the tube is provided through neutralizing capacitor C_n (since both input and output voltages are of the same frequency), preventing self-oscillation with the distortion which accompanies it. The antenna is inductively coupled to the tank, and the tank is series-plate-fed through RFC2 bypassed by C2. The modulation is applied through the secondary of T1 to the filament center tap of V1. It is evident, then, that as the modulation signal is applied to V2, considering a sine-wave input, the voltage at the secondary of T1 vanes first to a positive maximum and then to a negative maximum, returning to zero as the signal ceases. With the circuit biased so that tube VI is not driven to saturation, but just to the point where saturation will begin if driven further, only half of the normal r-f grid drive is needed, as compared with full plate modulation.

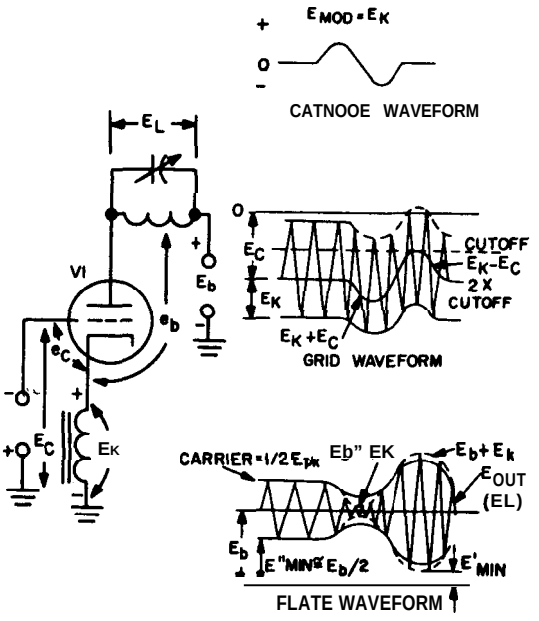


Cathode Modulator

491-044 0 '/3 69

Consider now one cycle of operation. As the modulating signal increases in the positive direction, an increasing positive voltage is applied in series with the cathode. This cathode voltage is instantaneously added to the freed bias and to the bias produced by r-f grid drive (through grid resistor R_g). The result is to increase the total effective grid bias by the amount of the modulating signal. Consequently, the instantaneous plate current, i_p, is reduced. At the same time, this cathode voltage is in opposition to the applied plate voltage, and reduces it accordingly. With a lower effective plate voltage, the plate current is still further reduced. This action continues sinusoidally until the modulation peak is reached, which corresponds to the point of almost zero plate current (if the plate current were entirely cut off, the output signal would be interrupted). At this time the plate current through the load impedance is at a minimum, and the output voltage is also at a minimum, as shown in the following illustration,

As the modulating signal turns in a negative direction the total effective bias is decreased, and the cathode voltage adds to the effective plate voltage. Consequently, the instantaneous plate current increases. At the completion of the positive half-cycle of modulation signal, the cathode bias (modulating signal) is zero, and the effective bias is the sum of the freed negative bias and the bias produced by the r-f drive. This is the quiescent, or resting, condition of the circuit where normal plate current is drawn and only the carrier is produced. While this plate current is about 20 percent higher than it would be in the grid modulator, and represents about 70 percent of the plate modulation rating of the tube, it is the normal value which is doubled at the modulation peak. Therefore, additional power is required when the modulation drives it above the carrier level. The increase of carrier power above that of the grid modulator is obtained from the transmitter power supply by a change in plate efficiency.



Oparating Polarities and Wavaforms

As the modulation cycle progresses sinusoidally below zero toward the negative peak, the cathode bias is further reduced by the negative-going cathode voltage. Since the cathode voltage is now in a direction to add to the effective plate supply, the instantaneous plate voltage is increased. With a reduced bias and an increased plate voltage, the plate current is increased. At the peak of the cycle the instantaneous plate current is twice the normal (carrier) value. At this time the drop across the load is the greatest, and the actual plate voltage reaches its minimum value, near zero. The minimum value of plate voltage (for triodes) is kept above the maximum positive grid swing at this point to prevent excessive grid dissipation. (If it were zero, the grid would act as the plate

during this interval.) Once the negative modulation peak is reached, the modulation signal again goes in a positive direction toward the zero or carrier level. The cathode voltage is now going in the opposite direction (increasing positive), and once again opposes the plate voltage, increases the total effective grid bias, and reduces the plate current. Thus we can say that the modulation signal effectively drives the tube to twice the norrnrd plate voltage and current on the peaks of modulation, and to almost zero on the troughs of modulation (the negative peaks).

Failure Analysis.

No Output. Lack of output should first be isolated to failure of the r-f amplifier stage or the modulator and speech circuits. Even though the modulator is operative, an open rfc or tank circuit, a shorted or gassy electron tube, or lack of grid excitation to the r-f amplifier will produce a no-carrier indication. An open modulator primary will permit a earner to appear, but no modulation will occur, while an open secondary will produce neither a carrier nor any modulation. "Observation of the amplifier r-f plate current meter will determine whether the circuit has continuity, while tuning for a maximum indication with a resonant dip will determine whether sufficient drive and load and the proper bias are present for operation without modulation. Grid-drive-meter indications will also show whether there is proper r-f drive. When the tank can be resonated for a minimum dip and then loaded to maximum plate current with a normal grid-current indication, the trouble is in the modulator or speech circuits.

Lack of grid drive places the trouble in the exciter stages of the transmitter or in the coupling network to the final stage. Lack of plate current indicates possible power-supply trouble, an open-circuited r-f stage, or a defective modulation transformer; if screen grid tubes are used, lack of plate current can also be due to an open screen-voltage dropping resistor or a short-circuited screen bypass capacitor.

High transmitter plate current usually indicates short-circuited components, a lack of bias, or improper tuning; low transmitter plate current indicates excessive bias, high-resistance joints, low tube emission, lack of sufficient r-f drive, a possible lack of sufficient coupling to the load, or possible antenna or transmission -line trouble. A simple resistance analysis made with the power off and the high-voltage supply grounded for safety usually will quickly determine the defective components, using the meter indications as a guide to the most probable location of the trouble.

Low Output. Determine first whether the low output is due to lack of sufficient audio drive or to an actual reduction in the percentage of modulation. Low modulation is usually caused by lack of sufficient audio output, and may be the result of a reduced setting of the audio gain control or from trouble in the speech amplifier stages. An oscilloscope should be used to view the waveform to determine whether 100 percent modulation is being obtained. For quick, simple tests of modulation percentage, the trapezoidal waveform check is useful. The envelope or waveform check, however, will show the percentage of modulation and also waveform distortion at the same time, so that it is usually more useful. Too high a grid bias will cause a reduction of output and an inability to obtain 100 percent modulation with the same r-f drive. The grid bias can be easily checked with a voltmeter (use an rfc in series with the test prod). A reduced' screen voltage is most likely of all to produce a low output, usually with overmodulation or distortion, since the plate and screen swings will be excessive. Such a condition may be caused by too heavy a screen current, causing a large drop in the screen-voltage dropping resistor, by a defective screen voltage dropping resistor, or by a partially shorted screen bypass capacitor. Where a separate screen supply is used, the latter trouble is the most likely.

Lack of proper tuning can also cause a low output. Too light a loading or too high an excitation will cause a flattening of the upward peaks of modulation, as in grid modulation. The antema loading must be such that a further increase in loading causes a slight drop in antema current. For optimum performance, the grid excitation should also be adjusted for minimum plate dissipation with maximum power in the antenna. The cathode current will be practically constant with or without modulation when the proper operating conditions have been established.

Improper load matching by the modulation transformer will produce a lack of sufficient audio power, as well as distortion. Where taps are provided, the proper tap may be selected. Where no taps are provided and the load appears to be mismatched when checked with an oscilloscope, the tube or the transformer may be defective. Lack of sufficient filament emission in the final amplifier tube can cause

peak flattening, inability to obtain 100 percent modulation, and distortion.

Distortad Output. Distortion can occur from a number of causes, and is easy to detect when monitoring the audio modulation. Overmodulation will cause a chopping off of the carrier (carrier shift), producing severe interference to stations operating near the transmitter frequency, as well as distortion.

In stages operating on the same input and output frequencies, there is always the possibility of sufficient internal plate-to-grid feedback to cause self-oscillations accompanied by severe distortion, particularly on the peaks of modulation. When this occurs with triodes, it indicates the necessity for readjustment and a check of the neutralization. With pentodes and tetrodes it can occur at the high frequencies, particularly if the lead dress is changed after a repair. Self-oscillation can usually be recognized on an oscilloscope by the characteristic fuzzy appearance of the display. Plate current meter indications will usually be excessive and erratic when this condition is present.

Lack of sufficient capacitance to supply the peak power requirements can occur through loss of falter capacitance, and can cause peak flattening with consequent distortion. Usually, however, such a condition will be indicated by a hum on the carrier, or in the modulation, before the distortion is excessive enough to notice unless an oscilloscope is used to monitor the transmissions.

A similar condition caused by lack of sufficient filament emission in the r-f amplifier stage will also cause peak flattening and resulting distortion. Sometimes this condition can be observed by noting the inability of the r-f output meter to respond to heavy modulation peaks, accompanied by a gradual reduction in plate current readings over a long period of time. Under normal conditions, the r-f ammeter will indicate approximately a 22 percent increase in output current at 100 percent modulation.

Improper bias and drive conditions will also cause distortion, and usually are accompanied by a reduction in output or an inability to attain 100 percent modulation.

EMITTER-INJECTION MODULATOR

Application.

Same application as Base-Injection Modulator.

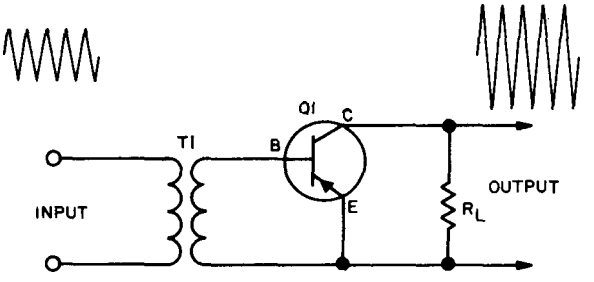
Characteristics.

Same characteristics as Base-Injection Modulator except it is operated by varying the emitter bias instead of the base bias.

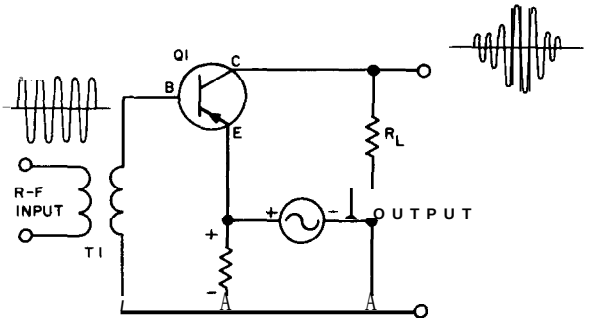
Circuit Analysis.

General. Emitter injection is very similar to base injection, since both methods vary the emitter-base bias. The carrier signal input is coupled to the base region of the transistor, while the modulating signal is applied across the emitter swamping resistor to regulate the gain of the transistor in accordance with the modulation. Consequently very little modulator power is required. Much iess than that required for electron tube cathode modulation which is the electron tube counterpart of this circuit. Since the transistor is operating under small-signal conditions, the r-f earner input (drive) is also small. Under these conditions the transistor is operated either Class A or Class AB. Injection of the modulation in the emitter circuit may be made by either the shunt or series method. In the series method a transformer is used in series with the emitter. Either method, however, operates similarly.

Circuit Operation. Amplitude modulation by emitter injection depends upon a widely separated r-f frequency and modulation (audio) frequency. There are two basic circuits involved, namely, the r-f amplifier and the modulating (bias gain control) circuit. A simplified schematic of the basic r-f amplifier is shown in the accompanying figure. For simplicity, the r-f circuit is shown without bias supplies and a resistive load in place of the tank circuit. It is assumed that normal forward bias is applied the emitter-base junction, and that a reverse bias is applied the collector junction. The secondary of T1 is effectively connected across the emitter-base junction, and the load is comected between emitter and collector as shown.



Simplified R F Amplifier Circuit



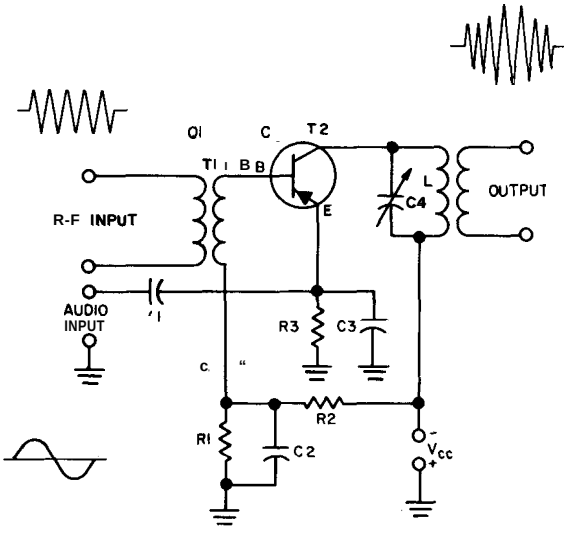
Simplified Modulator Circuit

With normal Class A bias applied, the r-f signal will vary the base voltage equally above and below the operating point (assuming a sine-wave signal), and a corresponding base current will flow. A similar but larger (amplified) collector current will flow through the load resistor, developing an oppositely polarized output voltage. This is the action of a conventional r-f amplifier.

Consider now the method by which modulation is accomplished in the bias circuit, using the following schematic, For simplicity, the modulator circuit is also shown without bias supplies and a load resistor in place of the tank circuit. It is assumed that normal bias is applied the emitter-base junction, and that a reverse bias is applied to the collector junction. The modulation is injected across the emitter swamping resistor. Since the modulating signal is effectively connected in series with the emitter circuit it adds to the emitter bias when of the same polarity. When this voltage is opposite in polarity to the emitter bias it partially cancels and reduces the total emitter bias.

Thus the bias on the transistor is made to vary instantaneously above and below the fixed emitter bias level in accordance with the modulating signal: Assuming a sinusoidal modulating signal, it is evident that the instantaneous bias will vary sinusoidally. Since a change in bias will produce a change in gain, the instantaneous gain will also vary similarly. Consequently, the instantaneous amplification of the r-f carrier signal will also vary in accordance with the modulation, but in a different and opposite direction. (Common-emitter output polarity is opposite the input polarity.) For maximum modulation the a-f signal must be slightly greater than the r-f carrier input signal. To prevent distortion produced by driving the transistor into cutoff or into saturation, the modulation signal voltage must never exceed the d-c bias value.

The circuit of a typical capacitance-coupled emitter injection modulator is shown in the following illustration.



Emitter-Injection Modulator

The r-f input is applied to the base of Q1 through r-f transformer TI shown untuned for simplicity. Resistor RI and R2 form a base bias voltage divider from the supply to ground, which places a freed forward bias on Q1. Capacitor C2 bypasses the divider to ground to prevent r-f feedback into the bias supply. Resistor R3 and capacitor C3 form a conventional emitter swamping resistor bypassed to prevent degeneration. Only very slowly varying temperature changes produce a voltage across R3. (See the Introduction to the Amplifier Section of this Handbook for explanations of Bias Circuits and Bias Stabilization.) Transformer T2 is the collector output transformer with tuned primary L and C4 acting as a conventional tank circuit across which the output signal is developed. The secondary of T2 is comected to the next amplifier stage, or to a load (an antenna in special cases).

The bias voltage appearing across RI is the effective bias applied to the base of Q1 through the secondary of r-f transformer T1. Thus the r-f input voltage is applied in series with the dc bias provided by R1. However, capacitor C2 bypasses R1 to ground for rf and together with C3 effectively connects the secondary of T1 from base to emitter. As the input signal varies between positive and negative alternations, the emitter current varies similarly but oppositely (decreases on the positive part of the cycle and increases on the negative part of the cycle). The pulses of collector current applied across the tank load C4 and L produce an amplified sine wave of r-f of the same frequency as the input.

Consider now the effect of the modulating signal. Since the modulating signal is coupled through capacitor Cl, it appears as a varying of voltage across R3. While C3 bypasses R3 for rf, it is not large enough to bypass the a-f modulation. Thus the emitter voltage is alternately increased and decreased by the modulation which changes the base bias accordingly, so that the bias varies at the modulation rate. Consequently, the gain of the transistor is rdso changed at the modulation rate. The transistor is not exactly linear in its emitter-collector relationships, but is more linear than the base-collector relationship. While the output is not an exact replica of the input modulation, it will be similar in shape with troughs and valleys occurring at the same time but slightly distorted. Modulation is effectively linear from about zero to 96 per cent before the transfer characteristic rounds off. Above this range the distortion tends to become excessive. Therefore, "applications requiring full 100 per cent modulation generally employ the collector injection circuit, which will be discussed later in this section.

While a resistive collector load has been assumed for ease of explanation in the simplified circuit discussions, in practice a tuned (LC) tank is necessary to select the proper output frequency. In every modulator, there are sum and difference frequencies, and spurious frequencies are also generated (even in so-called linear modulators). Therefore, it is necessary to select the desired output frequency. In this case it is the frequency of the r-f carrier plus the sidebands generated in the modulation process.

Failure Analysis.

General. When making voltage checks use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges of conventional voltohmmeters. Be careful also to observe proper polarity when checking continuity with the ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A defective transistor or open base circuit caused by a defective input transformer, or an open bias resistor will prevent operation. An open bias capacitor also can produce cutoff bias through degeneration if the r-f drive and the resistance in the

circuit are sufficient to block operation. Either of these conditions can be checked by means of a resistance or a continuity check with an ohmmeter. An open-circuited emitter, possibly caused by a defective swamping resistor, R3, will also stop operation. An open circuited collector will also stop operation; this condition can result from an open tank coil or a defective soldered joint, causing an extremely high resistance. Checking the collector voltage to ground will determine if this circuit is open. Improper supply polarity will reverse the bias, stop operation, and most likely ruin the transistor. In most cases, a simple resistance and continuity check combined with a voltage analysis, using a high impedance voltmeter, will locate any of the no-output troubles,

Low Output. Too low or too high a bias will cause clipping of the output signal, resulting in a low output with distortion. For maximum modulation, the a-f signal must be slightly greater than the r-f carrier input signal. Therefore, lack of audio gain, a defective coupling capacitor (Cl), or shorting the a-f signal to ground by a defective bypass capacitor (C3) can cause loss of or low audio, and produce a low-output condition. The use of an oscilloscope to check the waveform will permit the point in the circuit where the waveform is changed or lost to be observed. Lack of sufficient r-f drive will also produce a low-output condition, since the a-f functions merely to modulate the r-f carrier. A defective or mistuned tank circuit can also cause a low output condition, since the maximum output is developed on the same frequency as that of the input (carrier). Where the modulation is present but r-f drive is lacking no output will appear with normal af drive, since the collector load impedance (tank circuit) is too low to develop any voltage across it since it is tuned to the r-f signal.

Distorted or Incorrect Output. Distortion will be caused by improper bias and collector voltage, or by excessive input signals. Check the collector bias and voltage with a high resistance voltmeter. The r-f signal must not exceed the dc bias; otherwise, rectification of the rf will occur, and change the bias, and, as a result, produce clipping on the modulation peaks. If the a-f modulation is not of sufficient amplitude the peaks of modulation will also be lost and distortion will occur. In a similar manner, too great an a-f drive will send the collector current into the saturation region, and the troughs (negative peaks) will be cut-off, and distortion will result. The use of an oscilloscope permits waveform distortion to be observed and located. In the case of failure of the a-f modulation an unmodulated r-f output will be obtained.

If the tank circuit is too sharp (that is has too high a Q), sideband clipping will also result and the higher modulation frequencies will be lost. However, such a condition is not likely to be found in military equipment that meets specitlcations.

SUPPRESSOR GRID MODULATOR

Application.

The suppressor-grid modulator is employed as a low-level modulator for pentodes in applications where a minimum of audio (modulator) power is desired. It is particularly useful in portable or mobile communications equipment to reduce size and power consumption.

Characteristics.

Varies grid-plate transconductance to achieve modulation.

Requires less audio power than grid modulator since only voltage drive is required, and no power is needed for modulation.

Produces maximum efficiency at 100 percent modulation, and minimum efficiency with unmodulated (carrier) conditions.

Provides a carrier power of only 1/4 that available for same tube in CW operation, and about 1/3 that possible with high-level plate modulation.

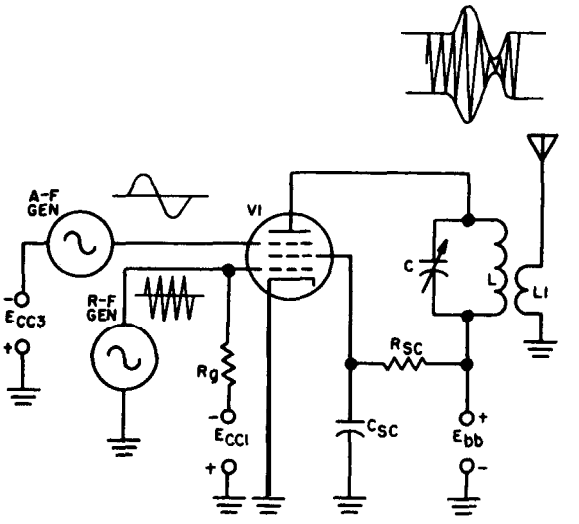
Circuit Analysis.

General. Suppressor-grid modulation is practically identical to control-grid modulation, with the exception that the suppressor grid is used to achieve the modulation instead of the control grid. This type of modulator, like the grid modulator, uses a form of efficiency modulation. It normally operates at half the maximum current under carrier conditions with no modulation, and at full current (twice normal) at 100 percent modulation. The efficiency is approximately 33 percent with no modulation and approximately 66 percent with full modulation. The carrier power represents 1/4 the maximum power available for the same tube operation, as a class C amplifier, with a peak power of four times the carrier value at 100 percent modulation. During modulation the average power increases to a maximum of 1.5 times normal at the peaks of modulation, and this power is

obtained from the same power supply by a change of efficiency within the tube.

It requires a negative supply for biasing the suppressor grid, which, since it acts as a gate between the screen and plate and is always negative, draws no current. Thus, very low modulation power is required, since only audio voltage is needed for control of the modulation. It does have the disadvantage, however, of causing a higher than normal screen dissipation. This is due to the fact that the plate current is cut off on the negative swing of the modulation signal, and the positive screen acts as a plate, resulting in greatly increased screen current. Distortion is approximately of the same order as that for grid modulation, since the linearity of the grid-plate transfer characteristic determines the basic minimum distortion inherent in the tube.

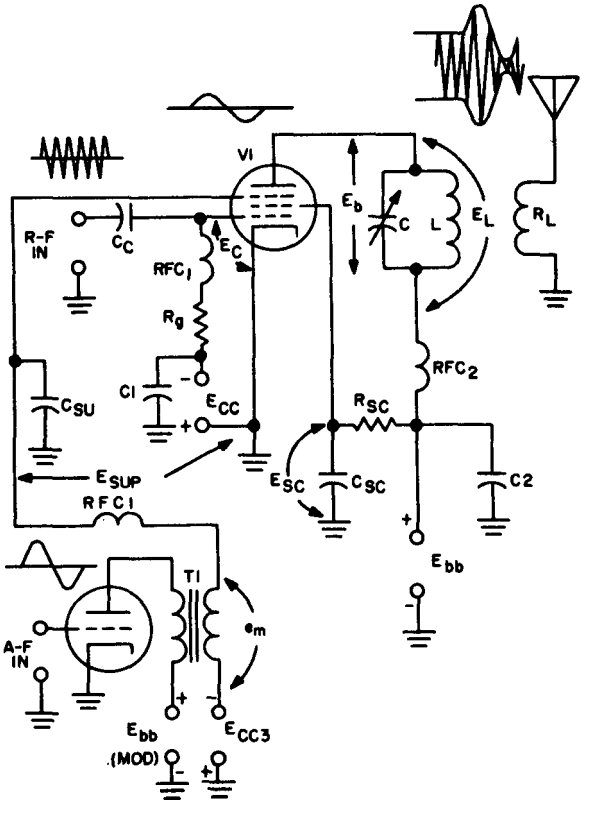
Circuit Operation. The basic suppressor-grid modulator is shown in the accompanying figure; for simplicity, sine wave generators are used to represent audio and r-f excitation. It is clear from the figure that the circuit is practically identical to that of the grid modulator except for the tube element used. The r-f amplifier stage operates as a conventional class C amplifier. Screen voltage is obtained through dropping resistor R_{sc}, bypassed by C_{sc}, and a fixed control-grid bias supplemented by grid-drive bias from R_g is used. With the suppressor grid biased negative from a separate supply, the carrier value of a current is one-half the maximum current. As the a-f voltage from the speech amplifier (represented by the a-f generator) is applied to the suppressor, it is (considering a sine wave) alternately aiding and opposing the suppressor freed bias. Thus on the positive half-cycles, it operates to reduce the suppressor bias and allow a heavier flow of plate current, while on the negative half-cycles, it adds to the suppressor bias to reduce the plate current. Therefore, the modulation is developed by plate current flow under control of the suppressor-grid voltage; in effect, the suppressor varies the grid-plate transconductance to achieve modulation.



Basic Suppressor-Grid Modulator

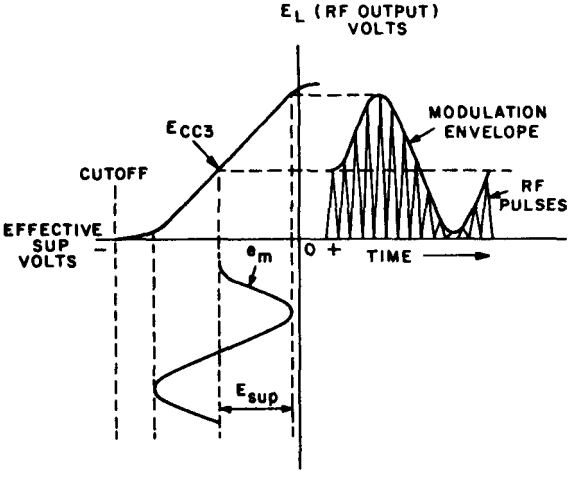
The schematic of a typical suppressor-grid modulator is shown in the following figure. In the figure, T1 couples the output of the speech amplifier to the suppressor grid through RFC1, which prevents any feedback of rf into the audio circuit; capacitor C_{su} grounds the suppressor for rf. Thus the d-c suppressor bias and instantaneous audio output signal (em), connected in series, are combined to provide an effective bias value, which adds on the negative peaks to increase the total bias, and subtracts on the positive peaks to decrease the total bias. The tube is biased class C with freed grid bias E_{cc}, bypassed by Cl. The freed bias is supplemented by grid drive bias through grid leak R_g, coupled from the r-f exciter stage through Cc. RFC1 isolates the bias supply, and Cl bypasses any excitation which may leak through the choke. The effective control-grid bias is that from cathode to grid, indicated by E_c. Screen voltage is applied through screen dropping resistor R_{sc}, bypassed by C_{sc}, with the plate series-fed through RFC2

and bypassed by capacitor C2 in a conventional series-feed arrangement. Tank LC is tuned to the excitation frequency applied to the grid, and is coupled inductively to the output load, R_L.



Suppressor-Grid Modulator

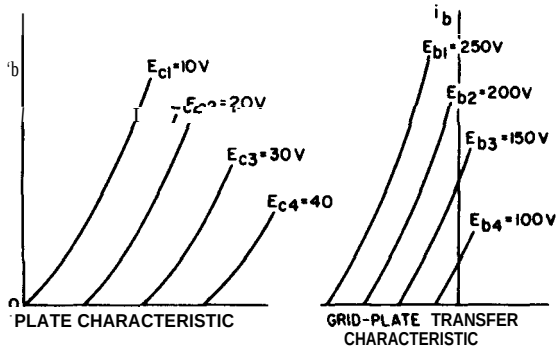
When the modulating signal is applied, e_m varies from some negative value to a positive value which just cancels E_{cc3}, producing a variation of suppressor bias, E_{sup}, from zero at the maximum positive peaks of modulation to some negative value at zero modulation, or carrier level; it then increases to a greater negative value which is sufficient to reduce the plate current almost to zero on the negative peaks of modulation. Thus the plate voltage varies from a small minimum to practically full plate voltage as the plate current varies from maximum to zero in accordance with the modulation. The voltage drop across the tank circuit, EL, varies simultaneously from zero to maximum and back to zero, and the tank current is increased during the positive peak and decreased during the negative peak, effectively producing the modulation envelope. Since the tank is oscillating sinusoidally, the output is also sinusoidal, and is produced by pulses of plate current which increase the tank current to form the envelope shown in the following figure. It is clearly seen from the figure that while the transfer characteristic between the grid and screen is mostly linear, it curves off at the beginning and end, which corresponds to a biased-off suppressor condition and a zero-voltage suppressor condition, respectively. This shape is similar to that of the grid modulator transfer curve, and indicates that distortion is inherent and must always be more than that produced by plate modulation.



Suppressor-Grid Voltage and Output Voltage Relationships

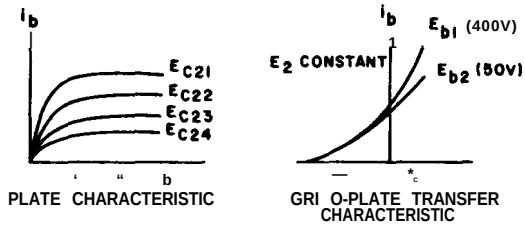
Use of the series screen-voltage dropping resistor, R_{sc}, tends to reduce the screen voltage more as the screen current increases. Thus when the suppressor is being biased-off to the nonconducting state between screen and plate (by the negative modulation signal) the increased current attracted to the screen (it tries to act as the plate) automatically reduces the effective applied screen voltage by the increased drop across the screen-voltage dropping resistor, R_{sc}. In this manner the extra screen dissipation is reduced somewhat at just the time it is becoming excessive. Hence, fixed screen voltage is usually never employed with this type of modulator.

Detailed Analysis. The basic functioning of the pentode modulator depends upon the suppressor grid and its control action. Consider the basic triode, for which a set of typical plate characteristics and transfer characteristics are shown in the following figure. It is evident from the plate characteristics that



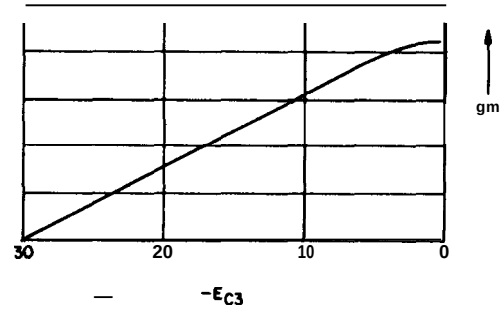
Triode Plate and Transfer Characteristics

for a fixed bias, there is a different plate current for each change of plate voltage. Note that the curves tend to be similar and equally spaced for equal steps of bias voltage. Likewise, on examining the transfer characteristic, it is seen that for each change of bias (with fixed plate voltage) there will be a different plate current; like the plate characteristic curves, these curves are similar and almost equally spaced for equal plate voltage steps. Thus it is clear that in a triode, one can vary the plate voltage and the plate current will follow, which is what is done in plate modulation. Likewise, one can vary the grid bias and the plate current will follow, which is what is done in grid modulation. Now examine the plate characteristics and transfer characteristics of a pentode, as shown in the following figure.



Pentode Plate and Transfer Characteristics

With the inclusion of the screen grid in the pentode, the plate current no longer follows the plate voltage, but is determined mainly by the screen voltage (assuming a fixed control grid voltage). That is, for a particular screen voltage, the plate current quickly reaches a particular value, as the plate voltage is advanced from zero toward a maximum, and remains substantially constant over a large range of plate voltage. Thus, varying the plate voltage has little effect on the plate current. Since these curves are parallel and almost equally spaced (for equal screen voltage steps), it can be seen that variation of the screen voltage will produce the desired variation of plate current, which is what is done in screen modulation (to be discussed separately). Upon examining the transfer characteristic it is seen also that for a specific screen voltage and for plate voltage from a low to a high value, there is little change in plate current as the bias is changed; in fact, for at least half of the operating curve they are identical. Now examine how the grid-plate transconductance varies with a change of suppressor voltage as the control-grid bias and screen voltage remain fixed, as shown in the following figure.



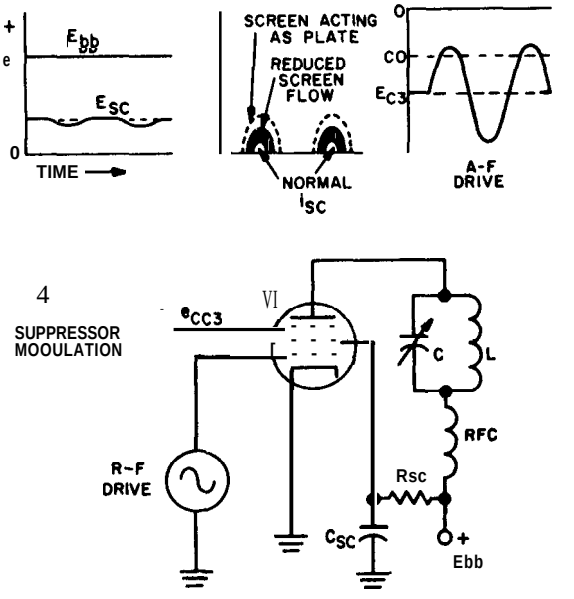
GM Variation with Suppressor Voltage

As can be seen, the transfer characteristic is practically linear, starting from a high value of transconductance at zero suppressor voltage and ending at a very small or zero value with a large negative suppressor voltage. It follows, therefore, that variation of the suppressor voltage will produce a relatively linear change in tube output. As a result, the suppressor-grid modulator is operated with a fixed negative control grid bias and a fixed screen voltage. (Since the control grid bias does not vary, the r-f excitation source need

not have as good regulation as with the grid modulator; consequently, it need not supply as much grid drive power.)

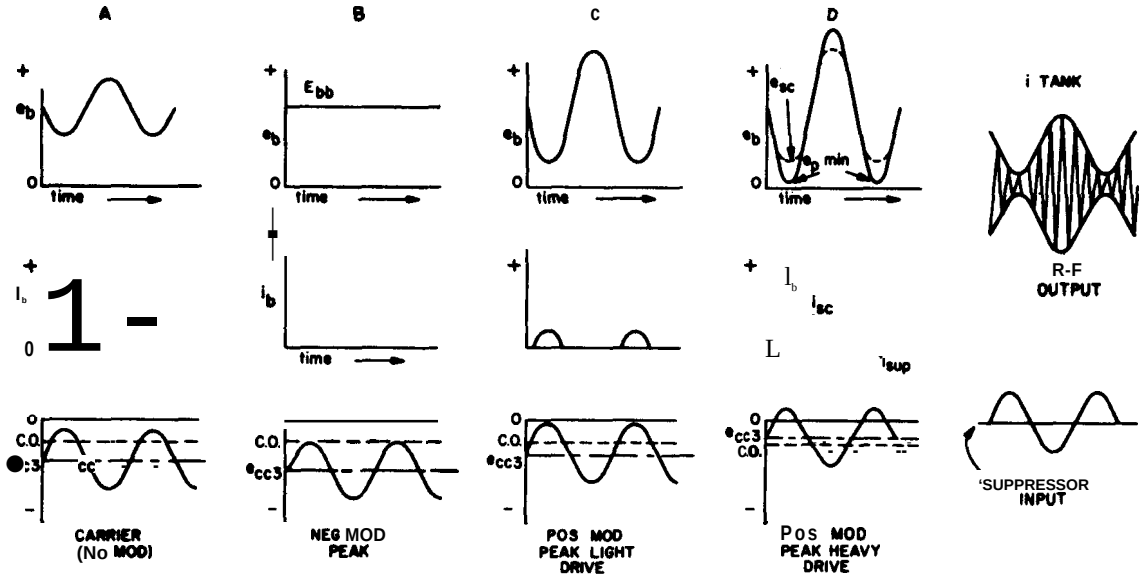
Since the suppressor is placed between the screen and the plate, it exerts complete control over the plate current; when biased sufficiently negative it will cause plate current cutoff, while at just about zero bias it will permit maximum plate current flow. Because the suppressor is never raised above zero and is always negative, it draws no current; thus very little modulator power is needed – less than that for any other type of modulator. The suppressor bias is usually on the order of – 100 volts, and a simple voltage amplifier will completely modulate a high-powered pentode.

As the plate current is prevented from flowing to the plate by the negative suppressor bias, the screen becomes the only collector of electrons, and the screen tends to absorb them, acting as the plate. Thus screen-grid power dissipation becomes large on the negative portion of the modulation signal (the troughs), as shown in the following figure. By obtaining the screen voltage through dropping resistor R_{sc} from the plate source, the increased screen current (i_{sc}) automatically causes a lower applied screen voltage, which reduces screen current flow during this period. Even so, the maximum screen dissipation is usually excessive during this period, because plate current cannot flow and all electrons are being handled by the screen.



Screen Circuit Conditions

Now consider the tube's operation under carrier conditions with no modulation. Here the dc suppressor bias is adjusted for a negative value which produces half the maximum (full class C) value of plate current). The r-f drive and grid bias are set for the optimum values to produce this maximum loaded plate current. No modulation is applied to the suppressor (only the fixed dc bias), and plate current flow is as shown in part A of the following figure.



Typical Operating Waveforms

As the modulation signal goes negative, the effective suppressor voltage is increased to further bias off plate current flow. At the negative peak of modulation (the trough), the instantaneous suppressor voltage, e_{cc3}, is just below cutoff (part B of the figure), and no plate current can flow. This is the time at which the screen is dissipating all the cathode (space) current, as explained in the previous paragraph. During the remaining half of the negative modulation cycle the suppressor voltage rises, becoming more positive as the negative modulation cycle approaches the zero modulation (carrier) level. At no modulation the conditions are as first represented in part A of the figure, with one-half the cutoff value of suppressor bias. Each drive pulse produces an output pulse of rf and a plate current pulse. The plate current averaged over the cycle is half maximum.

During the positive half of the modulation cycle, the negative suppressor bias rises above the cutoff level and reaches zero at the maximum positive modulation peak. At this time the plate current is twice normal (maximum) and the plate voltage is reduced to its minimum value, as shown in part C of the figure, but not to less than that of the screen voltage. If the modulation is sufficient to make the suppressor voltage positive, the suppressor tends to become the plate, and so does the screen (the screen voltage is now greater than the plate voltage as shown in part D of the figure). Thus, both the screen and suppressor grids carry the space current, and their dissipation ratings are exceeded. This is why the suppressor grid is never driven positive.

Once the modulation peak is reached, considering sine wave operation, the suppressor voltage becomes negative-going, and the resting or carrier condition is again reached at zero modulation. During the time of the positive peak the drop across the load (the tank circuit) is the greatest, and the greatest output voltage is developed and coupled to the antenna. Also, during this interval, the tank is actually absorbing power to replace any losses present as a result of resistance in the coil and leads. Conversely, during the negative peak, the tank is supplying the output since the tube is cut off and inoperative.

It can be understood from the previous discussion, then, that varying the instantaneous suppressor voltage in accordance with the modulation signal over a complete modulation cycle will vary the plate current to twice normal, and cause the plate voltage to vary similarly. Thus, on the modulation peaks, the power output is four times that of the carrier. Since

sine-wave modulation is used, the average value of plate power will vary from the carrier to 1,5 times the carrier at 100 percent modulation. Thus, the conditions for AM modulation are produced by effectively varying the tube plate current flow, using the suppressor grid to accomplish tie variation under the control of a modulation voltage. Because the power is low, this is effectively an efficiency type of low-level modulator. Actually, the suppressor varies the final load line by controlling the grid-plate transconductance to vary the efficiency from a minimum value (about 33%) at zero modulation to full value (about 68%) at 100 percent modulation, as in the grid modulator.

Failure Analysis.

No Output. Lack of output should first be isolated to failure of the r-f amplifier stage or the modulation signal circuit(s). Even though the modulator is operative, an open plate r-f choke (RFC2) or tank inductor (L), a defective electron tube, or a lack of grid excitation to the r-f amplifier will produce a no-carrier condition. Observation of the r-f plate current meter will determine whether the plate circuit has continuity. Tuning the tank capacitor for a maximum plate current indication with a resonant dip will determine that the tank circuit is operative, and that sufficient drive, a load, and the proper bias exist for operation without modulation. Grid drive meter indications will also show whether the proper amount of r-f drive exists. With the proper grid current, if the plate tank can be resonated for a minimum dip and then loaded to the maximum current, the trouble is in the modulator circuit.

Lack of grid drive places the trouble in the exciter stages of the transmitter or in the coupling network to the final stage. Lack of plate current indicates possible power supply trouble or an open-circuited r-f stage. Otherwise, proper performance but lack of ability to load to maximum current indicates antenna trouble, improper tuning, a weak power amplifier tube, or a defective transmission line.

With an r-f carrier existing, the trouble is definitely in the audio circuits or in the modulation transformer, r-f choke, or suppressor bypass capacitor. An open transformer secondary would remove the bias to the suppressor grid and cause an abnormal plate current reading without modulation, while a shorted transformer would allow the proper plate current and apparently normal carrier operation, but no modulation could occur (depending upon the effectiveness of the short circuit).

High transmitter plate current usually indicates short-circuited components or a lack of proper bias, while low plate current indicates excessive bias, high-resistance joints, low tube emission, or a possible lack of sufficient coupling to the load. With open-circuited conditions indicated on the equipment meters, a simple resistance analysis made with the power OFF, and with the high-voltage supply grounded for safety, will quickly determine the defective components.

Low Output. It must first be determined whether the low output is from lack of sufficient audio drive or from an actual reduction in the percentage of modulation. While low modulation is usually due to lack of sufficient audio drive, this can also occur because of a reduced setting of the audio gain control or because of trouble in the speech stages. An oscilloscope is very useful in determining the cause of malfunctioning, since the waveform itself may be directly observed. For simple, quick tests of modulation percentage, a trapezoidal pattern is useful. A waveform check, however, will not only show percentage of modulation but will also indicate waveform distortion, so that it is usually more useful. Too high a suppressor-grid bias will cause a reduction of output and an inability to reach 100 percent modulation with the same drive. The same effect will also occur if the control-grid bias is too high. Temporarily grounding the suppressor grid will produce maximum output if the control-grid bias is satisfactory. If incorrect control-grid bias is suspected, the bias can easily be checked by a simple voltmeter indication (use an r-f choke in series with the meter probe to avoid erroneous indications). As with the grid modulator, a steadily indicating plate meter does not necessarily indicate that there is no distortion or overmodulation. Since the changing of efficiency in the plate circuit is used to obtain the modulated output, although the plate current is changing instantaneously, one condition may cancel the other. Thus, either a steady current indication or a flickering current indication can be indicative of the same condition. It has been found that satisfactory operation requires the use of an oscilloscope to properly adjust the suppressor voltage and load for 100 percent modulation with a minimum of distortion.

Because of the low power involved, a partially shorted modulation transformer will not usually indicate its condition by external burnt spots or arcing.

It will probably show as an inability to obtain 100 percent modulation, with all other components checked and the circuit apparently working normally in all respects. Where available, a negative variable dc source can be used to simulate the change in bias with modulation, to quickly determine whether the stage is operating properly; if it is operating, the transformer certainly must be defective. Lack of sufficient filament emission in the r-f amplifier or modulator tube will cause peak clipping and a lower output because of the inability to obtain 100 percent undistorted modulation.

Distorted Output. Distortion can occur from a number of causes, and is easy to detect when monitoring audio modulation. Overmodulation will cause a chopping off of the carrier with carrier shift, producing severe interference to stations operating within a few hundred KHz of the carrier, and distortion. Nonlinearity in the control of the grid-plate transconductance by the suppressor grid bias will show as distortion; that is similar to the distortion caused by curvature of the grid-plate transfer characteristic in grid modulation.

In stages operating on the same input and output frequencies, there is the possibility of feedback from plate to grid, causing self-oscillation with severe distortion. Although the low plate-grid capacitance of the pentode makes this almost impossible, it does occur sometimes as a result of poor layout and extemaI coupling between the tube elements, particularly at high frequencies. Self-oscillation can be easily detected by the characteristic fuzzy pattern produced on an oscilloscope. Oscilloscope connections and waveforms are shown in the Basic Measurements section of the EIMB, NAVSHIPS 0967-000-0130, Test Methods and Practices.

Since the suppressor grid does not draw current, the modulator has no trouble with changing load conditions as in the grid modulator; thus the distortion is usually limited to that caused in preceding speech amplifier stages. GeneraLly speaking, there should be less distortion present in the suppressor-grid modulator than in other types of grid modulators.

SCREEN GRID MODULATOR

Application.

The screen grid modulator is employed as a low. level modulator for screen grid tubes (tetrodes and pentodes) in applications where it is desired to use a minimum of audio (modulator) power. It is particularly useful for portable or mobile communications equipment to reduce size and power consumption.

Characteristics.

Varies screen voltage to achieve modulation.

Requires slightly more power than control-grid modulator (about 1/4 the rated screen input for CW).

Produces maximum efficiency at 100 percent modulation and minimum efficiency for unmodulated (carrier) conditions.

Provides a carrier power of 1/4 that available from same tube in CW operation, and about 1/3 that possible with high-level plate modulation.

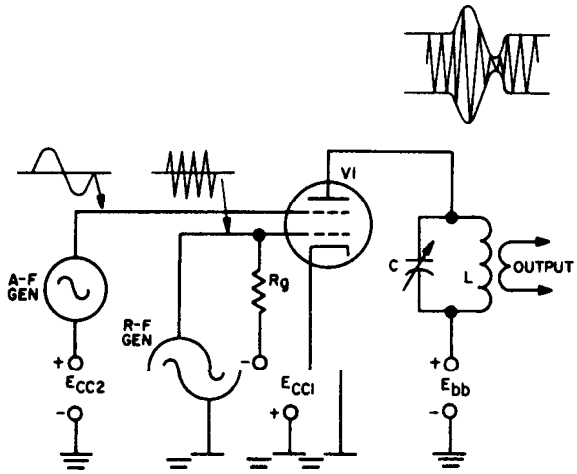
Circuit Analysis.

General. Screen-grid modulation is practically identical to the other types of grid modulation, with the exception that the screen grid is used to achieve the modulation instead of one of the other grids. This type of modulator, like the grid modulator, uses a form of efficiency modulation. It normally operates at half the maximum plate current in the resting or carrier condition, with no modulation, and at full current (twice normal) at 100 percent modulation. The efficiency is lowest, (about 33%) with no modulation, and highest (about 66%) with full 100 percent modulation. The carrier power represents onequarter of the maximum power available with normal class C operation, with a peak power of four times the carrier value at 100% modulation, During sine wave modulation, the average power increases to a maximum of 1.5 times normal at the peaks of modulation, and this power is obtained from the same power supply by the change of efficiency within the tube.

This type of modulator requires a screen supply with good regulation, since the load, plate, and screen

currents are instantaneously varying during modulation. It has the inherent disadvantage of being unable to achieve 100 percent modulation without distortion unless special compensation is provided.

Circuit Operation. The circuit of the basic screen-grid modulator is shown in the accompanying figure, using sine wave generators to represent audio and r-f excitation for simplicity.



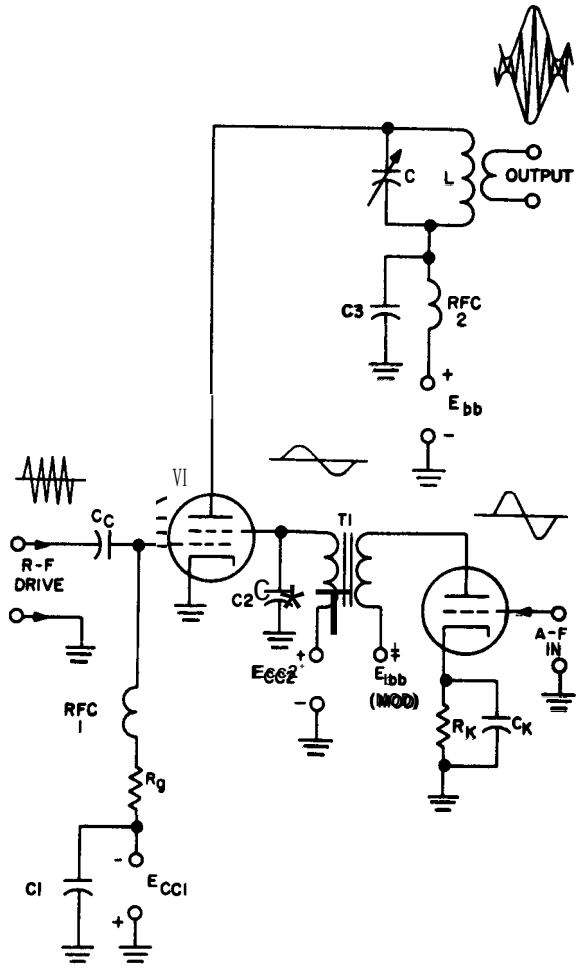
Basic Screen-Grid Modulator

It is clear from the figure that the circuit is practically identical to that of the control-grid or suppressor-grid modulator except for the tube grid element used. The conventional LC tank appears in the plate circuit, inductively coupled to the output load (antema). The r-f drive is simulated by the rf generator, and supplies grid drive bias through 1$ in addition to the fixed negative bias, E_{cc1}. As can be seen in the figure, the a-f generator supplies the modulation in series with the applied screen voltage. Thus as the modulation increases on the positive half-cycle (assuming a sine wave), the screen voltage and modulation add to produce a larger screen voltage. This increased screen voltage causes a greater plate current flow. On the negative half-cycles the modulation opposes the positive screen voltage, so that at the negative peak of modulation (at the trough) the screen voltage is effectively zero, almost preventing plate current flow.

Although the screen voltage is zero, the inherent construction of the tube requires that a negative potential be applied to the screen to completely stop plate current flow. Therefore, this type of modulator provides approximately 75% maximum modulation without distortion. If completely (100 percent) modulated, considerable distortion is produced.

Basically, however, by varying the screen potential in accordance with the modulation, a corresponding change in plate current is achieved, driving the plate current to twice the normal (carrier) value at 100% modulation and to almost zero on the negative peaks. This can be recognized as the same variations of current and voltage as described in the previous forms of grid modulators to produce amplitude modulation.

A schematic of a typical screen-grid modulator is shown in the accompanying figure.

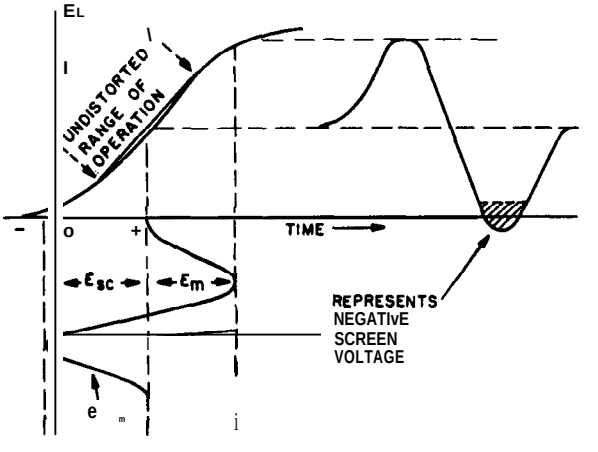


Screen-Grid Modulator

In the figure, the r-f drive is coupled through C_c to the grid of VI, producing grid current and developing griddrive bias across R_g, which is effectively in series with the freed negative bias supplied by E_{cc1}. (Actually, cathode bias could be used instead of E_{cc1} since screen current always flows.) The plate circuit contains the conventional series-fed tank, isolated from the power supply by the rfc and bypassed by C3. In the grid circuit the rfc isolates the rf drive from the bias supply; it is bypassed by Cl, which shunts to ground any rf leaking through the choke.

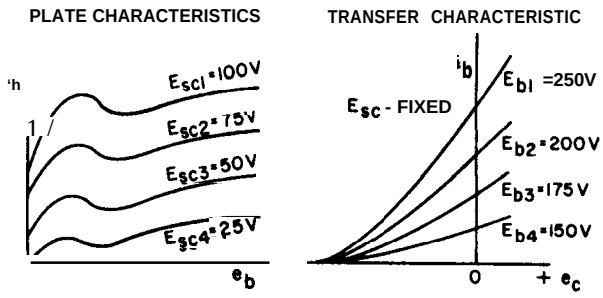
The audio modulation is coupled from the speech amplifier plate through transformer T1, whose secondary carries the d-c screen supply. Capacitor C2 serves to ground the screen grid as far as r-f variations are concerned, but is not large enough to bypass any of the audio modulation; otherwise, frequency distortion would result from a loss of the high frequencies bypassed to ground.

When the audio is applied to the screen of V1 through T1, and assuming a sine wave modulating signal, the screen voltage is increased on the positive half-cycle, and decreased on the negative half-cycle. Thus, as the positive modulating signal adds to the screen voltage, the screen current and the plate current both increase, reaching a peak at 100% modulation. Since the output voltage is the drop across the load, the output is the greatest at maximum plate current, and the actual plate voltage is at a minimum. As the modulation swings downward toward the negative half-cycle, the screen voltage is opposed by the negative modulation signal from T1. At the negative peak of modulation (the trough), there is practically complete cancellation of the screen voltage, and the screen current decreases to a minimum at this point. The output voltage is also minimum at this point, and the actual voltage, E_b, is practically equal to the applied plate voltage, Ebb. At resting or carrier value, the screen voltage is such as to produce one-half the maximum plate current obtained at 100 percent modulation (approximately one-half the value used for CW). Thus, as in other forms of grid modulation, the carrier value is one-fourth maximum, with a peak of four times the carrier value of power. The average power varies with sine wave modulation to 1.5 times the carrier value at full (100 percent) modulation. This extra power is obtained from the plate power supply. The power change is achieved by the changing efficiency of the plate circuit, produced by varying the screen voltage of the tube in accordance with the modulating signal. The following figure shows the screen voltage and output voltage relationships assuming that 100 percent modulation could be achieved, and illustrates the reason that screen-grid modulation cannot achieve 100% modulation without distortion. On the positive modulation peaks (approaching saturation), the grid-plate transfer curve flattens off so that large drive in the positive direction will flatten the peaks, causing distortion. Likewise, since zero screen voltage cannot produce plate current cutoff, the transfer curve drops off considerably at the zero screen voltage level. The effect is as though the bottom portion of the negative peak (the trough) of the modulation were cut off. To minimize this distortion, the screen must be operated between the limits where it is most linear; the practical result is to limit the modulation to about 70% for minimum distortion. In specially designed circuits where both the grid and screen are simultaneously modulated, this inherent fault can be overcome, but the modulation is no longer screen modulation; it is rather a combination of both types, and thus will not be further discussed.



Screen Grid Voltage and Output Voltage Relationships

Detailed Analysis. To understand the functioning of the screen-grid modulator, it is necessary to review the basic tube action and design. The accompanying figure shows a set of characteristic curves for a typical tetrode.

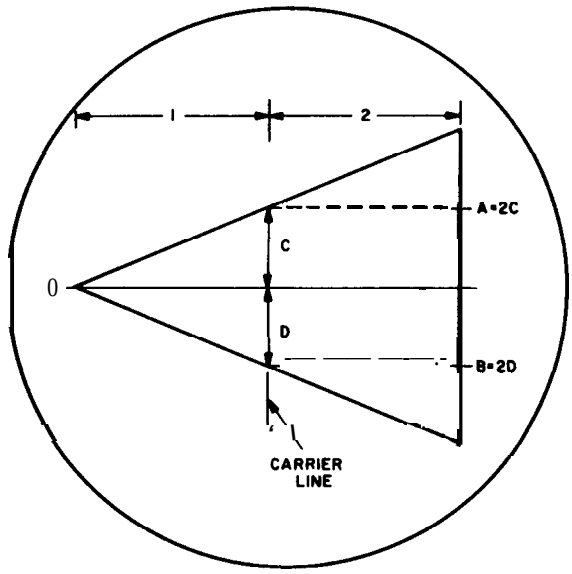


Tetrode Plate and Transfer Characteristics

First examine the plate characteristics and note that for each fixed value of screen voltage ($E_{sc1,2}$ etc) a particular plate current can be obtained, which, after the lower plate-voltage region is passed, increases constantly as the plate voltage is increased. This is not a linear relationship; it is actually considered mathematically to be a 3/2 power relationship. Note that at the higher-voltage end of the plate characteristic chart, the distances between the curves for each screen voltage are nearly the same, and the lines are roughly parallel. Hence, it can be inferred that if the plate voltage is held freed while the screen voltage is varied, there will be a somewhat linear relationship. That is, for a corresponding increase or decrease in screen voltage, there will be a proprotioml change in plate current. This means, then, that as the screen voltage is changed the plate current will follow, varying in a similar fashion. Since the output voltage is produced by the flow of plate current through the plate load, it is clear that the output voltage will vary similarly with the plate current. Examination of the grid-plate transfer characteristic shows that for a fixed screen voltage (E_{sc}) the plate current (i_p) does not vary much for low voltages (such as E_{b3} or E_{b4}), but does change somewhat for larger voltages (such as E_{b1}); it is affected more by control grid voltage changes (e_c). Thus, basic tube action indicates that either control-grid or screen-grid modulation is possible, and that plate modulation by variation of the plate voltage alone on screen grid tubes is not feasible.

Consider now the r-f drive and bias. Since the modulated r-f amplifier is to operate as a class C stage, the bias must be approximately twice the value of cutoff for a freed screen voltage, and sufficient drive must be applied to drive the stage into light saturation on the positive peaks of the drive signal. (Refer to Section 5, Part 5-6, RF Power Amplifiers Class B or C for background on Class C operation.) The value of bias and excitation must be such that the plate voltage never drops lower than the screen voltage on the peaks of the modulation. Otherwise, excessive screen dissipation would occur, with the screen -trying to act as the plate. The resting or carrier value of current is adjusted for exactly half the maximum load current, with the stage operating over the linear portions of its characteristics. Because of the varying efficiency and load changes, it is necessary to use an oscilloscope to determine proper operation.

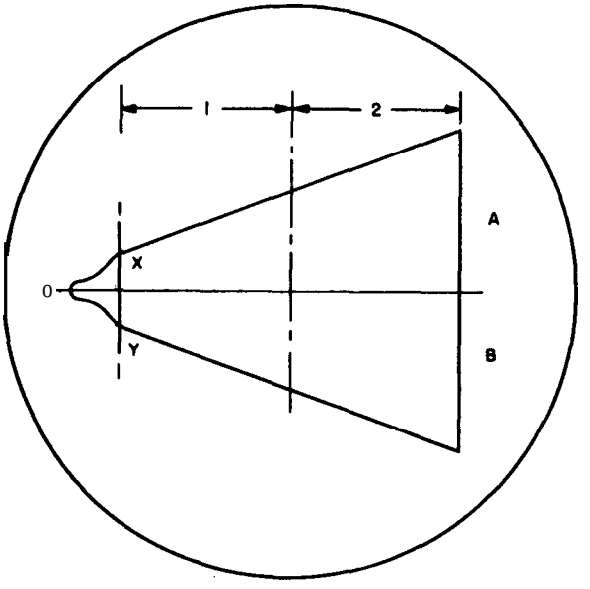
Assuming perfect linearity, a typical oscilloscope presentation showing 100% modulation would appear as shown in the following figure. Note that the amplitudes between the line representing the carrier (C and



Ideal Trapezoidal Pattarn

D) and the ends of the pattern are equal, with straight sides indicating equal and linear modulation. Also, note that lines A and B extend equal distances above and below the carrier level (with AB = 2 x CD), and that the pattern extends to a perfect point at O, indicating 100Yo modulation. Let us now examine a similar pattern illustrating screen-grid modulation, and note the differences.

491-044 0 73 70



Trapezoidal Pattarn for Screen Modulation

Note that the sides are straight from points X and Y upward, indicating linearity between these points, but between O and X-Y the curvature indicates serious distortion. The distance XY as compared with AB indicates that the distortion occurs at about 70 to 75% modulation. Thus, the carrier must be adjusted so that it is centered at the point where line segments 1 and 2 mark off equal distances over the linear portion of operation if distortion is to be avoided. The illustration graphically shows the limitations on maximum modulation percentage without distortion for screen modulation. If operation is held to the left of the indicated carrier line to achieve 100% modulation, the distortion shown between points O and XY must be accepted.

The inability of the pattern to attain a point at O indicates that the maximum negative portion of the modulation signal does not quite reach cutoff and 100% modulation is not obtained. The distortion shown between O and XY is caused by actually driving the screen negative with the modulated signal on the negative peaks, to attempt to produce the cutoff of plate current. The reason for the departure from linearity is that with zero screen voltage at points X and Y, any slight change in the negative direction of screen voltage changes the plate current much more rapidly than does a similar positive increase in screen voltage. Hence, the line no longer remains straight; it has a faster slope, and curves rapidly downward toward zero or maximum negative modulation (the trough). In effect, we can say that at the zero screen voltage level, the tube no longer modulates equally above and below this point; hence the reason for the rapid change of waveform. The point of zero screen voltage is determined to some extent by the bias and grid drive. Thus, for particular value of bias it is possible to apply just sufficient drive to reach the peaks on the positive modulation cycle and move point XY to the left slightly to attain linear modulation over a greater portion of the cycle. Such an adjustment, however, must be made with an oscilloscope; it cannot be predetermined by design.

In Navy equipment, the design and adjustments are preset by the manufacturer so that by setting the operating values of plate current and voltage to those listed in the Technical Manual for the equipment, the proper results will be obtained to meet the manufacturer's specifications.

Consider now the modulator power requirements. Since the screen is being modulated, the peak screen voltage divided by the peak screen current will provide the maximum load impedance value. A rough approximation of power can be obtained by using the peak screen voltage and current and dividing by 8. Thus, for a 400-volt, 10-milliampere screen load, 500 milliwatts (1/2 watt) is required for maximum modulation. To help stabilize the constantly varying load and keep power supply fluctuations to a minimum, and to achieve good regulation of the modulator, a power capacity of three to four times this value would be used (1–1/2 to 2 watts), and the modulator would be loaded down with a swamping resistor to stabilize the load. With the 400-volt, 10-ma load, 40,000 ohms would be indicated. By providing 40,000 ohms for each half-watt, a totrd load of 10,000 ohms would be obtained with a 2-watt amplifier as modulator. Thus, reflected load changes in the screen circuit are minimized so that the modulator provides sufficient current and voltage for stable operation.

Another method of accomplishing the same thing is to use negative feedback in the modulator. This tends to reduce the plate resistance and the sensitivity to voltage changes caused by load changes. In addition, negative feedback helps improve the modulator frequency response, so that resistance loading

has been generally discarded, although it may be occasionally encountered.

It is evident, then, that screen-grid modulation requires somewhat more power than the other types of grid modulation (because of screen load and regulation requirements); in turn, however, it provides better over-all linearity. In summation, it can be said that screen-grid modulation achieves its changing efficiency by operating on a different load line for each value of screen voltage, with maximum plate dissipation occurring at the carrier level.

Failure Analysis.

No Output. Lack of output should first be isolated to failure of either the modulated r-f stage or the modulator and speech circuits. Lack of a carrier output indicates failure of the r-f stage, while lack of modulation on the otherwise normal carrier indicates failure in the speech or modulator stages, or a lowered gain control. A no-carrier indication can be caused by an open plate rfc or tank circuit, a shorted or gassy electron tube, lack of grid excitation, too high a bias, or lack of screen voltage due to a defective modulation transformer, a shorted screen capacitor, or a defective screen supply.

Observation of the r-f plate current meter will determine whether the plate circuit is open, and tuning for maximum indication with a resonant dip will determine whether sufficient drive and load and the proper bias are present. Where grid current meters are part of the equipment, the obtaining of normal or greater than normal grid current indicates that the exciter stages are operating properly; with lower than normal grid current, the driver stages are at fault or the d-c bias on the control grid is too high. The bias may be determined by a simple voltage check (use an rfc in series with the voltmeter test prod, and check the grid to ground voltage). Inability to load the stage indicates a faulty antenna or a transmission line trouble.

With the r-f normal, the trouble must be in the modulation transformer, screen bypass capacitor, or the preceding speech stages. An open modulation transformer would remove the dc screen voltage, and the r-f stage would give a no-output indication. With a short-circuited transformer, the r-f stage would appear to operate normally, but no modulation would be obtained. With the low power usually involved, it is doubtful that visible evidence such as charred insulation or arcing would be apparent, so that it may be difficult to isolate modulation transformer trouble if the transformer is internally shorted. Usually a resistance analysis will check continuity. Checking the transformer for turns ratio with an ac source and a voltmeter will usually determine whether it is operating properly.

High plate current usually indicates short-circuited components or a lack of proper bias, while low plate current indicates excessive bias, high-resistance joints (poor soldering), low tube emission, or possible lack of sufficient coupling to the load. With open-circuited or short-circuited conditions indicated on the equipment meters, a simple resistance anrdysis made with the power OFF, and the high-voltage supply grounded for safety, will quickly determine the defective components.

Low Output. First determine whether the low output is due to lack of sufficient audio drive, or to an actual reduction of percentage modulation as a result of trouble in the modulator. With the speech gain control at its proper setting, low output indicates loss of audio (modulator) power or lack of r-f drive. Use an oscilloscope to determine the cause of malfunctioning. Make a trapezoidal check of modulation percentage to determine whether 100% can be obtained. Since some distortion is normal, the trapezoidal check can be used as a rough check on linearity by determining whether the sides of the pattern are straight and observing that the pattern expands equally on both sides of the carrier line; otherwise, the positive and negative peaks are unequal.

If you are unable to reach the 100% modulation mark, reduce the loading and see whether the percentage improves. Too great a load can produce too high an efficiency and make it impossible to obtain the proper output from the modulator. Under normal operation (no modulation) the tube must be drawing no more than half the maximum plate current possible in normal class C operation.

Since grid drive determines the efficiency to some extent, reduce the drive and see whether the percentage of modulation improves. It will probably be found that there is a point of minimum grid drive and minimum loading that will produce a completely modulated signal. At other settings the output may be greater, but it will be impossible to obtain complete modulation. Use the lower output, since loss of modulation varies as the square of the modulation factor; that is, 25% loss of modulation is actually a

50% loss of usable power, and can be the difference between being heard and not heard at all.

Low output caused by lack of sufficient drive will be indicated by a flattening of the positive peaks because of inability to reach full peak power. Lack of sufficient filament emission can also cause a similar condition.

Distorted Output. Distortion can occur from a number of causes, and is easy to detect when monitoring audio modulation. Overmodulation will result in a chopping off of the carrier, with carrier shift, causing excessive distortion and severe interference at stations within a few hundred kilocycles of the carrier. Since in screen-grid modulation it is necessary] to drive the screen negative to obtain 100% modulation, it is to be expected that a large amount of distortion will occur on the peaks. For undistorted output, the screen should never be driven negative.

Because of the constantly varying load, the speech amplifier producing the audio modulation will contain excessive distortion unless swamping resistors are used to load the modulation transformer, or unless negative feedback is used. In this event, using an oscilloscope to determine linearity between the input and output signals in the modulator will quickly locate any excessive distortion in those stages. (Refer to NAVSHIPS 0967-000-0130, Test Methods and Practices, Basic Measurements Section, for oscilloscope connections and waveforms.)

Although screen-grid tubes provide sufficient grid-plate isolation, so that neutralizing is unnecessary, it is possible that at the very high frequencies self-oscillation can occur in the r-f stage and cause distortion. This is particularly true if parts have been replaced and the lead dress has been disturbed. The characteristic fuzzy pattern (on an oscilloscope) produced by oscillation will quickly reveal this condition.

Inability to obtain full modulation can be due to the lack of filament emission in the r-f stage, which will cause flattening of the positive peaks and a consequent increase in distortion. This condition can be seen on an oscilloscope, but it will not normally be revealed by meter indications, except by a gradual reduction of plate current over a long period of time. A similar condition can result from drying out of electrolytic falter capacitors in the power supply, but it will usually show as hum on the carrier before the loss of peak current and voltage causes noticeable distortion. Such conditions are not apparent unless an oscilloscope is employed to monitor the waveform.

PLATE AND SCREEN MODULATOR

Application.

The plate and screen modulator is employed as a high-level modulator for screen-grid tubes (tetrode and pentode) in applications where the simplicity and fidelity of plate modulation are desired.

Characteristics.

Varies both the plate and screen voltages to achieve modulation.

Requires a modulator power equivalent to 50 percent of rated carrier plate and screen power.

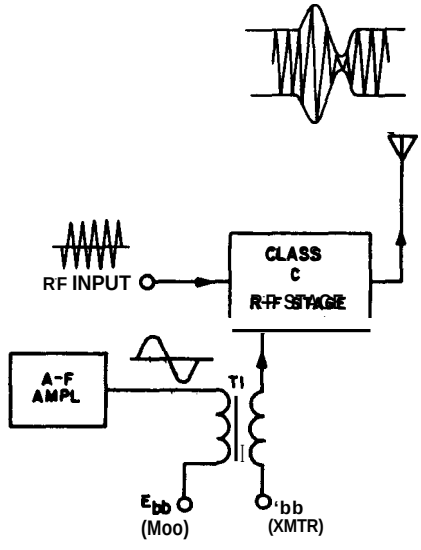
Operates at a constant efficiency of 70 percent or better.

Provides maximum carrier power for a given tube type.

Circuit Analysis.

General. The plate and screen modulator is practically identical to the triode plate modulator, except for provisions to accommodate the changes caused by introduction of the screen grid into the tube. This type of modulator is not a low-level form of modulator; instead, it is a high-level constant (high) efficiency type of circuit. The modulator itself must furnish the 50 percent additional power required for the production of the side-bands. The modulated r-f stage must also have a power supply capable of supplying the additional power for the screen circuit, or have a separate screen supply to furnish the power for the screen. During sine wave modulation the plate voltage and current are doubled to provide a peak power of four times normal, and the average power is increased to a maximum of 1.5 times normal carrier value, thus providing the proper conditions for 100 percent AM modulation. The use of the screen-grid tube, with its low grid-plate capacitance and shielding effect, reduces the internal plate-to-grid feedback, minimizing the possibility of self-oscillation and the need for neutralizing circuit arrangements. The increased sensitivity of the screen-grid tube also permits less excitation and driving power to be used as compared with the triode.

Circuit Operation. A simplified diagram of the basic transformer-coupled plate and screen modulator is shown in the accompanying figure. The a-f modu-



Basic Plate and Screen Modulator

later stage is represented as ablock, since it may be any one of a number of audio amplifier combinations as long as the proper audio power output is obtained. Likewise, the r-f output stage is also represented as a block, since it may consist of any arrangement of tubes to produce the desired carrier output to the antenna. The r-f stage is always biased so that it operates as a class C amplifier. Since class C operation requires twice the cutoff bias, a separate bias supply is usually used, with supplemental bias from grid drive through a grid leak. The total bias is a combination of the two types. In case of failure of grid drive, the freed bias provides a protective bias to prevent exceeding tube ratings and consequent damage to the tube. Thus far in the discussion the plate and screen modulator is identical with the plate modulator. The difference lies in the manner in which the modulation is achieved, that is, by also modulating the screen voltage. There are three basic methods used; each will be discussed in the following paragraphs. For the present it suffices to say that both the screen and plate voltages are varied from zero to twice normal to accomplish the modulation exactly as described for the plate modulator discussed previously.

Screen Voltage-Dropping Circuit. Since the screen voltage is always much lower than the plate voltage, it is necessary either to provi& the screen voltage from a separate power supply, or to obtain this voltage from the plate supply by means of a series dropping resistor. By far the simpler method, although somewhat wasteful of power, is the use of a "series dropping resistor, as shown in the following figure. As can be seen from the illustration, the screen voltage is obtained by a series voltage dropping resistor (R_{sc}) connected to the plate supply. The screen current through this resistor produces sufficient voltage drop to lower the plate supply voltage to the proper value for application to the screen. The actual screen voltage at all times is the supply voltage minus the drop across the resistor ($E_{sc} = E_{bb} - IR_{sc}$).

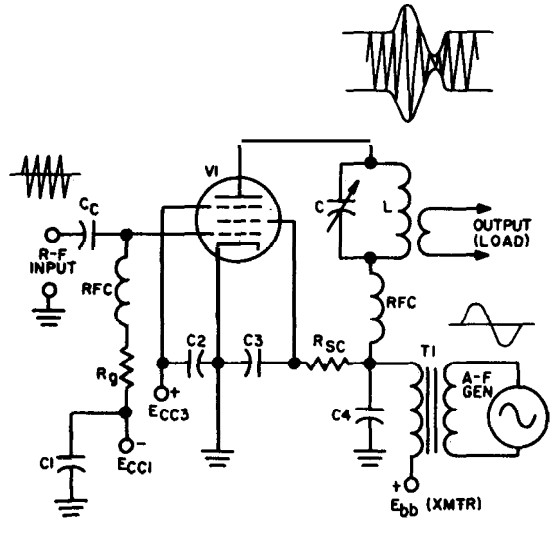


Plate-and-Screen-Modulated Pentode

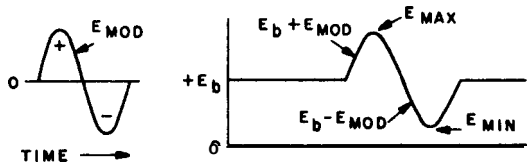
As shown, the r-f grid excitation is capacitively coupled through Cc, and grid drive bias is obtained through R_g, supplemented by freed negative bias. The rfc isolates the r-f drive and prevents it from feeding back through the grid supply or from shorting to ground, while Cl provides an r-f shunt to ground for any remaining rf which might leak through the rfc.

The suppressor grid is shown supplied with a small positive bias and shunted to ground for rf by C2. This connection will vary according to the type of tube. In tetrodes (since they do not have a suppressor grid) it

is nonexistent. In beam-forming screen grid tubes it will be the beam-forming plates, and will be connected as recommended by the tube manufacturer. In other types of pentodes the suppressor may be internally or externally connected to the cathode directly, and C2 is not needed. In those types of pentodes which require it, the suppressor connection will appear as shown on the schematic above. In this instance the slight positive bias is added to enhance the shielding effect of the suppressor at low plate voltages, and it also 'prevents the screen from intercepting any secondary electrons and acting as a plate. At almost zero voltage, any electrons will be attracted to the more positive suppressor and returned to ground. Thus zero plate current is possible with a sharper cutoff than when the suppressor has a negative potential applied. The screen grid voltage is obtained from the plate voltage source through screen voltage dropping resistor $\mathbf{R_{sc}}$ bypassed by C3 and C4. Capacitor C3 also insures that the screen is at ground potential to rf, permitting only dc or the relatively low-frequency modulation components to vary the screen voltage. Capacitor C4 is the conventional series plate-feed bypass capacitor. The secondary of T1 is connected in series between the plate-and-screen power supply, with the rfc isolating it from the tank circuit rf. Capacitor C4 also insures that any rf which might leak through the rfc is shunted to ground, and its reactance is high to audio frequencies in order to prevent loss of high-frequency response. The conventional tank components, C and L, are inductively coupled to the load. The audio output from the modulator appears at the secondary of T1, and is added to or subtracted from the applied dc plate voltage (and screen voltage) to produce an instantaneous effective plate (and screen) voltage which varies in accordance with the modulation.

Consider now one cycle of operation. At the resting condition, with no modulation, an unmodulated carrier is produced, and the applied plate and screen voltages at that time consist of only the dc component from the power supply. As the modulation is started, assuming a sine wave progressing from zero through the positive half-cycle, the instantaneous audio output voltage (from T_i) adds to the positive plate and screen voltages, and both voltages are increased. The following illustration shows how the plate and modulation voltages are combined to form the composite instantaneous plate voltage. (The screen voltage is also modulated similarly.) Since a resistor is not frequency-sensitive, equal voltage drops occur across the screen dropping resistor for all audio frequencies in the modulation; thus the screen voltage is dropped linearly and is also increased linearly with respect to the modulation signal. At the positive peak of modulation, the plate voltage is twice normal and the screen voltage is somewhere between 1.5 to 2 times normal, depending upon the screen current (usually around 1.5 times). It can be seen that, since the d-c screen voltage is increased by the addition of the instantaneous modulation component, the same result is produced as in screen modulation; that is, the plate current is increased. Because the plate voltage is also increased simultaneously and the class C output is proportional to the square of the plate voltage, the plate voltage also helps to increase the total tube current. Recalling from basic theory that the screen voltage determines the plate current much more than the plate voltage, it can be understood that variation of plate voltage alone would not produce 100ZO modulation since the tube current would not increase sufficiently on the peaks. (For an unmodulated screen, about 90 to 95 percent is the highest modulation obtainable.) Thus it is clear that variations of both the plate voltage and the screen voltage combine to produce the 100 percent modulation capability.

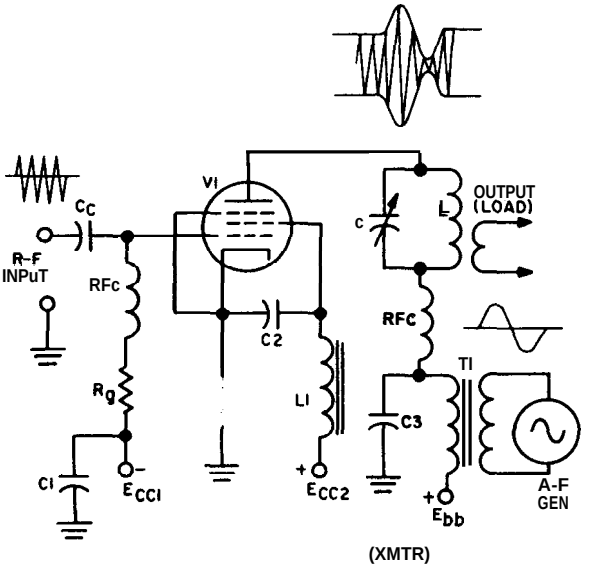


Combining of Plate and Modulation Voltages

As the modulation proceeds toward its negative half-cycle, both the screen voltage and the plate voltage are reduced, and the plate current follows. Thus at the negative peek (the trough) of modulation the plate voltage is almost zero, and so is the screen voltage. Actually to avoid excessive screen dissipation, the plate voltage is never driven below the screen voltage. In this case, since the screen voltage is obtained from the plate source through a dropping resistor, the screen voltage is always lower than the plate voltage; thus it is practically impossible to drive the plate voltage to zero, except if the screen is driven

negative. With negative screen drive, non-linearity causes distortion, so that normally the modulation is adjusted to just keep from driving the screen below zero. Normally, the plate current is reduced to a value near zero, and full modulation from zero to twice normal plate current and voltage are obtained. The peak power is four times the normal carrier value, and the average power increases supplied by the modulator is 1.5 times normal, or 50 percent of the rated carrier power.

Separate **Screen SupPIY Circuit. The** second and more complicated method of supplying screen voltage, but perhaps the more commonly used method, is to supply the screen voltage from a separate power source. This circuit is shown in the following figure, and is seen to be identical to that of the plate and screen modulator just discussed, except for the replacement of R_{sc} with choke L_1 and a separate screen supply. The screen power supply need only supply a fraction of the plate power. Most screen grid transmitting tubes use from 250 to 750 volts on the screen, with a plate voltage of 1000 to 4000 volts, and screen dissipation runs from 5 to 10 percent of the plate dissipation for high-power tubes, to 10 to 20 percent for low-power tubes, or a maximum of about 50 watts for medium power transmitters. This screen power supply provides only dc voltage; therefore, some provision must be made to increase and decrease the screen voltage in accordance with the modulation, to control the plate current. Such action is produced by the choke, L_1, placed in series with the screen lead. From basic theory it is known that the electrical inertia produced by the field around the choke tends to prevent a change in the flow of current through the choke. When the current ceases or reduces, the magnetic field collapses and tends to produce a voltage from the choke which will keep current flowing in the same direction. To do this it is evident that the voltage produced must be of the same polarity as that applied originally to the choke. When the modulation signal goes positive and increases the plate voltage, more electrons are attracted to the plate and less to the screen grid. That is, the total space current remains about the same, but the current distribution between the screen and plate changes. When the screen current reduces, an increased voltage is produced in the same direction, to add to the effective screen voltage before the modulation increased; this produces a slightly higher screen voltage, which, in turn, helps the plate current to increase. On the negative modulation swings, a similar but opposite condition occurs. As the plate current tends to reduce, the screen current tends to rise. The inertia of the choke tries to prevent the rising current and provides a negative-going voltage which decreases the effective positive screen voltage. Thus the plate current is helped to decrease. Since the screen grid controls the plate current much more effectively than changing the plate voltage, the slight changes in screen voltage produced by the choke, in turn, produce the desired effect. Capacitor C2 bypasses the screen to ground and prevents feedback of rf into the audio circuits. Capacitor C3 is the conventional plate bypass for series feed. The value of C3 is usurdly such that it has a high reactance to the audio frequencies, in order to avoid the possibility of frequency distortion due to shunting of the highs to ground. The screen bypass capacitor is usually about twice this value, since the reactance of choke L_1 is effectively in series with the capacitive reactance, limiting the shunting effect of C2. The choke must have sufficient power-handling capability to carry full screen current, and is usually on the order of 5 to 10 henrys. If it is too small, 100 percent modulation will not be obtained, and if too large it will produce phase shift at the low audio frequencies and attenuation at the high audio frequencies, causing some distortion. The actual value is chosen to have a reactance which is not less than the screen impedance at the lowest desired audio frequency. The screen impedance is approximately equal to the dc screen voltage divided by the dc screen current (Z = Esc/Isc).



Plata-and-Screen-Modulated Pentode with Separate Screen Supply

With this circuit, actual cutoff bias can be obtained, so that the bias can be adjusted for twice the cutoff value for proper class C operation. (With the voltage-dropping resistor type of circuit, the screen voltage becomes so high at low plate current that cutoff can never actually be attained; thus the theoretical value specified by the manufacturer is used to determine the operating bias.) As far as modulation is concerned, the choke produces voltage variations on the screen in phase with the modulation; this causes the plate current to increase on the positive modulation excursions and to decrease on the negative excursions, assisting the plate voltage variation, since variations in screen grid voltage have more control over the plate current than do variations in plate voltage. Thus the full limits of AM modulation are obtained, exactly as if' the tube were a triode and were completely controlled by plate voltage variations. Peak power is four times the normal carrier value, and the output increases 50 percent at full modulation, being supplied from the modulator. At the peak of modulation, maximum plate dissipation and power output occurs, with the efficiency remaining relatively constant throughout the audio cycle.

Transformer-Coupled Screen Modulator. The third basic method of plate and screen modulation is to provide an extra winding on the modulation transformer to provide the proper voltage ratio. In this method the dc screen voltage from a separate supply has amodulation component added which is proportional to the plate change in accordance with the transformer turns ratio. This method is costly, and is seldom used because of the simplicity of the previously described methods. The circuit operation is similar to that for the voltage-dropping method, except that the transformer, instead of the dropping resistor, supplies the proper voltage. Therefore, this method will not be further discussed.

Detailed Analysis. To understand the functioning of the plate-and-screen-modulated circuit, review the operation of the triode plate modulator previously discussed in this section before proceeding further. It is evident now that the only differences between the two circuits are those resulting from the addition of the screen grid to the tube. It is necessary to return to elementary electron tube theory to explain some of the differences in operation caused by the screen grid.

The addition of the screen grid provides a greater grid-plate transconductance, and, consequently, requires less drive power from the r-f driver to excite the modulated class C stage to saturation. Since the screen is located between the grid and the plate and always has a positive voltage applied, the problem of minimizing grid dissipation at minimum plate voltage is eliminated. (On the peak of the negative plate excursion, during modulation, the triode grid tends to become more positive than the minimum value of plate voltage. As a result, excessive grid current flows and causes the grid dissipation to increase.)

While in the preceding discussions we have spoken of having the modulation voltage reduce the screen and plate voltages to zero, during the modulation cycle, this does not exactly occur. The action which does occur can be understood more clearly if the desired action is first explained. In this instance, the object is to reduce the plate current to zero, during the conducting period of the class C cycle, coincidentally with minimum (almost zero) plate voltage, which is produced when the negative peak (trough) of the modulation effectively cancels the applied plate voltage. Since the screen voltage exercises a greater controlling factor than the plate voltage, it is possible to reduce the plate voltage practically to zero without actually reducing the screen voltage to zero. When the drop across the load makes the actual plate voltage zero, the applied voltage is still above zero by the

amount of voltage drop in the load. This is the applied screen voltage, which is still further reduced by the screen dropping resistor. However, the actual screen voltage always remains more positive than the small positive grid voltage swing. Thus grid dissipation because of low plate or screen voltage is minimized.

Consider now the effect of screen voltage on plate current, which mathematically follows a 3/2 power law as shown in the following table.

MULTIPLYING FACTOR	PLATE CURRENT VALUE (3/2)
.25	.125
.5	.35
.75	.65
1.0	1.0
1.25	1.4
1.5	1.64
1.75	2.3
2.	2.8

If the screen voltage exactly follows the power law, it is only necessary to vary the screen voltage to about 1.6 times normal to double the plate current. Likewise, it is only **necessary** to reduce the screen voltage to about 15 percent of normal to obtain practically zero plate current. It can be understood, then, why it is not **necessary** to drive the screen to zero and twice normal in order to drive the plate voltage and current to zero and twice normal. Thus it can be seen that the previous statements are not exactly true; however, since the tube does not exactly and always follow the 3/2 power law, it is not possible to make a more exact statement and be completely accurate. It is probably more accurate to say that the screen grid voltage is varied sufficiently to insure that the full plate current flow of twice normal is possible on the peaks of modulation when the plate voltage is increased twice normal. Under these conditions the requirement of a peak power of four times normal for **full** modulation is met, and the tube is used to its fullest capability.

Since the plate current does not vary linearly with screen voltage, it can be seen that varying the screen voltage linearly in accordance with modulation does not produce distortion-free plate components. That is, as long as the plate voltage and plate current do not vary exactly and linearly with the modulation, distortion exists. Thus the screen grid modulator inherently produces more distortion than the simple triode modulator produces, but with proper design this distortion is minimized to a low value. A comparison in this instance is the distortion products given with a simple triode audio stage as compared with pentode or beam tube audio stage. In every instance the distortion is greater, but the increased power-handling capabilities and low grid drive requirement make it mandatory to use the triode only where the increase in distortion cannot be tolerated.

In considering the action at low screen and plate voltages, the type of tube becomes an important factor. A typical comparison of plate current variation with plate voltage for two different types of screen grid tubes, and for pentode and beam tubes, is shown in the accompanying graph. It is easy to see that the beam and pentode types of electron tubes have much less variation of plate current at low voltages than the screen grid type has. Thus, when a suppressor grid is not included, reduction of plate voltage below the screen voltage produces undesired secondary emission effects, and can even cause the plate current to go negative (reverse its direction of flow). Since on the troughs of modulation (the negative peak modulation excursions) the plate voltage was said to be reduced practically to zero, together with the screen voltage, it can be seen that some unwanted effects can occur.

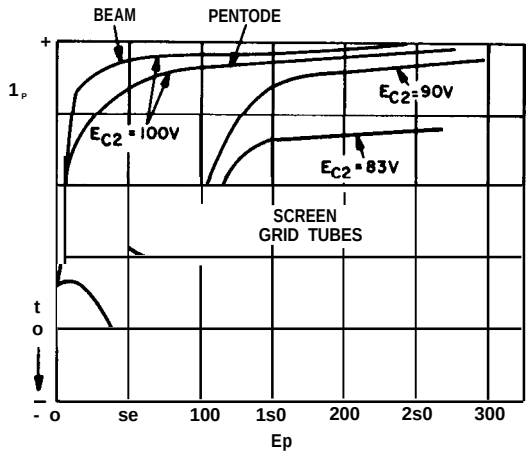


Plate Current Comparisons

Consider first the beam and pentode tubes, since their action is similar. From the graph it is clear that the plate voltage can be reduced to about 10 to 15 volts before the current changes appreciably and

suddenly drops off to zero. Thus it is possible to swing the plate voltage lower than the screen voltage without any unwanted effects. The plate current, however, does not change linearly with the plate voltage swing. Therefore, it is necessary to vary the screen voltage in order to change the plate current in accordance with the modulation, even though the plate voltage is varied. Because of secondary emission effects, it is clear from the graph that screen grid tubes (two different tubes are shown) cannot be used at low plate voltages. If they were used, extreme distortion would occur at low plate voltages, and, even though the screen voltage were varied likewise, a similar pattern would follow. Thus the screen grid tube cannot be operated with as low a plate swing as the pentode and beam tubes without excessive distortion. In considering the swing to practically zero voltage and current, it is evident that in most every case the swing is to a small minimum voltage rather than actual zero. Whether the minimum is very small or fairly large depends upon whether or not the tube is a beam-pentode or screen-grid type. It is also clear that because of the relatively high minimum plate voltage on a screen grid tube, less usable output is obtained than for a similar beam or pentode tube.

From a consideration of the small change of plate current with a large plate voltage swing, as shown in the preceding graph, it should also be clear that the screen-and-plate-modulated circuit functions primarily as a screen-modulated type of circuit with the plate voltage aiding. That is, while the' screen voltage changes the plate current, the corresponding change in plate voltage is in a direction which enhances the action. When the plate voltage is increasing, so is the screen voltage, and so is the plate current. Thus the problem of non-linearity on negative swings in the screen grid modulator is overcome because in the plate-and-screen-modulated circuit the plate voltage is reduced at the same time. Therefore, it is not necessary to swing the screen negative to get complete modulation.

Failure Analysis.

No Output. Lack of output should first be isolated to failure of the r-f amplifier stage or the modulation signal circuit(s). Even though the modulator is operative, an open rfc or tank circuit, a shorted or gassy electron tube, or lack of grid excitation to the r-f amplifier will produce a no-carrier indication. Observation of the r-f plate current meter will determine whether the plate circuit has continuity, and tuning for a maximum indication with a resonant dip will determine whether sufficient drive, load, and the proper bias exist for operation without modulation. Grid-drive meter indications will also show whether the proper r-f drive exists. When the tank can be resonated for a minimum dip and then loaded to the maximum plate current with normal grid current, the trouble is in the modulator circuit.

Lack of grid drive places the trouble in the exciter stages of the transmitter or in the coupling network to the final stage. Lack of plate current indicates possible power supply trouble, an open-circuited r-f stage, an open screen-voltage dropping resistor (in some tube types a very small plate current may still flow), or a shorted screen bypass capacitor. In the choke-fed screen modulator, an open choke would remove screen voltage and prevent plate current flow. Otherwise, proper performance, but lack of ability to load to maximum plate current, indicates antenna trouble, improper tuning, or a defective transmission line.

With an r-f carrier existing, the trouble is definitely in the audio circuits or in the modulation transformer, rfc, and screen or plate bypass capacitor.

High transmitter plate current usually indicates short-circuited components, a lack of proper bias, or improper tuning, while low plate current indicates excessive bias, high-resistance joints, low tube emission, or possible lack of coupling to the load. When the above conditions are indicated by the equipment meters, a simple resistance analysis made with the power OFF and the high-voltage supply grounded for safety will quickly determine the defective component(s).

Low Output. Determine first whether the low output is from lack of sufficient audio drive or from an actual reduction in the percentage of modulation. Low modulation is usually caused by lack of sufficient audio output, but it can also occur from a reduced setting of the audio gain control or from trouble in the speech stages. An oscilloscope is very useful in determining the cause of malfunctioning, since the waveform itself may be directly observed. For simple, quick tests of modulation percentage, the trapezoidal waveform is useful. The envelope or waveform check, however, will show percentage of modulation and also indicate waveform distortion; thus it is usually more useful. Too high a control grid bias will cause a reduction of output and an inability

to reach 100 percent modulation with the same drive. The grid bias can be checked simply with a voltmeter (connect an rfc in series with one of the prods). A reduced screen voltage is most likely of all to produce a low output, usually with overmodulation or distortion, since the plate and screen swing will be excessive. Such a condition can be caused by too heavy a screen current causing a large drop in the screen-voltage dropping resistor, by a defective resistor, or by a partially shorted bypass capacitor.

In the choke-fed screen circuit, a defective choke will prevent the obtaining of complete modulation and can also result in reduced output, as can a poorly soldered joint. Check the coil for the proper resistance with an ohmmeter. A partially shorted choke may give the proper indication when measured with a dc ohmmeter, but short across turns when operating. Such a condition will usually be indicated by audible noise or distortion when the signal is monitored.

Lack of sufficient filament emission can cause a flattening of the positive peaks, and inability to obtain 100 percent modulation. Lack of ability to reach 100 percent modulation at the high frequencies, while obtaining it at low and medium frequencies, would indicate a capacitive shunting by screen or plate bypass capacitors, provided the speech amplifier response is satisfactory.

Distorted Output. Distortion can occur from a number of causes, and is easy to detect when monitoring audio modulation. Overmodulation will cause a chopping off of the carrier (carrier shift), producing severe interference to stations operating near the transmitter frequency, and cause distortion.

In stages operating on the same input and output frequencies, there is always the possibility of sufficient feedback from plate to grid to cause self-oscillation, with severe distortion, particularly on the peaks of modulation. Although the low plate-grid capacitance (shielding effect) of the screen and pentode tubes makes this almost impossible, it will sometimes occur, especially at the higher frequencies, because of poor layout and external coupling between the tube elements. Such action can occur, particularly after part replacement and changed lead dress from a repair. Self-oscillation can usually be detected easily by its characteristic fuzzy oscilloscope pattern.

Lack of sufficient capacitance to supply the peak power requirements can occur through drying out of electrolytic filter capacitors, and cause peak flattening with its consequent distortion. Usually, however, such a condition will be indicated by hum on the carrier or in the modulation before the distortion is excessive enough to notice, unless an oscilloscope is used to monitor transmissions.

A similar condition caused by lack of sufficient emission in the r-f amplifier will cause peak flattening with noticeable distortion. This can sometimes be observed by noticing the lack of ability to respond to high modulation peaks and by a gradual decline in the plate current reading over a long period of time. Under normal conditions an r-f ammeter will indicate approximately a 22 percent increase in output current at 100 percent modulation.

SERIES MODULATOR (ELECTRON TUBE)

Application.

The series modulator is used to amplitude modulate a carrier (r-f) signal with an audio (or video) intelligence with a minimum of circuitry.

Characteristics.

Uses two triodes connected in series.

Has a wide bandpass.

Is critical to adjust.

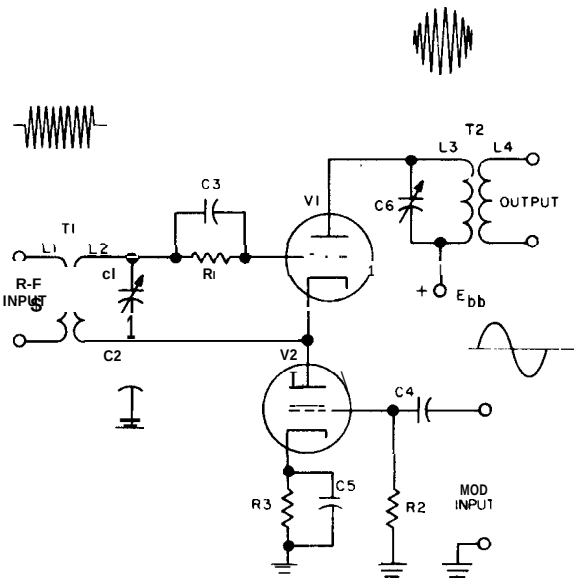
Used as either a high-level or low-level modulator.

Inefficient in comparison to other methods of producing AM.

Circuit Analysis.

General. The series plate modulator is used in a-m transmitters where it is desired that the modulator stage pass a wide band of frequencies. Because of its inherent wideband characteristics and relatively good quality, the series modulator is employed primarily in television applications; however, because adjustments are critical, the series modulator has not been widely accepted for common usage. Basically, the circuit consists of a triode modulator and a Class C r-f amplifier connected in series using a common dc plate supply. The modulator triode may be connected in either the plate or cathode circuit of the r-f amplifier with operation remaining basically the same, regardless of which method is employed. Only the cathode connected circuit is discussed in detail.

Circuit Operation. A cathode connected series modulator is illustrated in the accompanying schematic diagram,



Series Modulator

Modulator tube V2 is biased Class A by cathode resistor R3. Capacitor C5 bypasses the cathode resistor to prevent degeneration and helps to maintain a constant bias voltage. Resistor R2 is the grid return resistor with C4 acting as a coupling and dc blocking capacitor.

R-f amplifier V1 is biased Class C by the series grid leak circuit comprised of RI and C3. Transformer T1 couples the r-f signal into the tuned grid tank formed by secondary winding L2 and capacitor Cl. Capacitor C2 is the cathode bypass capacitor and prevents degeneration in the cathode and r-f from entering the audio circuits. C6 and L3 form a tuned plate tank (load) for V1, and L4 inductively couples the signal into the following stage.

When power is initially applied to the circuit no bias exists on either of the series connected triode tubes. As a result, plate current readily flows though the tubes to voltage source, E_{bb}. As the current flows through R3 and V2 voltage is developed across each component. The voltage dropped across R3 biases the modulator Class A so that any signal arriving on the grid will be faithfully reproduced in the plate circuit. The voltage dropped across the modulator tube, V2, protects the r-f amplifier in the event r-f drive is lost because of failure in the oscillator or multipliers. It will be helpful to remember that placing a positive potential on the cathode has the same effect as placing an equally negative potential on the grid. For the following discussion assume that no audio modulation voltage is applied to the grid of V2 and plate voltage remains relatively stable.

R-f signals arriving from the oscillator (or multiplier) stage are impressed across Ll, the primary winding of T1. The signals are transformer coupled into the secondary tuned tank formed by inductor L2 and capacitor Cl. The grid tank is tuned to the desired r-f frequency by Cl which is variable over a short range.

On the positive excursions of the r-f signal the grid is driven positive. Grid current flows and C3 charges quickly. As the signal swings negative, grid current ceases to flow and C3 begins discharging through RI developing a negative voltage which is applied to the grid. Discharge time is much slower than charge time because of the large grid leak and consequently, the charge on C3 is not completely dissipated before the next positive excursion of the r-f signal. The cycle repeats itself and eventually, after a few more cycles, the voltage applied to the control grid stabilizes. Thus, the tube is now biased by the grid leak (signal) bias on the control grid in addition to the bias voltage applied to the cathode. The sum of the voltage applied to the cathode and control grid of V1 biases the tube Class C (below cutoff) so that only the positive peaks of the r-f input signal results in plate current flow; therefore, plate current is broken into pulses at the signal frequency. Capacitor C2 bypasses any r-f plate current variation in the cathode to ground and prevents degeneration effects. The parallel resonant tank formed by C6 and L3 oscillates (flywheel effect) every time a pulse of current flows in the plate circuit. Hence, even though plate current flows in pulses, tank current flows for the entire cycle and a linear sine wave at the resonant frequency is transformer coupled into L4.

The preceding discussion describes the operation of the r-f amplifier with no modulation signal applied, and if operation was limited to this condition no intelligence could be transmitted. The following discussion concerns operation when modulating signals are applied.

A modulating signal from the finrd speech (or video) amplifier is r-c coupled through coupling capacitor C4 onto the grid of V2. R2 is the grid return resistor and provides a low impedance path for

dc return current. As the positive half-cycle of the modulating signal is applied to the grid, V2 bias is decreased and the cathode current through V2 increases. Consequently, V2 plate voltage decreases. Decreasing the plate voltage of V2 is the same as decreasing the plate voltage of V1 (since both tubes are in series) and, in effect, reduces the cathode bias from V1 to ground so that conduction in V1 is increased; this results in developing an increased output across the plate load (resonant tank). Conversely, when the modulating signal swings negative the opposite effect takes place, and the output across the plate load decreases.

Hence, in this application, the plate voltage decreases to nearly zero (with respect to the cathode) at maximum output, and increases to nearly the supply value, Ebb, at minimum output. Unlike other modulators, no voltage doubling takes place due to the absence of a reactive element (inductor) in the plate circuit. Instead, the circuit is initially adjusted so that full carrier output is obtained with half the supply voltage applied, so that swinging it from zero to the full supply value is the same as doubling the voltage in other types of modulators.

If the modulating signal is of sufficient amplitude to overdrive V1 into saturation, a loss of intelligence (clipping) results for the period of time the tube is in saturation. Hence, transmitters are usually equipped with a modulator gain control to insure that the modulating signal does not exceed design limitations. From basic theory it is known that when two signals are injected simultaneously into a non-linear device, new frequencies appear in the output. When the r-f and modulator signals are injected into V1, which is operated as a Class C (non-linear) r-f amplifier (whose output varies as the square of the applied plate voltage), two additional frequencies appear in the output; namely, the sum and difference frequencies. In transmitters these "new" frequencies are referred to as upper and lower sidebands and represent approximately 1/6 of the total power, per sideband with 2/3 of the power in the carrier. The sidebands contain the same modulation as the earner and in some transmitters, such as single-sideband (ssb) and double sideband (dsb), the sidebands are transmitted in preference to the carrier. However, in this instance the carrier and two sideband frequencies are selected by the tuned tank and coupled into the output circuits by the transformer action of T2.

Failure Analysis.

No Output. A loss of r-for audio signal will result in either a no output or unmodulated carrier condition. Use an oscilloscope equipped with a high impedance probe to check the r-f (across Ll) and audio (across input terminals) signrds. If either signal is absent the modulator will not function properly, and the absent signal must be secured before further troubleshooting is accomplished. Next, check each tube element on the base of the tube socket for correct operating voltages. Check the bias voltages carefully as an abnormal bias voltage may cause erroneous readings on the plate elements. If voltage are abnormal, use an ohmmeter to measure the dc resistance of R3, R1 and inductors L1, L2, and L3 also, use an in-circuit capacitor checker to check Cl, C2, C3 and C5 for a shorted or leaky condition.

Weak or Distorted Output. A weak or distorted output will be caused by: weak or distorted input signals; improper bias; improper power supply voltages; defective tubes; or improper tuning or loading of the grid or plate tank.

DOUBLE SIDEBAND MODULATOR (ELECTRON TUBE)

Application.

Double sideband modulation is used in double sideband communication systems where upper and lower sideband are transmitted and the carrier frequency used to generate these sidebands is eliminated.

Characteristics.

Generates upper and lower sidebands at high power levels while suppressing the r-f carrier.

Utilizes two push-pull connected triodes operated class c.

Uses low level grid modulation.

Modulating signal is applied to the control grids in push-pull, while the r-f carrier is applied to the control grids in parallel.

Utilizes nonlinear characteristics of electron tubes to generate sidebands.

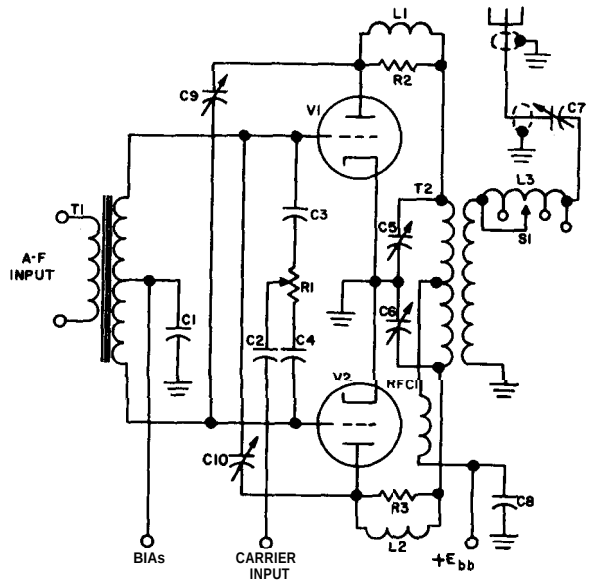
Even-order harmonics are cancelled through push-pull action.

Circuit Analysis.

General. Double sideband communications systems differ from conventional a-m systems and from single sideband systems in that both sidebands and no carrier is transmitted. It should be noted that carrier elimination is achieved in a specially designed power amplifier. The modulator is a conventional AM modulator. This discussion will pertain to the power amplifier, since the power amplifier is the ordy unit in the DSB transmitter which is significantly different from units in the conventional full carrier AM transmitter. Single sideband systems achieve the same result by transmitting only one sideband. Both DSB and SSB provide the advantage of eliminating "whistles" or beats caused by the beating of the earner with other carriers and sidebands in the receiver, since both DSB and SSB do not transmit a carrier. At first glance it may appear that a single sideband system makes more effective use of the available transmitter power, since the SSB transmitter concentrates all of the available transmitter power into one sideband while the DSB transmitter transmits two identical sidebands. However, this apparent gain of SSB over DSB is not realized at the receiver output, since double sideband signal voltages combine vectorially in the receiver detector and produce audio frequency voltage proportional to twice that produced by one sideband. For example, a double sideband r-f envelope containing 100 watts (50 watts in each sideband) produces the same receiver audio output as a 100 watt SSB r-f envelope (all 100 watts in the sideband). It has been reasoned that a double sideband system can provide results equal to or greater than that produced by a SSB system. In a conventional full carrier AM system the r-f carrier transmitted with the sidebands heterodynes with the sidebands in the receiver detector circuit and audio frequency voltages are produced. In the DSB system and in the SSB system no carrier is transmitted and an artificial carrier, generated in the receiver must be combined with the sideband, or sidebends in the case of DSB, to properly demodulate the signal. This artificial carrier frequency must be very stable and must be as close as possible to the frequency of the earner used to generate the sidebands in the transmitter in order to keep distortion of intelligence to a minimum. One of the arguments in favor of DSB over SSB is the distortion caused by the phase shift inherent in SSB due to the loss of the opposing phase shift of the other sideband. This shift can be minimized by maintaining a sufficiently high level of carrier insertion at the receiver. This phase shift has little effect on voice transmissions but pulse and data transmissions may be seriously affected. In a DSB system the effects of this phase shift are greatly minimized since the phase shift of one sideband tends to oppose the phase shift of the other sideband. The DSB system, however, requires that the locally inserted carrier be of the same phase relationship as the originrd modulation at the transmitter. This is accomplished by the use of a phase-locked oscillator to generate the carrier to be reinserted in the receiver. Another advantage seen in DSB transmission over SSB is the possibility of greater reliability of reception under varying conditions of fading. Under such conditions one sideband may be phased out by multi-path fading while the other sideband may not be excessively attenuated. By definition, selective fading results when the various frequency components of a transmission are not received exactly as transmitted with respect to power levels and phase relationships. The adverse effects of this condition on full carrier AM is distortion of received intelligence, and decreased receiver output. It can then be said that SSB is not subject to selective fading since only one sideband is transmitted. However, if propagation conditions are such that the frequency of the sideband being transmitted is excessively attenuated the receiver output is likewise decreased, whereas a DSB system operating at the same frequency will probably maintain satisfactory communications since the other sideband will probably be unaffected. Another advantage of DSB over SSB is the simplicity of the DSB transmitter. To convert a conventional full carrier AM transmitter to a DSB suppressed carrier transmitter only the power amplifier must be modified. The modified DSB power amplifier closely resembles the balanced modulators used in SSB transmitters. The DSB power amplifier discussed here consists of two push-pull connected triodes operating class C with r-f carrier applied to the control grids of both tubes in parallel (in-phase), and the audio modulating signal applied to the control grids in push-pull (180° out-of-phase). In push-pull amplifier

circuits a push-pull input is required to produce an output and an in-phase input cancels in the output. The r-f carrier and the audio modulation present simultaneously on the control grids of the tubes beat together, and four basic frequencies are present in the plate circuit of the modulator tubes. These frequencies are the original r-f carrier, the original audio modulation and sum-difference frequencies generated as a result of heterodyning. Heterodyning results when two or more frequencies are applied to any element of a non-linear resistance such as an electron tube or a transistor. If the reader desires detailed information on heterodyning he may find it in the introduction to chapter 13 of this Handbook. The r-f carrier frequency present in the plate circuit is canceled out by push-pull action in the output transformer (the r-f carrier is applied to the push-pull amplifier in parallel) and the output transformer presents a very low impedance to audio frequencies. Therefore, the original audio modulating signal is not developed in the output. The generated sidebands, which are a product of the in-phase r-f earner input and the out-of-phase audio modulation input are therefore, out-of-phase at the plates of the tubes and add in the output transformer, rather than cancel as in-phase signals do, and they are inductively coupled to the antenna circuit through the output transformer. The power amplifier described here uses two power triodes, however, the use of power tetrodes may be encountered.

Circuit Operation. The following schematic diagram illustrates a final power amplifier designed to suppress or elimimte the r-f carrier and produce a double sideband output.



Double Sidebend Generator

Transformer T1 couples the audio modulation from the modulator to the grids of the power amplifier. Capacitor Cl places the centertap of T1 at a-f ground potential so that 180° out-of-phase audio voltages are developed across the top and bottom halves of the secondary of Tl, and are felt on the grids of power amplifier tubes VI and V2. Coupling capacitor C2 couples the r-f carrier from the preceding stages to the slider of carrier balance potentiometer Rl, which provides a means of varying the amplitude of the r-f carrier coupled to the grids of V1

and V2 with respect to each other. Capacitors C3 and C4 couple the r-f carrier from carrier balance potentiometer RI to the grids of V1 and V2, respectively. Power triodes V1 and V2 are the nonlinear devices used to generate upper and lower sidebands at high power levels. Resistor R2 which is shunted by inductor L1, and resistor R3 which is shunted by inductor L2 form parasitic suppressor networks intended to decrease the tendency for parasitic r-f oscillations to develop. Center-tapped transformer T2 serves as the push-pull output transformer for the power amplifier and capacitors C5 and C6 form a split-stator type of tank capacitor used to resonate T2 to the output frequency. Radio frequency choke RFC1 together with bypass capacitor C8 prevent r-f energy from entering the power supply. Tapped inductor L3, whose inductance can be varied by switch S1, together with variable capacitor C7 couple the transmitter output to a coaxial transmission line which transmits the sideband r-f energy to the antenna. Since triodes are used the circuit must be neutralized or the relatively high value of grid to plate capacitance of the triodes would provide a feedback path and the amplifier would break into self oscillations. Capacitor C9 and C1O couple r-f energy from the plate of one tube to'the grid of the other and cancel or "neutralize" the effects of grid to place capacitance and thus prevent self oscillations.

To more easily examine the operation of the DSB power amplifier assume first that only the r-f carrier is applied.

The r-f carrier is coupled from the preceding driver stage through coupling capacitor C2 to the slider of carrier balance potentiometer R1. The r-f carrier appears at both ends of RI and is coupled in-phase through capacitors C3 and C4 to the grids of VI and V2. The amplitude of the r-f carrier at the grid of each tube is controlled by the adjustment of half cycle, both plates draw an increasing amount of plate current (the input is in phase) and the voltage drop across each half of the tapped primary of the output transformer T2 is negative going, so that opposing voltages are developed in the transformer primary which cancel, and no output is produced. If the circuit is properly balanced by the adjustment of R1, these opposing signals are equal in amplitude and the carrier is effectively suppressed. Since the amplifier is operated with class C bias (approximately twice cut-off) only the peaks of the positive half cycle of the r-f input have an effect on conduction. Neither tube conducts during the negative half cycle of r-f earner input and again no output is produced. Therefore, an output is not produced by the DSB power amplifier when only the r-f carrier is applied. When audio modulation is applied in addition to the r-f carrier, upper and lower sidebands are generated and are coupled through the output circuit to the antenna.

Audio modulation is applied to the primary of T1 and since the center tap of the secondary of T1 is - placed at a-f ground potential by capacitor Cl, audio modulation signal voltages are developed across each half of the winding, which are 180° out-of-phase with each other. This modulation signal is applied directly to the grids of VI and V2. Capacitors C3 and C4 are of such a value that they present a high impedance to audio frequencies and, thus, prevent the out-of-phase audio modulation from crossing over from one grid to the other and canceling each other out. During the period when both tubes are driven into conduction by the positive half cycle of r-f carrier input, the audio modulation and the r-f carrier beat together, and sum and difference frequencies (sidebands) are generated as the result of heterodyning. Actually there are four basic frequencies present in the plate circuit of V1 and V2. There are the original r-f carrier, the original audio modulating signal, and the upper and the lower sideband. Other higher order harmonics are also present but are of little consequence. Of the frequencies present only the sidebands are developed in the output circuit since the r-f carrier cancels in the push-pull output transformer, as explained previously. The audio modulating frequency is not developed because of the low value of - impedance offered by the r-f output transformer. The sideband frequencies, being a product of the out-of-phase modulating signal, are developed across the primary of the output transformer and are inductively coupled through the secondary of T2 to the output circuit. The even order harmonics present in the plate circuit are cancelled through push-pull action and the odd order harmonics are shunted around the primary of T2 to ground by capacitors C5 and C6. The sidebands are coupled through inductor L3, whose inductance can be varied by switch S1, and variable capacitor C7 to the coaxial transmission line. L3, S1, and C7 match the impedance of the power

amplifier output to the impedance of the coaxial line so that maximum power is transferred to the antema and minimum power is reflected.

Failure Analysis.

No Output. Dangerous high voltages are present in the power amplifier and all applicable safety precautions should be taken when working with the power amplifier. Since each branch of the power amplifier performs essentially the same function, failure of one branch is not likely to cause a no-output condition to exist. Failure of the power supplies or failure of the input or output circuits are likely causes of output. If the power amplifier is at fault, make resistance checks with the equipment deenergized, and pay particular attention to the resistances measured from the plates to ground; since components having high voltages applied to them are more likely to breakdown and short than components having lower voltages applied to them. Capacitors C5, C6 and C8 would short the high voltage to ground if they broke down, and capacitors C9 and C1O would short the high voltage supply to the bias supply if either capacitor broke down. Capacitor Cl would short the bias supply to ground if it failed. Transformer T2, inductors L1 or L2 or RFC1 could become shorted to ground. This would also short the HV power supply to ground as well as a possible shorted tube. Insulation breakdown on any of the wires carrying high voltage could also be the cause of a shorted power supply.

If the no-output condition does not manifest itself in the form of blown H.V. fuses, lack of high voltage at the plates of V1 and V2 could be the trouble. Observing all applicable safety precautions, measure the plate voltage of the power amplifiers with the transmitter keyed. If there is no plate voltage on either tube, the power supply is defective or RFC1 is open. If proper plate voltage is applied but there is no output, failure of either the r-f carrier, or modulation, to reach the grids of V1 and V2 could be the cause of no output, since the DSB power amplifier, like the SSB balanced modulator, produces an output only when both inputs are present simultaneously at the grids. Presence of these signals can easily be determined by observing, with an oscilloscope, the waveform present at the grids of V1 and V2. If either input signal is missing, signal trace from the grids of VI and V2 to the preceding stage to determine the defective component. Failure of T1 is a likely cause for no modulation drive to V1 and V2. Resistance checks of transformer windings and leakage checks to ground should reveal any defects that may exist in T1. Failure of Rl, or an open C2, could prevent the r-f carrier from reaching the grids of V1 and V2, hence, no output would result. Failure of output transformer T2 could also result in a no-output condition. Resistance checks of transformer windings and checks for leakage to ground, and leakage between windings should reveal any defects existing in T2.

Low Output. A low output condition can be caused by defective tubes, improper power supply voltages, low amplitude inputs, or improper tuning of the output circuit. Observe all applicable safety precautions and check the high voltage applied to the plates of the power amplifier. Also check the bias voltage applied to the grids V1 and V2. If the tubes are good and the power supply voltages are correct, low output could be caused by insufficient r-f carrier, or modulation drive applied to the power amplifier. This condition can be checked by observing with an oscilloscope, the amplitude of the r-f carrier and the modulating signal on the grids of VI and V2. If either input signal is weak on the grids of VI and V2, check the amplitude of that signal at the point where it enters the power amplifier, in order to determine whether the defect exists in the power amplifier, or in the preceding stages. A defect in T1 such as a partially shorted winding or excessive leakage to ground could result in a decreased amplitude modulating signal on the grids of VI and V2, and a partial failure of C2 or R1 could result in decreased amplitude r-f carrier on the grids of V1 and V2. Both situations could result in a low output. Likewise, if one of the input signals is unable to reach the grid of either V1 or V2 that branch of the power amplifier would be inoperative, since both modulating signal and r-f carrier must be present at the grid simultaneously to produce an output, and low output would result. If C3 or C4 opened, or RI opened, the r-f carrier would not be coupled to the grid of either V1 and V2. Likewise, a similar situation would arise if either the top or bottom half of the tapped secondary of T1 become shorted. In this case the audio modulation signal would not be coupled to the grid of one of the tubes and low output could, again, result. Another possible cause of low output is a defect in the parasitic suppressors networks L1-R2 and L2-R3. If the resistor in either network opened, a decreased output could result since much of the

sideband voltage would be dropped across the inductor shunting the open resistor.

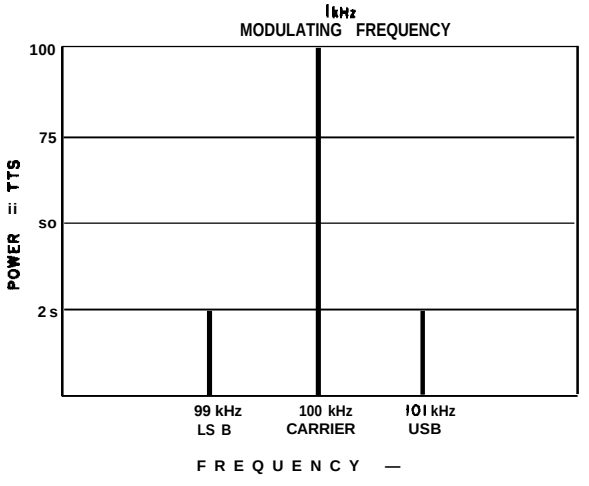
Distortad Output. A distorted output condition may be caused by defective tubes, improper power supply voltages, excessive input drive, or a distorted input. Check the power supply voltages taking care to observe all safety precautions, and make any required adjustments, if necessary. If the output is still distorted it would be wise at this point to observe, with an oscilloscope, the amplitude and waveshape of the input signals. It should be noted that if the input signals are excessive or distorted the fault lies in the stages preceding the power amplifier.

PART 12-2. SINGLE SIDEBAND

SINGLE SIDEBAND MODULATION (SSB)

General

An amplitude modulated r-f signal can be separated into three different frequencies. They are, the carrier frequency, the upper sideband frequency (USB) and the lower sideband frequency (LSB). A 100-percent modulated A-M signal utilizes two thirds of its total power in the carrier. The following diagram illustrates the frequency versus power relationships of a fully modulated AM envelope.

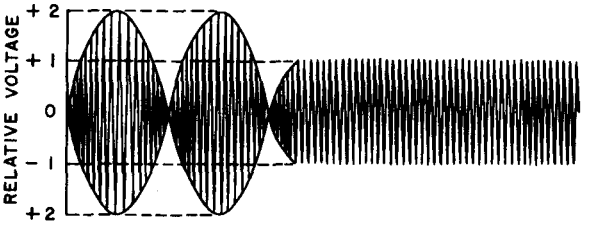


100% Modulated A-M Signal (100 Watt Carrier Power)

An understanding of the principles of Amplitude Modulation is essential to the understanding of SSB modulation since SSB is basically a form of AM. A brief review of the principles of amplitude modulation as discussed earlier in this Section of the Handbook will greatly facilitate the understanding of SSB modulation for the reader who is not thoroughly familiar with A-M.

Since only the AM sidebands carry all of the intelligence (modulation) the carrier can be eliminated, and the available transmitter power utilized to a much greater advantage. Both upper and lower sidebands are identical in waveform except for a difference in frequency. Therefore if one of the sidebands along with the carrier is suppressed or eliminated leaving only a single sideband, an even greater efficiency may be obtained.

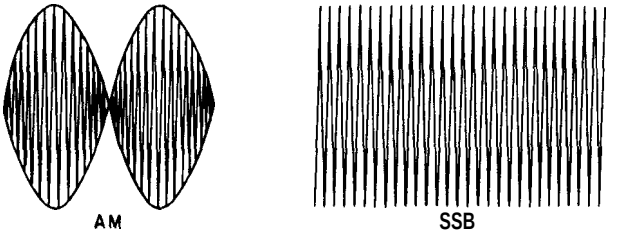
Normally, an effective 6 dB power gain can be obtained from a r-f power amplifier, capable of dissipating say 400 watts of peak power, by using SSB instead of conventional DSB AM. For comparison purposes we shall use a 100 watt rated carrier power AM signal and a 400 watt peak envelope power (abbreviated PEP) SSB signal. Note that the 100-watt rated carrier A-M signal also dissipates 400 watts on audio peaks when fully modulated as shown in the following illustration.



100% Modulated AM Envelope

As can be seen from the illustration, the peak to peak voltage of a fully modulated A-M envelope is twice that of the unmodulated carrier. Peak power is four times carrier power, since $P = E^2/R$.

The following illustration compares a fully modulated 100 watt rated carrier power envelope to a 400 watt PEP single sideband envelope for a single sustained tone.

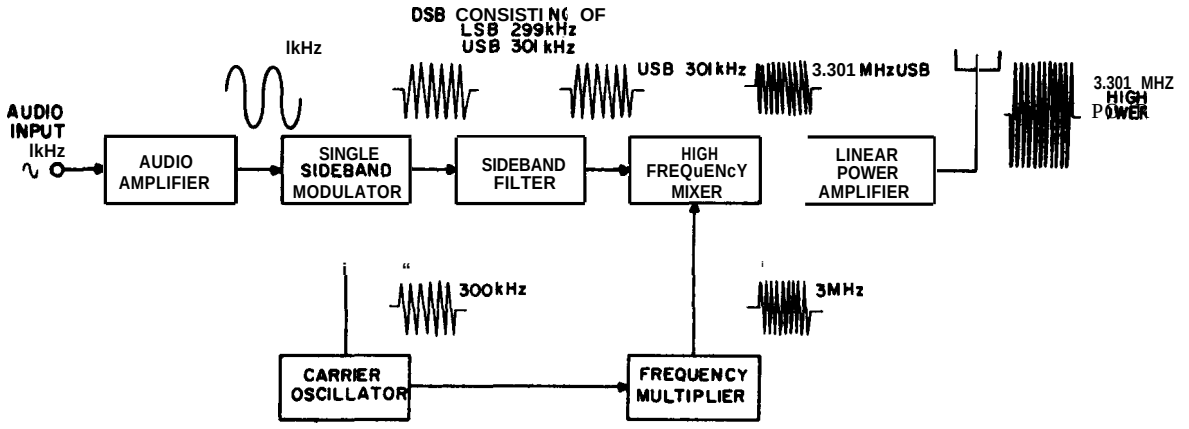


Comparison of A-M and SSB Modulation Envelopes

Note that while the peak power ratings of both signals are identical, the conventional AM modulated signal only reaches full peak power at the instant of 100 percent modulation. On the other hand, the single-sideband signal operates constantly at full peak power. Assuming that the AM envelope consists of a 100 kHz carrier modulated by a 1 kHz audio tone, an upper sideband at 101 kHz and a lower sideband at 99 kHz are produced, rdong with the 100 kHz basic carrier in the r-f envelope. Thus, the average sideband power is only 50 watts (25 watts in each sideband). On the other hand the 400 watt single sideband r-f envelope is either the upper sideband or the lower sideband (depending upon which sideband is selected to be transmitted), and there is no carrier frequency present. Hence all 400 watts of PEP is usable power. Consequently, there is an apparent 8-fold (9 dB) increase in usable power of SSB over conventional DSB AM. Actually this only amounts to a 6 dB gain m useful power, since a conventional DSB AM signal containing 50 watts of total sideband power produces twice the receiver output that a 50 watt PEP SSB signal produces. This is because the upper and lower sidebands of the DSB AM signal combine in the receiver detector circuit, and produce an audio voltage which is proportional to double the amplitude of each sideband. The loss of one sideband reduces the apparent 9 dB gain of the SSB transmission over conventional AM to an actual 6 dB advantage.

Up to this point we have only discussed the power advantages gained through the use of single sideband in the transmitting system. Another important advantage realized through the use of SSB is that of frequency spectrum conservation. For good intelligibility modulating frequencies up to 3 kHz are required for voice transmissions. A conventional DSB AM contains the carrier frequency and sideband frequencies deviating 3 kHz on both sides of the carrier frequency, when the carrier frequency is modulated by a 3 **kHz** tone. Thus the total bandwidth of this signal is 6 kHz. With the same modulating frequency the bandwidth of the SSB system is only 3 kHz, since only one sideband is transmitted. It is apparent that a SSB system will provide twice the number of channels of a comparable conventional DSB A-M system. Still another advantage of SSB operation is reduced receiver noise, since the required bandwidth of the receiver is halved due to the reduced bandwidth of the transmitted signal. Since noise power is directly proportional to bandwidth, a 3 dB gain in signal-to-noise ratio results because of the increased selectivity. From the above discussion, it can be seen that the SSB system provides an effective 9 dB overall improvement (6 dB in the transmitter, and 3 dB in the receiver) over the conventional DSB AM system. The power comparison between SSB and AM stated previously is also based on ideal propagation conditions. Over long distance transmission paths, AM is subject to selective fading, which causes severe distortion and sometimes a weaker received signal. Only the A-M transmission is subject to this type of deterioration under poor propagation conditions, because the upper sideband, the lower sideband, and the carrier must both be received exactly as transmitted to realize full fidelity, and the full theoretical power from the signal. If one, or both, of the transmitted sidebands is attenuated more than the carrier, a loss of received signal results. The most serious and most common result is selective fading which occurs when the carrier is attenuated more than the sidebands. The effect of this type of selective fading is severe distortion of the received intelligence. Selective fading can also cause a phase shift between the relative phase positions of the carrier and sidebands. This condition also results in distortion of intelligence. On the other hand, a SSB sigral is not subject to selective fading, which varies the amplitude or phase relationship between the sidebands and the carrier, since only one sideband and no carrier is transmitted.

The following block diagram illustrates a simple SSB transmitter arrangement.



Single Conversion SSB Transmitter

The audio amplifier stage increases the speech input voltage to a level sufficient to drive the SSB modulator. An extremely stable r-f signal is provided for use in generating the desired r-f sidebands by the carrier oscillator. The SSB modulator generates both upper and lower sidebands when both audio modulation and r-f carrier are applied simulatenously. The sideband falter stage passes the selected sideband and rejects the undesired sideband. The frequency multiplier stage multiplies the r-f carrier generated in the carrier oscillator to a higher frequency for use in the high frequency mixer stage, where this multiplied frequency heterodynes with the sideband frequency from the sideband falter, and produces the desired transmitter output frequency. The linear power amplifier stage is used to amplify the signal from the HF mixer stage to a power level suitable for transmission. Since very stable oscillators and very sharp falters are much easier to produce for low frequency applications, SSB generation is made to occur at relatively low radio frequencies. The generated sideband frequency is brought to the desired high r-f output frequency by frequency conversion. Although the simple single sideband transmitter discussed above uses single conversion for ease of understanding, it is normal practice to use double conversion to obtain the desired high frequency output.

The single sideband modulator is used to generate amplitude modulated upper and lower sidebands, meanwhile suppressing or canceling the r-f carrier which was used to generate the sidebands. By beating the audio modulation against the unused carrier frequency, sum and difference frequencies are produced to provide the actual sideband frequencies. It is also important to note that the carrier frequency does not appear in the output of the modulator because circuit elements are arranged to produce this effect. All types of single sideband modulators such as the balanced modulator, the balanced-bridge rectifier-type modulator, and the product modulator produce the same end result. They differ, however, in the manner in which they achieve carrier suppression and generate sidebands. Each of these circuits is discussed in detail in the following paragraphs.

BALANCED (PUSH-PULL CARRIER INPUT) MODULATOR (ELECTRON TUBE)

Application.

The balanced (push-pull carrier input) modulator is used to produce amplitude modulated upper and lower sidebands for use in single sideband transmitters.

Characteristics.

Operates class C with push-push output.

Both r-f carrier and audio modulation are applied to the modulator in push-pull.

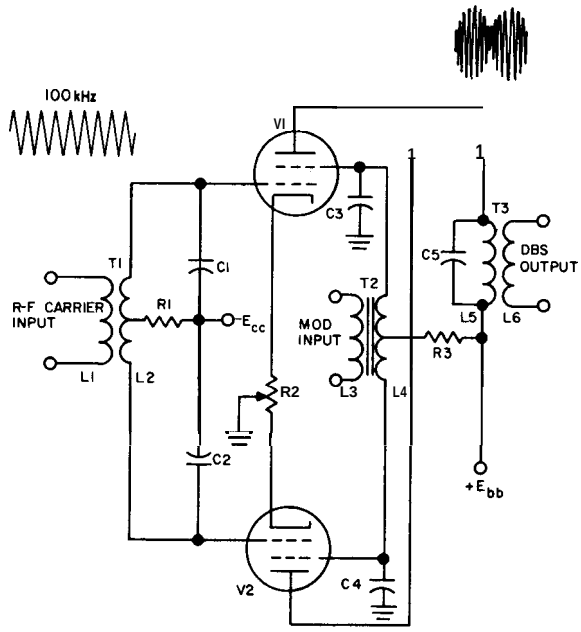
Generates upper and lower sidebands while suppressing the r-f carrier.

Utilizes two tetrodes with their plates connected in parallel.

Circuit Analysis.

General. While all modulators have the characteristic of producing sidebands the balanced modulator is unique in that it produces only upper and lower sidebands and suppresses, or cancels the r-f carrier in the output. Different types of balanced modulators differ in the manner in which they achieve carrier suppression. This discussion concerns the manner in which the balanced (push-pull carrier input) modulator achieves carrier suppression. The balanced modulator discussed here utilizes two tetrodes with their plates connected in parallel, and operated class C. The r-f carrier is applied to the modulator control grids in push-pull (out of phase) while the modulating signal is applied to the screen grids in push-pull, also out of phase. The r-f carrier signal is cancelled in the output tank circuit and upper and lower sidebands are generated. It is important to consider that carrier suppression occurs in the output tank circuit and not in the plate circuit. The parallel-plate comected modulator tubes are operated with Class C bias, and conduct only on positive-going input signrds. Since the r-f carrier input is applied to the modulator control grids push pull, the modulator tubes conduct and produce an r-f output on alternate half cycles of the r-f input. Since ordy one tube is conducting at a given instant, the r-f pulses appearing in the plate circuit of each tube are not affected by the other tube. In the tank circuit, however, the r-f pulses occur at a rate which tends to cancel rather than reinforce tank circuit oscillations. The generated sidebands do not cancel in the output, since the output tank is resonant to only the carrier frequency. The audio modulation signal is not developed in the output due to the low impedance presented to audio frequencies by the r-f output transformer. This discussion concerns the use of tetrodes in the push-pull carrier input balanced modulator. Triodes or pentodes may be used in place of tetrodes, the need being determined by system requirements.

Circuit Operation. The following schematic diagram illustrates a typical balanced (push-pull carrier input) modulator.



A-886

Push-Pull Carrier Input 8alanced Modulator

Transformer T1 couples the r-f carrier signal from the carrier oscillator to the control grids of balanced modulators V1 and V2. Secondary L2 of T1 is effectively centertapped by RI and capacitors Cl and C2. Resistor R1 also permits fixed bias insertion for V1 and V2, and serves as a bias decoupling resistor. Potentiometer R2 provides a means for electrically balancing the circuit by varying the cathode resistance of V1 and V2. V1 and V2 are the nonlinear devices used to generate the upper and lower sidebands. Transformer T2 couples the audio modulation to the screen grids of V1 and V2. The secondary of T2 is center-tapped to forma push-pull screen circuit so that the induced audio frequency voltages will be 180 degrees out of phase at the screen grids of the modulator tubes. The audio frequencies do not appear in the output since the output transformer, T3, presents a low impedance to audio frequencies.

Capacitors C3 and C4 are screen grid r-f bypass capacitors preventing r-f from entering the screen supply. Resistor R3 is a screen voltage dropping resistor intended to keep screen voltage always lower than the plate voltage, so that the negative resistance effects inherent in the tetrode are not encountered. Transformer T3 serves as the tuned output transformer. The primary L5 of T3 together with capacitor C5 form a parallel resonant tank circuit which is sharply tuned to the carrier frequency.

To more easily understand the operation of the balanced (push-pull carrier input) modulator assume first that only the r-f carrier is applied. Assume that the first half cycle of r-f carrier drives the grid of V1 positive and the grid of V2 negative. Since V2 is cutoff due to class C bias, the negative signal on the grid of V2 has no effect on V2. On VI, however, the positive half cycle of r-f drives the tube into conduction and a negative going r-f signal appears in the plate circuit. Capacitor C5 charges during the period of increasing plate current. When plate current starts to decrease C5 discharges building a magnetic field around L5. When plate current ceases the magnetic field around L5 would normally collapse and charge C5 in the opposite direction. This is normal tank circuit oscillation sometimes called, "flywheel action".

At this time, however, the next half cycle of r-f input drives V2 into conduction and a negative going r-f pulse appears in the plate circuit. Capacitor C5 charges and prevents the magnetic field around L5 from collapsing. When plate current starts to decrease C5 discharges and maintains constant current through L5. With constant current through L5 the magnetic field around L5 remain unchanged, and an output is not inductively coupled to the following stages. In effect, the r-f output pulse from V2 cancels the r-f output pulse from V1. The amplitude of these pulses should be approximately equal, considering the losses in the tank circuit, for the r-f carrier signal to be effectively canceled. The relative amplitude of the r-f carrier pulses can be varied by the adjustment of potentiometer R2.

Under actual operating conditions with both the r-f carrier and the audio modulation applied, upper and lower sidebands are produced through the beating of the r-f carrier and the audio modulating signal in the non-linearly operated modulator tubes. It is important to note that the sideband frequencies, unlike the carrier frequency, are not canceled in the output tank circuit. This is because the output tank circuit is sharply tuned to the carrier frequency and the side-band frequencies will deviate sufficiently from the carrier frequency for the output tank circuit to appear non-resonant to these frequencies. Hence no sideband energy will be stored in the tank circuit from one half cycle of r-f input to the next and cancellation of the sidebands will not occur.

Failure Analysis.

No Output. Failure of one of the modulator tubes is not likely to cause a no-output condition to exist. Failure of the power supply or a circuit component common to both branches of the balanced modulator is a much more likely cause of no output. Voltage checks of VI and V2 with a voltmeter would reveal a defective component that could be the cause of no output. Power supply voltages should be checked and adjusted if necessary. Any discrepancies found during voltage checks can be followed up, with the equipment deenergized, with resistance checks of associated circuit components to reverd the component at fault. Since both r-f carrier and modulation inputs are required to produce a sideband output, lack of either signal could be a cause of no output. Presence of these input signals can be readily determined with an oscilloscope. The r-f carrier should be present on the control grids of both tubes and should have sufficient amplitude to drive the tubes above cutoff. If the r-f carrier is not present on the grids of the modulator tubes, check for presence of the r-f carrier on the primary of T1. If no signal is present on the primary of T1 the fault likely lies in the stage, or stages, preceding the balanced modulator. If a signal is present on the primary of T1 but absent on the control grids of VI and V2 the fault likely lies in transformer T1. If the audio modulating signal is not present on the screen grids of the modulating tubes, check for presence of the modulation signal on the primary of T2. If modulation is present on the primary of T2 but absent on the screen grids of V1 and V2, transformer T2 is defective. If the modulation signal is absent at the primary of T2 the fault likely lies in the preceding stages.

Low Output. A common cause of low output is decreased emission of the modulator tubes. The power supply voltages should be checked and corrected if necessary. Voltage checks of V1 and V2 would reveal if a defective circuit component is the cause of low output. Should a discrepancy be found

during voltage checks a resistive analysis of circuit components would reveal the component at fault. Another possible cause of low output could be decreased amplitude r-f carrier input or decreased amplitude modulation input. The existance of this condition can be determined by observing with an oscilloscope the amplitude of the r-f carrier signal on the control grids, and the amplitude of the modulating signal on the screen grids of V1 and V2.

Distorted Output. Distortion of intelligence in SSB systems will occur if the transmitter and receiver are not exactly on frequency. Distortion in SSB transmitter is usually caused by improper operation of the linear power amplifier or by operating any stage in the transmitter beyond its capabilities. If the balanced modulator is determined to be the cause of distortion a possible cause could be defective tubes. Check the power supply voltages with a voltmeter. If the tubes are good and the power supply voltages are correct, a resistive analysis of circuit components with the equipment deenergized would reveal a component failure that could be a cause of distorted output. Do not overlook the possibility that the audio modulation is distorted before it reaches the balanced modulator. The existance of this condition can be determined by observing, with an oscilloscope, the quality of the modulation signal on the screen grids of V1 and V2 with an audio tone from an audio signal generator applied to the transmitter.

BALANCED (PARALLEL CARRIER INPUT) MODULATOR (ELECTRON TUBE)

Application

The parallel carrier input balanced modulator is used to produce amplitude modulated upper and lower sideband frequencies for use in suppressed-carrier, single sideband transmitters, commonly abbreviated as SSSC.

Characteristics.

Utilizes nonlinear characteristics of electron tubes to produce sidebands.

Produces amplitude modulated upper and lower sidebands while suppressing the r-f carrier.

No output is produced unless both r-f carrier and modulation are present.

Modulation is accomplished at low power levels, therefore, no large modulator power supply and transformers are needed.

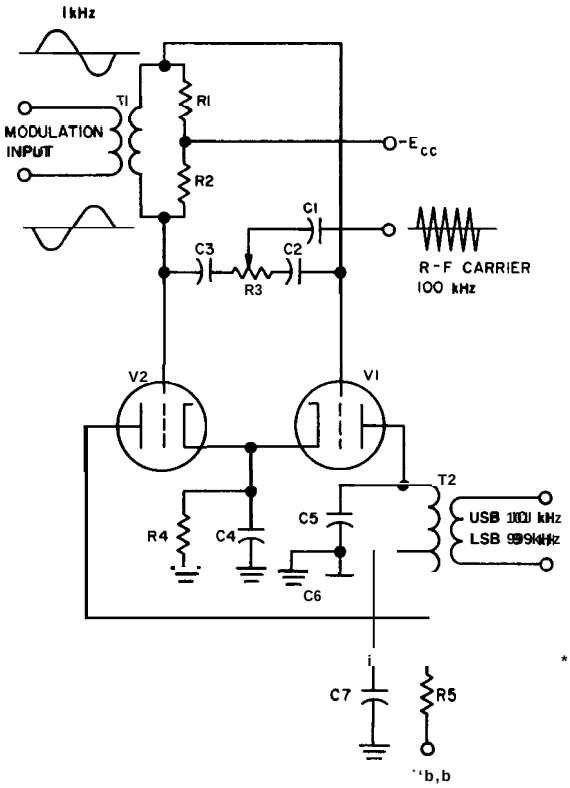
Uses push-pull output and parallel input to cancel out the carrier.

Can provide conversion gain, i.e., sideband output greater than modulation input.

Circuit Analysis.

General. The parallel carrier-input balanced modulator produces amplitude modulated sidebands and suppresses the r-f carrier. This is achieved by coupling the r-f carrier, in-phase, to the grids of two tubes whose output is connected in push pull (out-of-phase). The r-f carrier signal voltage is kept 8 to 10 times as large as the modulating voltage to keep distortion to a minimum. In push pull amplifiers an input signal inserted in-phase on the grids (in parallel) will cancel in the output. The modulating signal is applied in series to the grids of the balanced modulator through a transformer. This transformer is effectively centertapped by a resistance network connected across the secondary winding for bias insertion. The center tap arrangement produces a 180-degree phase different between the audio modulation signal voltages on the grids of the modulating tubes. When both r-f carrier and modulating audio signal are applied to the grids of the balanced modulators, sum and difference frequencies (side-band) are produced by the modulating frequencies beating against the carrier, since any amplitude modulation process is essentially the same as heterodyning. As in a frequency converter, any modulation which exists on one of the mixing frequencies is linearly transposed to the resultant sum and difference frequencies. The plate circuit contains the upper and lower sidebands, which are the sum and difference frequencies, respectively, the r-f carrier, and the audio modulation. The carrier is cancelled out by push-pull action in the output transformer and the output transformer also presents a low impedance to the audio modulating signal. Therefore, the original modulating signal is not developed in the output. The generated sidebands are out-of-phase with each other at the plates of the tubes, since the modulating signal is out-of-phase at the grids. These out of phase signals add in the output rather than cancel as in-phase signals do, and they are inductively coupled to the following stages through the output transformer. Tetrodes and pentodes may be used with equal or greater effectiveness, their use being determined by system requirements.

Circuit Operation. The accompanying diagram illustrates a typical parallel carrier-input balanced modulator.



Parallel Carrier Input Balanced Modulator

Transformer T1 couples the audio modulation to the grids of balanced modulator tubes VI and V2. Resistors R1 and R2 provide grid bias and an effective centertap for T1. Capacitor Cl couples the r-f carrier from the carrier oscillator to carrier balance potentiometer R3. Carrier balance potentiometer R3 is adjusted to vary the relative amplitude of the carrier signrd on the grids of V1 and V2, so that the circuit may be completely balanced and the carrier suppressed in the output. Capacitors C2 and C3 couple the r-f carrier from balance potentiometer R3 to the grids of V1 and V2. Modulator tubes V1 and V2 are the nonlinear devices used for developing the modulation. Resistor R4, which is bypassed by C4, provides cathode bias for both tubes. Center-tapped plate transformer T2 provides a push-pull plate load for the modulators. Capacitors C5 and C6 bypass any higher order harmonics that might be generated in the plate circuit to ground. Resistor R5 is a plate voltage dropping resistor, while C7 bypasses any unwanted signals to ground, and places the center tape of T2 at ground potential.

The operation of the parallel carrier-input balanced modulator can be more easily examined by first applying only the r-f carrier. The r-f carrier generated in the carrier oscillator is coupled through Cl to the slider of variable resistor R3. Thus the carrier signal appears at both ends of R3 and is coupled through **C2** and **C3** to the grids of V1 and V2. The carrier signal voltage is inserted in-phase on the grids of V1 and V2, and the amplitude, at each tube is controlled by adjusting R3. Assuming that the r-f input is operating on the positive half-cycle, both plates draw an increasing plate current (the grid input is in-phase), and the voltage drop across each half of the transformer winding is negative going, so that equal and opposing voltages are developed in the transformer primary which cancel, and no output is obtained from the secondary. Likewise, on the negative half-cycle less plate current is drawn and the drop across the transformer is positive going, and equal and opposing voltages are developed in the primary and also cancel out, so no carrier again is produced. If the circuit is properly balanced by the adjustment of R3, these opposing signals are equal in amplitude and the carrier is effectively suppressed.

The amount of carrier suppression obtained depends upon the degree of balance between the two legs of the balanced modulator circuit. When two tubes of the same type are used in a balanced modulator circuit (without any balancing adjustment), carrier suppression of 10 to 15 dB generally results. Since carrier suppression of at least 35 dB is usually required in suppressed-carrier, single-sideband systems, it can be seen that some type of fine balancing adjustment is required. In this circuit R3 is used for carrier brdancing, but other methods (such as varying the bias or plate voltage on the modulator tubes) may be encountered in other circuits.

When audio modulation also is applied, a different situation arises. The audio modulation is applied through transformer T1. Since the secondary of T1 is effectively center tapped by resistors RI and R2 modulation signal voltages will be developed across each half of the winding which are out of phase with each other. This modulating signal is applied directly

to the grids of V1 and V2. Capacitors C2 and C3 are of such a value that they present a high impedance to audio frequencies and prevent any audio modulation from crossing over, from one grid to the other, and canceling each other out. The audio modulating signal modulates the r-f carrier and produces upper and lower sidebands in the plate circuit of the modulator tubes. These sidebands are produced by mixing the r-f carrier frequency and the modulation signal across a nonlinear device. To illustrate the operation of the parallel carrier-input balanced modulator with both r-f carrier and modulating signal applied assume that the first half cycle of the modulating voltage applied to the grid of V1 is positive and the first half cycle of the modulating signal applied to the grid of V2 is negative. It can readily be seen that conduction of V1 will increase with negative going sideband frequencies being generated across the top half of the output transformer. At the same time, the negative half cycle of audio modulation applied to the grid of V2 decreases conduction of V2, causing positive going sideband frequencies to be developed across the bottom half of the output transformer. Push pull action thus occurs and the sideband frequencies add to each other, causing both upper and lower sidebands to be developed and inductively coupled to the secondary of T2. The r-f carrier is suppressed, as explained earlier, and the original audio modulating signal is not developed due to the low reactance of T2 to the basic audio modulation frequencies. Therefore, only the upper and lower amplitude modulated sidebands are produced by the balanced modulator.

Failure Analysis.

No Output. Since both modulator tubes perform the same function it is unlikely that failure of one tube or associated circuit would cause a no-output condition. A much more likely cause of no output would be failure of something common to both tubes such as the power supply, the cathode resistor or the circuits associated with the r-f carrier input or modulation input. Voltage checks on V1 and V2 with a voltmeter would reveal a defective component that could cause no output. Should all the voltages check good the cause of no output could be the lack of either r-f carrier or modulating signal. This can be easily checked with an oscilloscope. Check the grids for presence of both signals with the carrier oscillator operating and modulation applied. If the modulating signal is not present on the grids, check for presence of the modulation signal on the primary of T1. This will determine whether T1 or the preceding audio stages are at fault. Should the r-f carrier be missing check the output of the carrier oscillator. If there is an output from the carrier oscillator, signal trace the components linking the carrier oscillator to the grids of the modulator tubes. Should all the conditions necessary for proper operation by met, i.e. proper voltages on the tube elements, proper carrier and modulation inputs, and there is still no output, transformer T2 could be defective. Check all windings of T2 for proper resistance and check all windings for leakage to ground.

Low Output. Low output can be caused by a defective tube or tubes, improper power supply voltages or by a defective circuit component. Low output could also be caused by decreased amplitude of the r-f carrier signal voltage or possibly by decreased amplitude of the modulating signal. Check the power supply voltages. If the power supply voltages are good, voltage checks of the tube elements would reveal whether or not a defective circuit component was the cause of low output. Should these voltage checks reveal a discrepancy, resistance checks, with the circuit deenergized, would reveal the component at fault. The possibility of decreased amplitude r-f carrier signal or modulating signal input can be checked by observing these signals on an oscilloscope. If all the conditions necessary for proper operation are met, i.e., good tubes, proper power supply voltages, and good circuit components, poor operation could be the result of a defective output transformer. Since the resistance of the output transformers windings are relatively low a shorted winding could easily be overlooked when making resistance checks. Check the resistance of each half of the primary winding, each half should be equal, and check the resistance of the secondary winding. With the centertap disconnected check the windings for leakage to ground.

Distorted Output. It should be noted that distortion of intelligence will occur if the single sideband transmitter and receiver are not exactly on frequency. Distortion in single sideband transmitters is frequently caused by improper operation of the linear amplifiers, or by operating any stage beyond its capabilities. If system distortion is determined to be caused by the brdanced modulator a likely cause could be improper voltages applied to the tubes, or defective tube or tubes, or failure of some circuit

component. Check the power supply voltages, if they are good, voltage checks of the tube elements would indicate whether or not a defective circuit component is the cause of distorted output. Incorrect voltages found to be present on the tube elements can be traced to the component at fault with resistance checks of associated circuit components. The possibility of a distorted audio input or possibly a distorted r-f carrier should not be overlooked. The existance of these conditions can be determined by observing these signals on an oscilloscope.

BALANCED (PARALLEL CARRIER INPUT) MO OULATOR (SEMICONDUCTOR)

Application.

The semiconductor basic balanced modulator is used to produce amplitude modulated upper and lower sideband frequencies for use in single sideband transmitters.

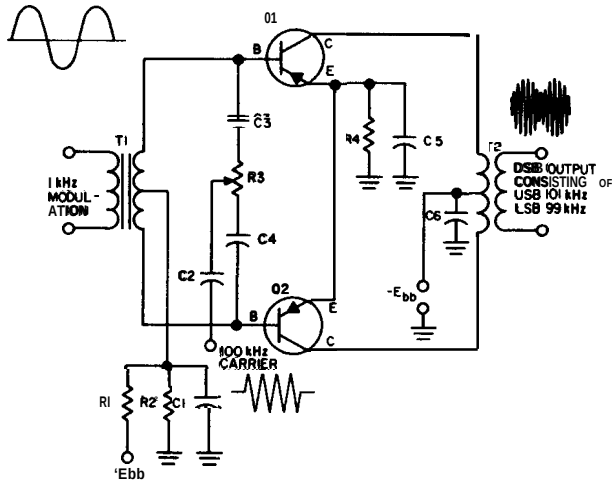
Characteristics.

Same characteristics as electron tube version, except it uses semiconductors instead of electron tubes.

Circuit Analysis.

General. The basic balanced modulator produces amplitude modulated upper and lower sidebands and suppresses the r-f carrier. This is achieved by coupling the r-f carrier, in-phase, to the bases of two transistors whose output is connected in push-pull, (out of phase). The r-f carrier is kept 8 to 10 times as large as the modulating voltage to keep distortion to a minimum. In push-pull amplifiers an input signal must be out of phase to produce an output since any in-phase inputs cancel in the output. The modulating signal is applied to the base of each transistor in push-pull (180 degrees out of phase) through a center tapped transformer. When both r-f carrier and audio modulating signals are applied simultaneously to the bases of the balanced modulators, sum and difference frequencies (sidebands) are produced by the modulating frequencies beating against the carrier, since any amplitude modulation process is essentially the same as heterodyning. As in a frequency converter, any modulation which exists on one of the mixing frequencies is linearly transposed to the resultant sum and difference frequencies. The collector circuit contains the upper and lower sidebands which are the sum and difference frequencies, respectively, the r-f carrier, and the audio modulation. The carrier is cancelled out by push-pull action in the output transformer, and the output transformer also presents a low impedance to the audio modulating signal. Therefore, the original modulating signal also is not developed in the output. The generated sidebands are out-of-phase with each other at the collectors of the transistors, since the modulating signal is out of phase at the bases. These out-of-phase signals add in the output transformer rather than cancel as in-phase signals do, and they are inductively coupled to the following stages through the output transformer.

Circuit Operation. The accompanying diagram illustrates a basic semiconductor brdanced modulator.



8esic 8alanced Modulator (Common Emitter).

Audio transformer T1 couples the audio modulation to the bases of transistors Q1 and Q2. Resistors R1 and R2 form a base bias voltage divider which provides the proper bias for the transistor. Capacitor Cl places the center tap of T1 at a-f ground potential to supply an out-of-phase (push-pull) input. Capacitor C2 couples the r-f carrier from the carrier oscillator to the slider of carrier balance potentiometer R3. Potentiometer R3 can be adjusted, to vary the relative amplitude of the r-f carrier signal voltage on the bases of Q1 and Q2, to provide a carrier balance control, so that the r-f carrier can be completely suppressed in the output. Capacitors C3 and C4 couple the r-f carrier from balance potentiometer R3

to the bases of Q1 and Q2, and also act as dc bias blocking capacitors to prevent base shorting. Transistors Q1 and Q2 are the nonlinear devices used for generating the sidebands. Resistor R4, which is bypassed by C5 is a conventional emitter stabilization resistor intended to prevent changes in temperature from altering transistor characteristics. Center-tapped output transformer T2 provides a push-pull collector load for the modulators. Capacitor C6 places the center-tap of the primary of T2 at r-f ground potential.

To more easily examine the operation of the basic balanced modulator, assume first that only the r-f carrier is applied. The r-f carrier generated in the carrier oscillator is coupled through C2 to the slider of potentiometer R3. Hence, the carrier signal appears at both ends of R3 and is coupled through capacitors C3 and C4 to the bases of Q1 and Q2, respectively. The carrier signal voltage is in-phase on the bases of Q1 and Q2 (they are parallel connected) and the amplitude of the carrier signal at the base of each transistor is controlled by the adjustment of R3. Assuming that the r-f input is operating on the negative half cycle, the negative forward base bias is increased and both collectors draw an increasing amount of collector current, (the base input is in phase). Thus, the voltage drop produced across each half of output transformer T2 is positive-going, and equal but opposing voltages are developed in each half of the transformer primary by current flowing in opposite directions which cancel, so that no output is obtained from the secondary winding. Likewise, on the positive half cycle of r-f input the forward bias is reduced and less collector current is drawn. Thus, the drop across transformer T2 primary windings is negative going and equal and opposing voltages are developed in the primary because the current flow through each primary is opposite. These voltages also cancel out (since they are out-of-phase) so no carrier again is developed in the output. If the circuit is properly balanced by the adjustment of R3, the opposing signals are exactly equal in amplitude and the carrier is completely suppressed. Thus, it can be seen that an output is not produced with only an r-f carrier input applied.

When audio modulation and the r-f carrier are both applied simultaneously, a different situation arises. The audio modulation is applied through transformer T1. Since the secondary of T1 is effectively center-tapped by Cl, R2, and the bias supply, modulation signal voltages are developed across each half of the secondary winding of T1 which are out of phase with each other. The out-of-phase modulating signals are applied directly to the base of each transistor. Capacitors C3 and C4 are of such a value that they present a high reactive impedance to audio frequencies and thus prevent any audio modulation "from feeding back from one base to the other and canceling each other out. Meanwhile, the audio modulating signal modulates the inserted r-f carrier and produces upper and lower sidebands in the collector circuit of transistors Q1 and Q2. These sidebands are produced by mixing the r-f carrier frequency and the modulation signal together across a nonlinear device. (Detailed information concerning frequency conversion, (mixing or heterodyning), can be found in the introduction to the Mixers and Heterodynes Section of this Handbook. To better illustrate the operation of the basic balanced modulator with both r-f carrier and modulation applied, assume that the first half cycle of the modulating signal voltage applied to the base of Ql is positive and the first half cycle of the modulating signal applied to the base of Q2 is negative.

The conduction of Q1 decreases as a result of the positive half cycle of modulation input opposing the forward bias of the emitter base junction. This results in negative going sideband frequencies being developed across the top half of the output transformer. At the same instant the conduction of Q2 increases as a result of the negative going half cycle of modulation input aiding the forward bias of the emitter base junction, and causing positive-going sideband voltages to be developed across the bottom half of the output transformer T2. Push-pull action occurs and the side band frequency signal voltages add to each other causing both upper and lower sidebands to be developed and inductively coupled to the secondary of T2. The r-f carrier is suppressed, as explained earlier, and the original audio modulating signal is not developed due to the low reactance of T2 to audio frequencies. Therefore, only the upper and lower sidebands are produced by the balanced modulator.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of the standard 20,000 ohms-per-volt meter. Be careful also be observe proper polarity when

checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No **Output.** Since each leg of the basic balanced modulator performs essentially the same function, failure of one leg of the balanced modulator is not likely to cause a no-output condition to exist, unless the failure occurred in a manner that would affect the power supply such as a shorted transistor or a shorted C6. Failure of the power supply itself is a likely cause of no output. If the power supply measures normal when checked separately and no collector voltage appears on Q1 or Q2, check T2 primary and C6 for a short or ground. An open or shorted R1 or R2 or a shorted Cl would remove the bias from transistors Q1 and Q2 and could also cause a no-output condition to exist. Since R4 is a common emitter resistor for both transistors a no-output condition would also result if R4 opened. Check for proper value with an ohmmeter. Since any balanced modulator produces an output only when both the r-f carrier and the modulating signal are present, absence of either of these signals on the base of each transistor would cause the balanced modulator to be inoperative. Presence of the input signals can readily be determined by observing, with an oscilloscope, the waveform present at these points with the carrier oscillator operating and with modulation applied to the transmitter. Absence of the audio modulation on the bases of the transistors could be caused by a defective audio input transformer, T1, or by failure of the audio stages preceding the balanced modulator. Presence of audio modulation on the primary of T1 indicates that the preceding audio stages are functioning properly. Should the modulation be present on the primary of T1 but absent on the bases of the transistors, T1 is most likely defective (check the primary and secondary for continuity with an ohmmeter). Presence of the r-f carrier at the input to coupling capacitor C2 indicates that the carrier oscillator is operating. In the event that the r-f carrier is present at the input of C2 but is absent on the bases the transistors, capacitor C2 or potentiometer R3 may be open. Check R3 for proper vahre and C2 for value with an in-circuit capacity meter. Failure of C3 or C4 would only disable one leg of the balanced modulator and an output would still result. Signal tracing from C2 to the bases of the transistors will reveal which component is at fault. Another possible cause of no output is a defect in output transformer T2. Continuity checks of the transformer windings and checks for leakage between the primary and secondary and between each winding and ground w-ill reveal whether or not a defect exists in the transformer.

Low Output. A low output condition could be caused by a defective transistor, a faulty circuit component, a defective power supply, or by low amplitude r-f carrier or modulation input. Voltage checks should be made of the power supply voltage and of transistor elements to determine whether or not a defective power supply or a faulty component is the cause of low output. A change in value of resistors R1 or R2 or leakage in capacitor Cl would change the base bias of transistors Q1 and Q2 and could cause a low output condition. If C5 opens the resulting degeneration would lower the gain of the modulator circuits and could cause low output to result. Likewise, an increase in value of emitter stabilization resistor R4 would alter the operating bias of the transistors and could cause a decreased output. Check the value of R4 with an ohmmeter. The amplitude of the inputs to the balanced modulator can be checked by observing with an oscilloscope the waveform present at the base of each transistor. If either input signal is low in amplitude, the cause can be determined by signal tracing from the bases of the transistors to the stages preceding the balanced modulator. If either C3 or C4 opens, one leg of the balanced modulator would be inoperative and low output would result. Do not overlook the possibility that a defective output transformer can also cause low output. Check the resistance to ground with an ohmmeter.

Distorted Output. Distortion of intelligence will result in SSB systems if the receiver and transmitter are not exactly on frequency. Distortion in SSB transmitters is usually the result of improper operation of the linear power amplifier or of operating any stage beyond its capabilities. Should the distortion be determined to be caused by the balanced modulator, check the modulation level to make sure that the audio circuits are not overdriving the balanced modulator. If the modulation level is correct, distortion could still be caused by a defective transistor. If the transistors are determined to be good and distortion persists, voltage checks of transistor elements with a high resistance voltmeter would reveal whether or not a defective component or a defective power supply is the cause of distortion. Low amplitude r-f

carrier input could also cause distortion. The r-f carrier input should be 8 to 10 times the amplitude of the modulating signal.

BALANCED COMPLEMENTARY SYMMETRY MODULATOR (SEMICONDUCTOR)

Application.

The balanced complementary symmetry modulator is used in single sideband transmitters to produce amplitude modulated upper and lower sidebands.

Characteristics.

Produces amplitude modulated upper and lower sidebands while suppressing the r-f carrier.

Utilizes a PNP and an NPN transistor connected in a complementary symmetry circuit.

Requires two collector power supplies (one positive and one negative supply).

Static current does not flow through the output transformer.

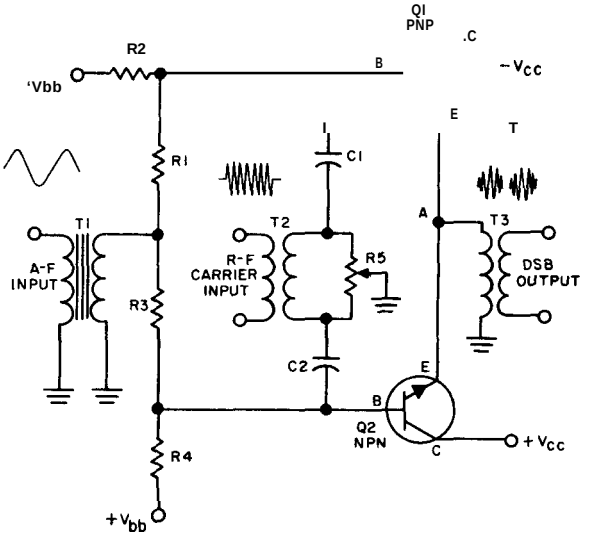
Utilizes the common collector configuration.

Requires two separate bias supplies.

Circuit Analysis.

General. The balanced complementary symmetry modulator produces amplitude modulated upper and lower side-bands and suppresses or cancels the r-f carrier, which is used to generate the sidebands. Basically this is achieved by coupling the audio modulation in parallel (in-phase) to the bases of two opposite polarity (PNP and NPN) transistors connected in a complementary symmetry configuration, and simultaneously coupling the r-f carrier in push pull (180° out-of-phase) to the bases of the transistors. It should be noted that, while the transistors are of opposite polarities, they have the same-operational characteristics. The audio modulation and the r-f carrier beat together in the nonlinear resistance of the transistors, and sum and difference (sideband) frequencies are produced. The sideband frequencies are developed across the output transformer and are inductively coupled to the following stages. Circuit elements are arranged so that the r-f carrier and the original audio modulating signal do not appear in the output. For minimum distortion the r-f carrier is maintained at a level 8 to 10 times greater than the audio modulating signal.

Circuit Operation. The accompanying diagram illustrates a balanced complementary symmetry modulator.



Balanced Complementary Symmetry Modulator (Common Collector Configuration)

Audio transformer T1 couples the audio modulation from the preceding stages to the bases of Q1 and Q2 through bias resistors RI and R3. RI and R2 form a voltage divider network to bias transistor Q1 and resistors R3 and R4 form a voltage divider to bias transistor Q2. Transformer T2 couples the r-f carrier from the carrier oscillator to both sides of carrier balance potentiometer R5. Carrier balance potentiometer R5, which has its slider grounded, effectively centertaps the secondary of carrier input tramformer T2, causing 180° out-of-phase r-f carrier signal voltages to be present at the top and bottom of T2. Coupling capacitors Cl and C2 couple the r-f carrier from transformer T2 to the base of each transistor and prevent a dc path from being formed from the base of each transistor to ground through carrier balance potentiometer R5. Transistors Q1 and Q2 are the nonlinear devices used to generate the sidebands, and transformer T3 serves as the output load for the balanced complementary symmetry modulator.

Since both transistors have the same operational characteristics both transistors conduct equally with no signal input, and thus both transistors have equal

equivalent emitter-collector resistance. Thus, it can be seen that a balanced condition exists between Q1 and Q2, and the voltage drop across Q1 is equal to the voltage drop across Q2. Since the absolute value of voltage between each power supply and ground is the same and the voltage drop across the transistors is equal, there is no voltage between point A in the figure and ground, and thus no current flows through output transformer T3, and no output is produced.

When a push-pull, (180° out-of-phase) input a signal is applied, in this case the r-f carrier, the following takes place. During the period of the input cycle when the base of Q1 is driven positive and the base of Q2 is driven negative conduction of both Q1 and Q2 decreases. This is due to a reduction in forward bias applied to each transistor (PNP transistor Q1 normally has its base biased more negative than its emitter and NPN transistor Q2 normally has it base biased more positive than its emitter). This decrease in conduction of Q1 and Q2 is in effect an increase in equivalent emitter-collector resistance and, since both transistors have the same operational characteristics, both transistors decrease conduction in equal amounts. Although the equivalent emitter-collector resistance of both transistors increases, it increases equally in both transistors and, therefore, the voltage drop across Q1 remains equal to the voltage drop across Q2. Once again the balanced condition between Q1 and Q2 is maintained and no output is produced, since no current flows through output transformer T3. During the next half-cycle of r-f carrier input a negative-going half-cycle of r-f is coupled from transformer T2 to the base of Q1 and increases the forward bias on Q1 causing the conduction of Q1 to increase. Simultaneously, a positive half-cycle of r-f is applied to the base of Q2, where it again increases the forward bias on Q2, causing the conduction of Q2 to increase. Both transistors increase conduction at the same rate, and the equivalent emitter-collector resistance of both transistors decreases equally. Again the voltage drop across each transistor is equal and a balanced state is maintained. Hence no output is produced. In this manner the r-f can-ier is effectively suppressed in the complementary symmetry balanced modulator. In actual practice, the slight differences in characteristic found between evenly matched pairs of transistors necessitates the use of some external method of balancing the circuit. The complementary symmetry balanced modulator achieves precise carrier balance by making it possible to vary the amplitude of the r-f carrier coupled to the base of Q1 with respect to the amplitude of the r-f carrier coupled to the base of Q2. This is achieved by effectively center-tapping the secondary of r-f carrier input transformer T2 by connecting both sides of potentiometer R5 across the secondary of T2. Varying the position of the grounded slider of R5 has the same effect as varying the position of the center-tap on a center-tapped transformer.

When audio modulation in addition to the r-f carrier is applied simultaneously to the balanced modulator, upper and lower sidebands are generated as the result of the r-f carrier frequency and the audio modulating frequency beating together in the non-linearly operated transistors. Four basic frequencies are present in the emitter circuit of the transistors. These frequencies are the original r-f carrier frequency, the original audio modulating frequency and the sum and difference frequencies (sidebands) resulting from heterodyning action. However, only the sideband frequencies are present in the output.

The audio modulation is applied to the base of each transistor in parallel (in phase) through transformer T1. During the positive half-cycle of modulation input the forward bias on Q1 is opposed by the modulating signal (Ql is a PNP transistor) and conduction of Q1 decreases. At the same time, the positive half-cycle of modulating signal aids the forward bias on Q2 (Q2 is an NPN transistor) and conduction of Q2 increases. The balance between Q1 and Q2 is now upset since the equivalent emitter-collector resistance of Q1 increased causing an increased voltage drop across Ql, while the equivalent emitter collector resistance of Q2 decreased causing a decreased voltage drop across Q2. Point A in the figure is no longer at ground potential but at some positive voltage and current flows through output transformer T3 causing an output to be produced. The r-f carrier component of emitter current is cancelled as explained previously. The sideband component of emitter current and the original audio modulation component of emitter current flows through the primary of output transformer T3, but the output transformer presents a very low impedance to audio frequencies, therefore, audio frequency voltage is not developed across the primary of T3. Only the upper and lower sideband signal voltage is developed across the primary of output transformer T3 and is inductively coupled to the following stages. Overall circuit operation is the same

for the negative half cycle of audio modulation input. That is, during the negative half-cycle of modulation input the forward bias on Ql is increased and conduction of Q1 increases. At the same time, the negative half-cycle of modulation signal decreases the forward bias on Q2 (an NPN transistor) and decreases conduction of Q2. The balance between Q1 and Q2 is now upset because the equivalent emitter-collector resistance of Ql decreased, causing a decreased voltage' drop across Ql, while the equivalent resistance of Q2 increased causing an increased voltage drop across Q2. Point A in the figure, is therefore, no longer at ground potential, but is at some negative voltage so that current flows through output transformer T3, causing an output to be produced. The r-f carrier component of emitter current is cancelled as explained previously. Although both the sideband component of emitter current and the original modulation component of emitter current both flow in the primary of T3, the low impedance offered to the audio modulation is insufficient to develop an audio frequency voltage across it. Therefore, only the upper and lower sidebands are inductively coupled to produce an output in the secondary of T3.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low vrdues of multiplier resistance employed on the low voltage range of the standard 20,000 ohms-per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No **Output.** Since transistor Q1 and its associated circuit performs essentially the same function as transistor Q2 and its associated circuit components, failure of either transistor or associated circuit components is not likely to cause a no-output condition to exist. Likewise, failure of either the positive or negative power supply is not likely to cause a no-output condition to exist, since each power supply serves only one branch of the modulator. Failure of a component, such as the audio modulation input transformer T1, the r-f carrier input transformer T2, or output transformer T3 all of which serve both branches of the modulator could be a cause of a no-output condition. Continuity checks of the transformer windings and resistance checks for shorts to ground or excessive leakage between windings will reveal a defect in either Tl, T2, or T3 which could cause a no-output condition to exist. Failure of T1 or T2 could cause a no-output condition to exist by failing to couple either the audio modulation or the r-f carrier to the balanced modulator. Likewise, failure of the source of the signals (modulating signal or r-f carrier) would also create a no-output condition. To determine whether or not the signals are reaching the brdanced modulator observe, with an oscilloscope, the waveform present on the primary of audio input transformer Tl, and the waveform present on the primary of r-f carrier input transformer T2. Absence of either of these signals results in a no-output condition and indicates that the fault lies in the stage, or stages preceding the modulator.

Low Output. Failure of almost any component in the complementary symmetry balanced modulator could result in a decreased output. Failure of, or improper output from either power supply could result in low output and the power supplies should be checked and repaired or adjusted, if necessary, before any component substitutions are attempted. Deterioration of either of the transistors could also be a cause of decreased output. A low output condition could also be due to improper base bias applied to either transistor. Check the voltage present on the base of Q1 and Q2 with a vacuum tube voltmeter. If a discrepancy is found the most likely cause is a change in value of voltage divider resistors RI and R2 (for the base of Ql) or R3 and R4 (for the base of Q2). Improper base bias could also be caused by a short in coupling capacitor C 1 or C2. If Cl or C2 opened, a low output condition would result since the r-f carrier would be unable to reach the base of either Q1 or Q2. A partial failure of transformers T1 or T2 could result in decreased amplitude audio modulation, or decreased amplitude r-f carrier, reaching the bases of the transistors. This condition would likely result in decreased output. Careful resistance and leakage checks, with an ohmmeter, would usually indicate a partial failure that could be the cause of low output. Likewise, decreased amplitude r-f carrier or audio modulation before it reaches the modulator could be the cause of low output. The existence of this condition can be determined by observing, with an oscilloscope, the amplitude of the input signals on the primary of the respective input transformer. Another possible cause of low output could be due to a defect in output transformer T3. Resistance and leakage

checks of the transformer windings should indicate a possible defect.

Distorted Output. Distortion of intelligence will occur in single sideband systems when the transmitter and receiver are not exactly on frequency. Distortion in single sideband transmitters is usually the result of improper operation of the linear power amplifier, or of operating any stage beyond its rated capabilities. If system distortion is determined to be caused by the modulator, almost any component which could cause low output can rdso be suspected of causing a distorted output. The power supply voltages should be checked first and adjusted, if necessary. A check of base bias voltage of both transistors would reveal if a fault exists in voltage divider resistors RI, R2, R3, and R4. An open or shorted carrier balance potentiometer R5 could also cause a distorted output to result. Since the r-f carrier input amplitude should, for good fidelity, be 8 to 10 times the amplitude of the audio modulating signal, a decrease in amplitude of the r-f carrier or excessive audio input could be the cause of distorted output. The amplitude of the r-f carrier input and the amplitude of the audio modulation input can be easily checked by observing, with an oscilloscope, the waveform present at the primary of the respective input transformer. Do not overlook the possibility that the audio modulating signal is distorted before it reaches the modulator.

BALANCED BRIDGE MODULATOR (ELECTRON TUBE)

Application.

The balanced bridge modulator is used in single sideband generators to produce amplitude modulated upper and lower sidebands while suppressing the r-f carrier.

Characteristics.

Produces upper and lower sidebands while suppressing the r-f carrier.

Utilizes four diodes connected in a bridge configuration.

Produces sidebands by heterodyning action produced by nonlinear diodes.

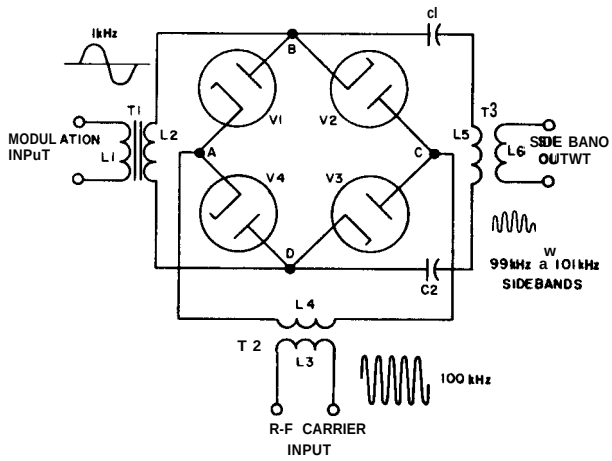
Requires both an r-f carrier and modulation applied simultaneously to produce an output.

Circuit Analysis.

General. The purpose of the balanced bridge balanced modulator is to produce amplitude modulated upper and lower sidebands and suppress the r-f carrier. Basically this is achieved in the balanced bridge modulator by arranging the circuit elements so that a balanced condition exists between the two legs of the bridge when only an r-f carrier is applied. This balanced condition will prevent an r-f output from being produced. Modulation is applied so that the bridge becomes unbalanced, that is, more current flows through one leg than the other. This causes current to flow through the output transformer, and an output is produced. The current flowing through the output transformer is the upper and lower sidebands generated by the heterodyning of the r-f carrier and modulating signal within the non-linear diodes.

Carrier suppression is achieved because the current through one leg represents the carrier and sideband currents plus the modulating signal current, while current through the other leg consists of only the carrier current. The overall effect is to cancel the r-f carrier currents. The audio frequency component is blocked from the output by capacitors whose reactance is high to audio frequencies. Only the sidebands are present in the output.

Circuit Operation. The accompanying diagram illustrates a typical balanced bridge modulator utilizing electron tube diodes.

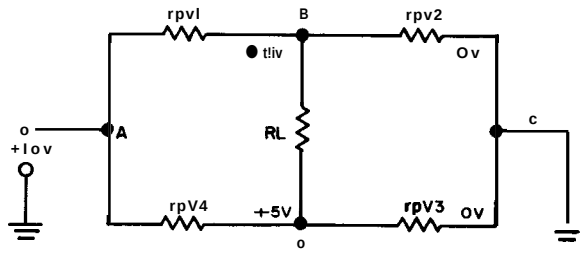


Balanced Bridge Modulator

Transformer T1 couples the modulation signal to the balanced bridge, and Transformer T2 couples the r-f carrier from the carrier oscillator to the balanced bridge. Diodes Vl, V2, V3, and V4, form the balanced bridge. Capacitors Cl and C2 block audio frequencies, thereby preventing the primary of T3 from shunting the secondary of T2. This is necessary since T3 is an r-f transformer and would present a very low impedance to audio frequencies. Transformer T3 serves as an output transformer. Designations at points A, B, C, and D are used only to illustrate circuit operation.

To more easily analyze the operation of the balanced bridge modulator, assume first that only the r-f carrier is applied. Assume that during the first half-cycle of r-f, point A is positive with respect to point C. This back biases the diodes and no current flows, hence no output results, since the bridge appears as an open circuit.

When the negative half-cycle appears point A becomes negative with respect to point C. This forward biases the diodes and current flows from point A through V1 and V2 to point C. An equal current will flow from point A through V4 and V3 to point C. When the current through leg V1, V2 is equal to the current through leg V4, V3, a state of balance exists and no current will flow through winding L5 of the output transformer, T3. The following illustration shows the equivalent circuit of the bridge in a balanced state.



Equivalent Circuit of Balanced Bridge Modulator With Only r-f Carrier Applied

The resistances represent the plate resistance of the diodes. Since the diodes are all of the same type and have the same characteristics, their conduction and plate resistances are the same. Resistor RL represents the load presented by the output transformer. There is no difference in potential between points B and D, and no current flows through the output transformer. Thus there is no output from the

balanced bridge modulator when only the r-f carrier is applied.

When only the modulation signal is applied, circuit operation is as follows. Assume first that a positive half-cycle of modulating voltage is applied; causing point B to be more positive than point D. It can be seen that the instantaneous potential created by the positive half-cycle of modulation signal will cause current to flow from point D through V3 to point C. Since the plate of V2 is connected to point C, current will not flow through V2. Current will, however, flow from point C through the secondary, L4, of T2 to point A, and through VI to point B. Current also will not flow through V4 since V4 like V2 is back-biased to current flow in this direction. The return path for current flow is through secondary L2, of T1. The primary, L5, of T3 does not effect the modulation signal since Cl and C2 offer a high impedance to the relatively low modulating frequency and prevent any shunting effects of L5 on L2. When the polarity of the modulating signal reverses, current flows from point B through V2 to point C. From point C current flows through the secondary, L4, of T2 to point a and then through V4 to point D. The return path is through the secondary, L2, of T1.

Under actual operating conditions with both r-f carrier and signal applied, the balance between the upper and lower legs of the bridge caused by the equal r-f carrier currents through each leg is disrupted by the modulating signal and a sideband output results.

To examine the circuit under actual operating conditions, consider first that r-f carrier current is flowing in equal amounts through the upper and lower legs, V1 and V2, and V4 and V3 respectively. When a positive going cycle of audio modulating signal is applied to T1, modulation signal current flows from point D through V3 to secondary L4 of T2 and to point A, and then through V1 to point B and back to secondary L2 of T1. Since the diode is a nonlinear device, mixing, or heterodyning, takes place between the r-f carrier currents and the modulating signal currents flowing through V1 and V3, and both upper and lower sidebands are produced. These sideband currents follow the same path as the modulating signal except that they flow through the output transformer T3 instead of the secondary L2 of T1. This is because transformer T1 offers a high impedance to the relatively high sideband frequencies. The sidebands are inductively coupled through T3 to the following stages. The overall effect is the same for a negative half-cycle of modulation except that sideband current flow is through V2 and V4 and the flow is through the output transformer in the opposite direction.

Failure Analysis.

No Output. A no-output condition could be caused by an open or shorted winding on any of the three transformers. With the equipment de-energized, a resistance check of the transformer windings will indicate an open or partially shorted winding. Failure of one of the diodes will not be likely to cause no-output, however if the diode filaments are connected in series an open fdament could cause the other diodes to be inoperative. A visual check with the equipment energized will reveal whether or not any fdament failures occur. Since a balanced modulator does not produce an output unless both r-f carrier and modulation signals are present, lack of either of these signals could be a cause of no output. Presence of these signals can be determined with an oscilloscope. To check for the presence of the modulating signal, observe the waveform present at points B and D. If the modulating signal is not present at these points check for modulating signal on L1 the primary of T1. If the modulating signal is present here, but is absent at points B and D the fault most likely lies in transformer T1. If there is no signal present on the primary of T1 the trouble is likely to be in the preceding stages. The presence of the r-f carrier can be determined in the same manner by observing the waveform present at points A and C. If the r-f carrier is not present at A and C the trouble can be localized by signal tracing with an oscilloscope through T2.

Low Output. A common cause of low output can be from decreased emission of one or more of the diodes. If any tubes are replaced it would be good procedure to check all the tubes on a tube checker and use only tubes which have approximately the same emission. This is particularly advisable if a high degree of balance is desired within the bridge of diodes. If the tubes are good, another possible cause of low output could be insufficient modulation input or insufficient r-f carrier input. This .condition can be checked by observing the amplitude of the waveforms present at the modulation inputs to the bridge, and at the r-f carrier inputs to the bridge. If one of the inputs are low the cause can be determined by signal tracing with an oscilloscope and noting any excessive

attenuation through the input transformers. If the amplitude of either signal is proper on the primary of the respective input transformer but low on the secondary, the transformer is defective. If the amplitude of the input signal is low on the primary of the respective input transformer the trouble likely lies in the stages preceding the balanced modulator.

Distorted Output. Distortion could be caused by a defective tube. Another cause of distortion might be a low r-f carrier input. The r-f carrier should be 8 to 10 times the amplitude of the modulating signal for distortion to be at a minimum. Do not overlook the possibility that the modulation input is distorted before it reaches the balanced modulator. Analysis of the modulation input with an oscilloscope would reveal if this condition existed.

PRODUCT MODULATOR (ELECTRON TUBE)

Application.

The product modulator is used in single-sideband transmitters to produce amplitude modulated upper and lower sidebands while suppressing the r-f carrier.

Characteristics.

The output of a product modulator is proportional to the product of the amplitudes of the input signals.

Does not require input transformers.

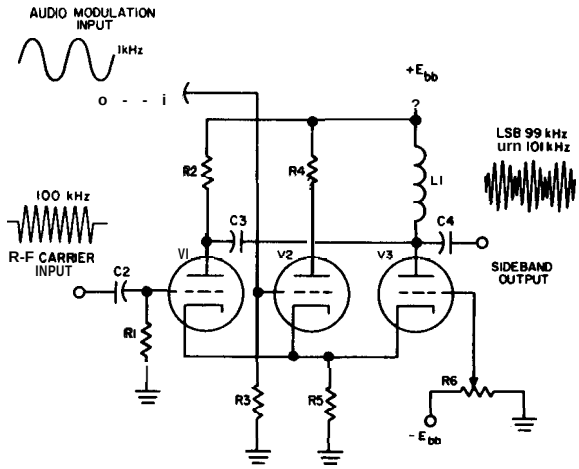
Utilizes three triodes with two of them operated as cathode followers.

Operates with class A bias.

Circuit Analysis.

'General. The product modulator in single sideband applications produces amplitude modulated upper and lower sidebands while suppressing, or canceling the r-f carrier. The single sideband product modulator utilizes three triodes with two of them operated as cathode followers. It is interesting to note that all three triodes have a common cathode resistor. The r-f carrier and the audio modulation are impressed on the grids of cathode followers, and r-f carrier and audio modulation are developed across the common cathode resistor. Since the modulator tube also uses the same cathode resistor, audio modulation and r-f carrier signal voltage appear on the cathode of the modulator tube. The r-f carrier and audio modulation beat together in the modulator tube and upper and lower sidebands are generated. Carrier suppression is achieved by coupling the r-f carrier signal developed at the plate of VI to the plate of V3. Since there is 180° phase difference between the r-f carrier signrd developed at the plate of V1 and at the plate of V3, the r-f carrier is effectively canceled. The product modulator when used in single sideband applications produces a sideband output only when both the r-f carrier and the audio modulator are applied simultaneously. The use of cathode followers eliminates the need for r-f carrier and audio modulation input transformers, since the cathode followers provide the necessary impedance match between the r-f carrier oscillator and the product modulator, and also between the audio amplifying circuits and the product modulator. The cathode followers also provide isolation between the r-f carrier oscillator and the audio circuits. By eliminating the carrier suppression provision the product modulator can also be used as a low distortion A-M modulator.

The following circuit diagram illustrates a typical product modulator for use in single sideband systems.



Product Moduletor

Circuit Operation. Capacitor Cl couples the audio modulation to the grid of V2 and capacitor **C2** couples the r-f carrier to the grid of V1. Resistor R1 and R3 are grid resistor for V1 and V2, respectively. Capacitor C3 couples the r-f carrier signal voltage from the plate of VI to the plate of V3 for the purpose of carrier cancellation. Resistor **R2** and R4

are plate dropping resistors and load for VI and V2, respectively. Resistor R5 is a common cathode resistor for all three tubes and potentiometer R6 provides a carrier balance control by varying the fixed bias on V3. VI and V2 which serve as cathode followers couple the r-f carrier input and the audio modulation input to the cathode of V3 which serves as the modulator tube. Inductor L1 is the plate load for V3, and C4 capacitively couples the generated sidebands to the following stages.

To more easily examine the operation of the single sideband product modulator, first assume that only the r-f carrier is applied to the modulator.

During the positive half cycle of r-f carrier input the conduction of VI increase and the voltage drop across plate resistor R2 increase causing a negative going r-f carrier pulse to appear at the plate of V1, and the voltage drop across common cathode resistor R5 increases, causing a positive going r-f carrier pulse to appear at the cathode of V1. Since the cathode of V3 is directly connected to the cathode of VI, the positive r-f pulse appears on the cathode of V3 and decreases the conductor of V3 causing a positive going r-f pulse to appear at the plate of V3. The negative r-f pulse on the plate of VI, is coupled through capacitor C3 to the plate of V3. If the r-f pukes from V1 are equal in amplitude to the r-f pulses from V3 there will be complete cancellation, and the r-f carrier will not appear in the output. The relative amplitude of these r-f pulses may be varied by the adjustment of R6 which varies the gain of V3. The positive half cycle of r-f input was used only to illustrate circuit operation. Circuit operation is the same for a negative half cycle of r-f input.

Thus with only the r-f carrier applied there will be no output from the product modulator.

When audio modulation is applied in addition to the r-f carrier upper and lower sidebands are generated. Audio modulation is coupled through coupling capacitor Cl to the grid of cathode follower V2. Audio frequency voltage are developed across common cathode resistor R5 and are directly coupled to the cathode of V3. The r-f carrier and audio modulation beat together in V3 and four basic frequencies appear in the plate circuit of V3. These frequencies are the original audio modulation, the original r-f carrier, and newly generated sum and difference frequencies. The r-f carrier frequency present in the plate circuit of V3 will be canceled by the 180° out-of-phase r-f carrier signal coupled to V3 from VI, as explained in the previous paragraph. The audio modulator present in the plate circuit of V3 is not developed in the output since inductor L1 presents a low impedance to audio frequencies. The generated sideband frequencies, referred to earlier as sum and difference frequencies are developed across inductor L1 and capacitively coupled through C4 to the following stages.

Failure Analysis.

No Output. Failure of almost any component could be a cause of no output in the product modulator. Check the power supply voltages to make certain that a defective power supply is not the cause of no-output. Voltage checks of tube elements will reveal if a component failure is the cause of no-output. Any discrepancies found during voltage checks can be followed up, with the equipment de-energized, by a resistive analysis of circuit components to reveal the component at fault. It should be noted that the product modulator will produce an output only when both r-f carrier and audio modulation are present on the cathode of V3. Presence of the r-f carrier and the audio modulation can be determined by observing the waveform with an oscilloscope on the cathode of V3 with modulation applied to the transmitter and the carrier oscillator operating. If either signal is missing the trouble can be localized by signal tracing from the signal source, either the carrier oscillator, or the audio amplifying circuits, to the cathode of V3.

Low Output. A likely cause of low output in the product modulator is decreased emission of the electron tubes. If proper operation is not restored, a defective circuit component could be the cause of low output. A resistive analysis of circuit components with the equipment de-energized would reveal a defective component that could be the cause of low output.

Another possible cause of low output is decreased amplitude r-f carrier input or decreased amplitude audio modulation input. The existence of this condition can be readily determined by observing the amplitude of the r-f carrier signal and audio modulation present on the cathode of V3, with an oscilloscope.

Distorted Output. It should be noted that distortion will occur in SSB systems if the transmitter and receiver are not exactly on frequency. Distortion in SSB transmitters usually results from improper

operation of the linear power amplifiers or by operating any stage beyond its capabilities.

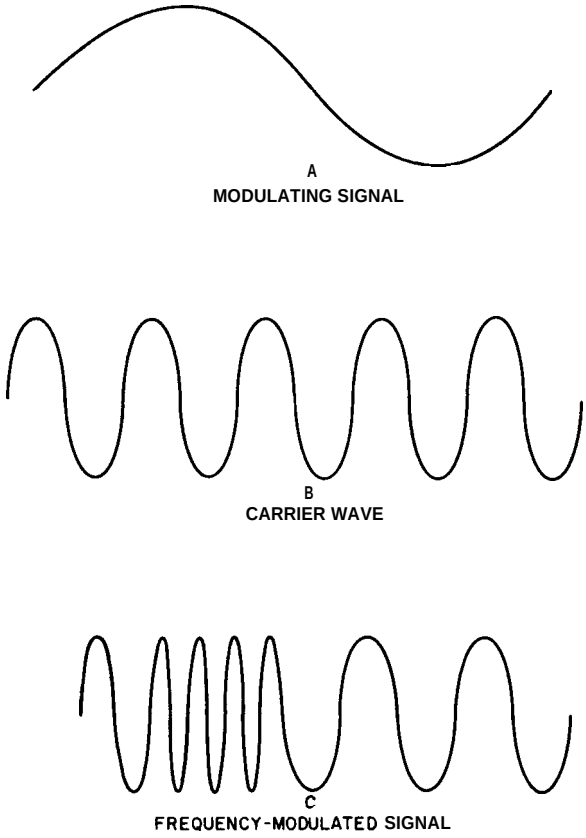
If the modulator is determined to be the cause of distortion a likely cause of distortion would be defective tubes or a defective circuit component. The tubes can easily checked by exchanging them with tubes known to be good. Resistance checks of circuit components would reveal if a defective circuit component is the cause of distorted output. Power supply voltages should be checked and adjusted if necessary to make certain that a defective power supply is not the cause of distorted output. Don't overlook the possibility that the audio modulation may be distorted before it reaches the product modulator. To check for this condition, observe with an oscilloscope the quality of the audio modulation present on the grid of V2, with an audio tone from an audio signal generator applied to the modulation input of the transmitter.

PART 12-3. FM

FREQUENCY MODULATION (FM)

General.

In frequency modulation, an audio signal is used to shift the frequency of an oscillator at an audio rate. The rate at which the oscillator changes its frequency depends upon the frequency of the modulating signal, and the deviation (the amount that the frequency shifts from the center frequency) depends upon the amplitude of the modulating signal, as shown in the following illustration.



Frequency Modulation Waveforms

The frequency of the carrier is called the center frequency. When this carrier is modulated by a positive signal, its frequency changes; for example, it may become higher in frequency, proportional to the

amount that the signal goes positive. Conversely, when the signal goes negative, the frequency becomes lower. Thus, when the sine wave shown in part A of the illustration is applied to a carrier, shown in part B, the carrier frequency changes from the normal center frequency to higher frequency, back to normal, to a lower frequency, and back to normal again as shown in part C. This variation is in direct accordance with the polarity and amplitude of the voltage of the sine wave. The maximum frequency change from center frequency, which depends upon the amplitude of the signal, is called the deviation. Note, in part C of the figure, that the amplitude of the modulated carrier is constant. As a result, frequency modulation is not so susceptible to static as in amplitude modulation, and it is for this reason that it is used for highquality transmission of sound, such as for music.

Since random noise usually consists of higher frequencies, the signal-to-noise ratio at the higher frequencies may be lower. It is for this reason that the audio modulation is coupled through a pre-emphasis network before being applied to the modulator circuit. The pre-emphasis network increases the relative signal strength of the higher frequency components of the audio signrd, and thereby compensates for any decrease in signal-to-noise ratio as caused by random high frequency noise. This creates a state of unbalance between the amplitudes of the high and low frequency components, but it is compensated for in the receiver by the use of a de-emphasis circuit, which performs the opposite function of pre-emphasis.

The primary difference between f-m and a-m is that the amplitude of the f-m signal is constant, while a-m depends upon amplitude variations for the transmission of intelligence.

The advantage of this type of modulation over a-m is its noise reducing capabilities. Most noise signals produce amplitude modulation of the carrier, or the carrier-plus-modulation signal, which is applied to the demodulating circuit in the receiver. If the receiver is responsive to amplitude variations, as in a-m receivers, this random noise is detected and amplified. If the receiver is responsive only to changes in frequency, as in f-m receivers, frequency modulation makes possible a considerable increase in the signal-to-noise ratio.

BASIC REACTANCE MODULATOR (ELECTRON TUBE)

Application.

The frequency modulator is used in fm transmitters to vary the frequency of an r-f signal in accordance with the intelligence to be transmitted.

Characteristics.

Output is used to change the frequency of an oscillator.

Has a high signal-to-noise ratio.

Output frequency is independent of modulating frequency.

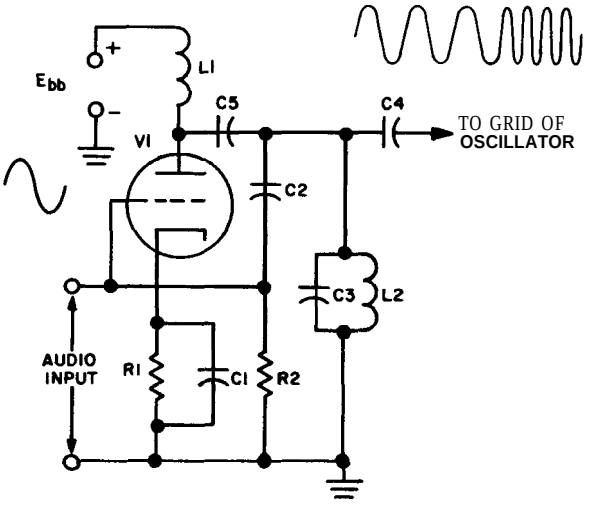
Has relatively low inherent distortion.

Circuit Analysis.

General. The purpose of the modulator stage is to convert an audio signal into a radio frequency containing the audio intelligence.

In the basic reactance tube modulator, a tube is used to change the resonant frequency of an oscillator by an amount proportional to the amplitude of the modulating signal. The polarity of the modulation determines the direction of the frequency shift; for example, an increase in oscillator frequency for a positive polarity, and a decrease in frequency for a negative polarity. The rate at which this frequency deviation occurs is determined by the frequency of the audio modulation.

Circuit Operation. A schematic diagram of a basic reactance tube modulator is illustrated.

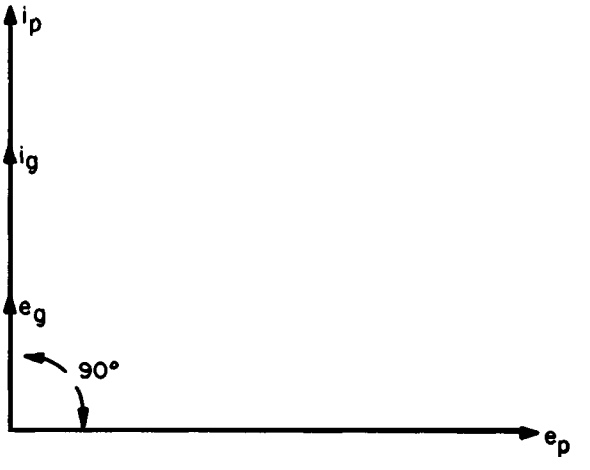


Basic Reactance Tuba Modulator

VI performs the function of the reactance tube, using cathode bias, supplied by RI and Cl. L1 is an r-f choke which acts as the plate load, and keeps the a-c component of plate current out of the power supply. Capacitor C2 and resistor R2, in parallel with the oscillator tank circuit consisting of C3 and L2, performs the function of a variable variable **reactance.** C4 and C5 are grid and plate coupling capacitors, respectively.

With no audio signal applied to the grid of VI, the only voltage present across the C2, R2, network is the voltage across the oscillator tank circuit, C3 and L2. The values of C2 and R2 are chosen so that the reactance of C2 is large in comparison to the resistance of R2. This factor permits the capacitive reactance to be the current controlling component, and causes the voltage across it to lag the current through it by approximately 90 degrees. This same current flows through R2 and another voltage drop is produced which leads the applied voltage by 90 degrees. Actually, the current and voltage at the resistor are in phase, but since the current through the resistor leads the applied voltage (because of the capacitive reactance of C2), the voltage developed by this current also leads the applied voltage by the same amount. The reactance tube is effectively in shunt with the oscillator tank (C3 and L2) and the phase shift network (C2 and R2). Capacitor C5 allows the ac component of current to pass through it, **and** at the same time, blocks the dc plate voltage from the phase-shift circuit and the tank.

The relationship of the currents and the voltages in the circuit can be best explained through the use of a vector diagram, as illustrated below.



Relationships of Currents and Voltage with no Modulation Inputs

Voltage e_p is the alternating component of the plate to ground voltage which appears simultaneously across the reactance tube, the phase-shift network, and the oscillator tank circuit. The reactance tube receives its ac grid-input voltage, e_g, across R2. This voltage is the voltage drop across R2 and is in phase with the plate current i_p and the grid current, i_g. This relationship is characteristic of amplifier tubes.

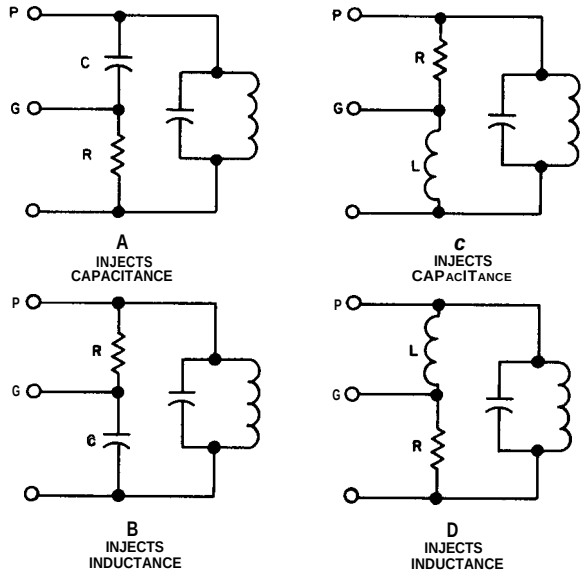
Since both i_p and i_g are in phase with e_g, and since e_g leads e_p by approximately 90 degrees, i_p and i_g also lead e, by 90degrees. Both of these currents are supplied by the oscillator tank circuit, and since they lead the tank voltage, they act like the current in a capacitor. Thus the injection of these currents into the tank circuit accomplishes the same effect as placing a capacitor across the oscillator tank circuit. The frequency of the tank in this case is, therefore, decreased. With no audio modulation input, this frequency is the operating, or center frequency of the modulator.

Consider now the application of audio modulation to the grid of the tube. It is important to keep in mind that we are not speaking of actual capacitive

reactance or capacitance changes. Our concern here is an effective capacitance produced by the leading currents in the R2, C2, combination. If the signal applied on the grid of V1 increases in a positive direction, the plate current of VI also increases, and since this current is an effective capacitance shunt across the oscillator tank circuit, the frequency of the oscillator is decreased. Conversely, when the grid signal shifts in a negative direction under audio modulation, VI plate current decreases, and since this current is an effective reduction in capacitance across (shunting) the oscillator tank circuit, the frequency of the oscillator is increased.

The frequency of the audio modulation does not actually affect the frequency of the output. Its only effect is that it determines the number of times per second that the oscillator changes its frequency. The amount and direction of the frequency change is determined solely by the amplitude and the polarity of the modulation input. That is, a positive signal causes an increase of frequency, while a negative signal causes a decrease in frequency. Likewise, a larger amplitude signrd causes a greater frequency change than a smaller amplitude signal.

Circuit Variations. There are several circuit variations of the basic reactance tube modulator, but most of these variations are only differences in the arrangement of the phase shifting circuit (the R2, C2, combination in the previous example). The following illustration shows how the circuit variations cause the phase shift to be either inductive or capacitive. There is no particular advantage to any one of them over any of the others.



Circuit Variations

Part A of the figure has been explained in the previous discussion. In part B of the figure, R and C are connected in the opposite manner, and the reactance values are chosen so that the resistance of R is large in comparison to the reactance of C. Since the resistive component is so much larger, the r-f voltage applied to the plate load by the tank circuit causes the current to be in phase with the r-f voltage. The current through C, however, leads the applied voltage by 90 degrees. The voltage across C, therefore, lags

both the current and the applied voltage by 90 degrees. This voltage is coupled to the grid of the reactance tube, and causes an r-f variation in the plate current that is in phase with the grid voltage. This r-f current is coupled to the oscillator tank and since it is in phase with the grid voltage, it must lag the current in the tank by 90 degrees. This produces the same result as injecting inductance into the tank circuit.

By substituting a small inductor in the place of C in part C of the figure, it is also possible to inject an effective capacitance into the tank circuit. The oscillator voltage applied across the plate load of the reactance tube causes a current to flow whose phase is controlled by the large resistance of R. This current is in phase with the applied voltage, since R is large with respect to L. Since tie voltage across L leads the current through it by 90 degrees, this voltage also leads the applied voltage by 90 degrees. This voltage is coupled "to the grid of the reactance tube, and r-f plate current flows which is in phase with the grid voltage and 90 degrees leading in respect to the oscillator tank voltage. The effect is, therefore, the same as injecting capacitance into the tank circuit, and the frequency is decreased.

By the same token, the reversing of R and L produces the same result as injecting inductance into the tank circuit as shown in part D of the figure. The inductive reactance of L, of course, must be large in comparison to the resistance of R. The r-f voltage from the oscillator tank circuit causes a current to flow through the plate load which lags the applied voltage by 90 degrees. This voltage then is applied to the grid of the reactance tube, producing an r-f plate current which is lagging the current in the tank circuit by 90 degrees, producing the effect of injecting inductance into the tank circuit.

Failura Analysis.

No Output. An open or shorted L2, an open or shorted C3, or an open C4 are the only components that can cause a no output condition to exist. Check L2 for continuity and C3 and C4 for value with an in-circuit capacitor checker.

Unmodulated Output. The absence of plate voltage, an open L1, an open C5, an open RI, an open C2 or R2, or a defective V1, can cause an unmodulated output condition to exist. Check for the presence of plate voltage with a voltmeter. Check L1 for continuity and C5 for an open or short with an ohmmeter. Also check RI and R2 for proper value, and C2 for an open or short with an ohmmeter. If a modulated output is not restored, check all capacitors with an in-circuit capacitor checker.

BASIC REACTANCE MODULATOR (SEMICONDUCTOR)

Application.

The reactance modulator is used to frequency modulate low power semiconductor transmitters.

Characteristics.

Uses collector to emitter output capacitance to provide reactive frequency control.

Operates at relatively low power levels.

Shunts a portion of the oscillator tank coil.

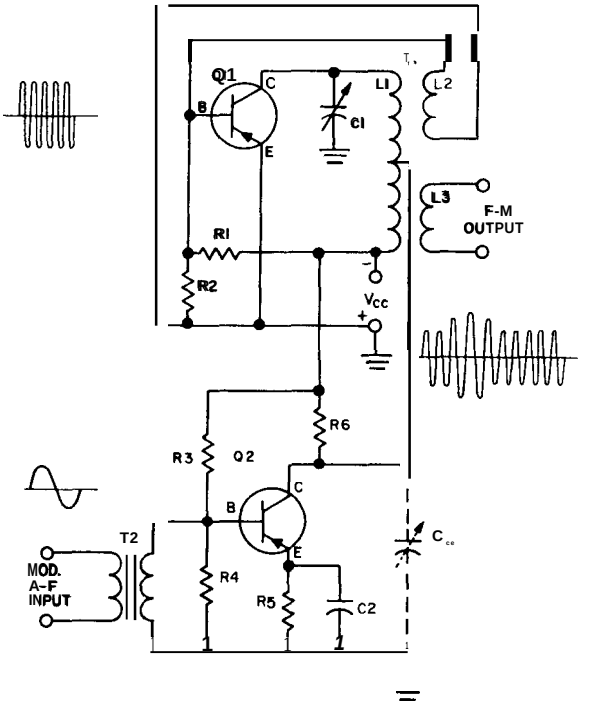
Requires further limiting or clipping to eliminate a residual 10 to 15 percent amount of AM modulation.

Uses a single transistor to achieve full modulation.

Circuit Analysis.

General. In an fm transistor, modulation is accomplished at the oscillator stage. The transistor oscillator is frequency modulated in the same manner as an electron tube oscillator, or by varying the gain at the modulating rate as is done with AM transistors. When the oscillator is fm modulated a slight amount of AM modulation is also inserted. Thus the modulated fm oscillator requires a limiter stage to remove the amplitude modulation before it is further amplified or multiplied in frequency. This is easily accomplished in a single stage.

Circuit Operation. The accompanying schematic shows the circuit of a typical frequency-modulated oscillator stage operated as a reactance modulator.



Reaetance Modulator

Transistor Q1 is the FM oscillator. Resistor R1 and R2 are base bias voltage dividers. Primary L1 of transformer T1 together with capacitor Cl form the tuned tank adjusted to the oscillator output frequency. R6 is the modulator load resistor. Secondary L2 of T1 is the collector to base feedback winding of the oscillator. Tertiary winding L3 is an inductively coupled output winding which couples the FM output signal to the next stage, or in special cases to an antenna. Transformer T2 is an audio transformer which inductively couples the modulation input to the base-emitter junction of Q2, the modulator stage. Resistors R3 and R4 are base bias voltage dividers, while R5 is an emitter swamping resistor bypassed by C2 for temperature stabilization. The output capacitance of Q2 shown dotted as C_{ce} shunts a portion of the r-f oscillator coil L1. As the modulator operates the output capacitance of Q2 is varied. Thus, the frequency of the oscillator is shifted in accordance with the modulation the same as if Cl were varied instead.

When the modulation is applied to the primary of T2 it is coupled into the base circuit. Thus the emitter-base bias changes constantly at the modulation rate. Since the bias is increasing and decreasing at the modulating rate, the collector voltage of Q2 also increases and decreases at the modulating rate. When the collector voltage increases, output capacitance C_{ce} decreases, and conversely, when the collector voltage decreases. (An increase in voltage has the effect of spreading the capacitor plates further apart by increasing the width of the PN barrier. Conversely, the reduction of collector voltage reduces the width of the PN junction and has the same effect as pushing the capacitor plates together to provide more capacitance).

When the output capacitance of C_{ce} decreases because of the increase in collector reverse bias, the resonant frequency of the Q1 oscillator tank circuit increases as if Cl were decreased, and produces a higher frequency r-f output. Conversely, when the output capacitance of C_{ce} increases because of a decrease in collector reverse bias, the resonant frequency of Q1 oscillator tank circuit decreases and produces a lower frequency r-f output because of the shunting effect of Ccc. Thus the resonant frequency of the oscillator tank circuit is increasing and decreasing at the modulating rate. Hence, the oscillator frequency is also increasing and decreasing at the modulation rate. The output of the oscillator, therefore, is a frequency modulated carrier signal. Since the audio modulation causes the collector voltage to increase and decrease, there is an AM component induced into the output. This produces both an FM and AM output. By placing a limiter stage after the reactance modulator, the amplitude variations are removed and only the frequency modulation remains, with a constant amplitude output. Frequency multipliers are then used to increase the oscillator frequency to the desired output frequency. For high power, linear r-f amplifiers are used to increase the steady amplitude signal to a particular level and power output. With the initial modulation occurring at low levels fm represents a saving in power as compared with conventional AM, with the FM noise reducing properties providing a better signal to noise ratio than is possible with AM.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges of conventional voltmeters. Be careful also to

observe proper polarity when checking continuity with the ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No-Output. Open bias resistors, open collector resistor R6, or open windings on T1, can cause a no-output condition. Check the resistors for proper value with an ohmmeter and the transformer for continuity. If satisfactory indications are obtained but Q1 does not oscillate, the transistors may be defective. If QI operates but no modulation is obtained, Q2 is defective.

Low Output. Low collector voltage, low bias voltage, or a weak transistor may cause a low output. Check the supply voltage first to be certain it is normal, then check the collector voltage of both Q1 and Q2, and the base bias of Q1 and Q2 also, if the collector voltage is normal. Also check collector resistor R6 for proper value if the modulation appears weak. Low bias can be caused by a change in bias voltage dividers R1 and R2, and R3 and R4; check for proper resistance value with an ohmmeter. A high resistance connection in output winding L3 of T1 may also occur and course a reduced output.

BALANCED REACTANCE MODULATOR (ELECTRON TUBE)

Application.

The balanced reactance tube modulator is used in fm transmitters to vary the frequency of an r-f signal in accordance with the intelligence to be transmitted.

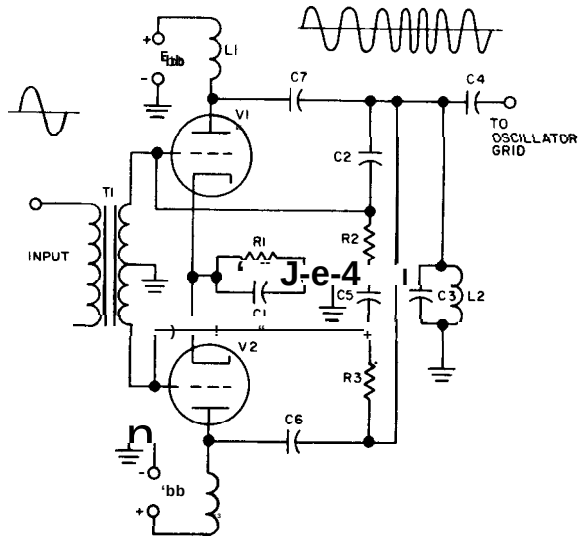
Characteristics.

Has relatively high degree of frequency shift.
Has low inherent distortion.
Has high signal-to-noise ratio.

Circuit Analysis.

General. The purpose of the modulator stage is to convert an audio signal into a radio frequency containing the audio intelligence. In the balanced reactance tube modulator, two tubes are used to change the resonant frequency of an oscillator by an amount proportional to the amplitude of the modulating signal. The polarity of the modulation determines the direction of the frequency shift, for example, an increase in oscillator frequency for a positive polarity, and a decrease in frequency for a negative polarity. The rate at which this frequency deviation occurs is determined by the frequency of the audio modulation.

Circuit Operation. A schematic diagram of a balanced reactance tube modulator is shown in the accompanying illustration.



Balanced Resistance Tube Modulator

V1 performs the function of one of the reactance tubes, and operates in conjunction with V2, in a push-pull manner. Cl and R1 form a cathode bias circuit, which is common to both of the tubes. L1 and L3 are r-f chokes which act as plate loads for the tubes, and keeps the a-c component of plate current out of the power supply. The C2-R2 combination, together with the C5-R3 combination, both in parallel with the oscillator tank circuit, made up of L2 and C3, perform the function of a variable reactance. C4, C6, and C7, are grid and plate coupling capacitors, respectively.

Circuit operation can be easiest understood, if analyzed and discussed as two separate circuits. One circuit, consists of V1, L1, C7, C2, and R2, while the other circuit consists of V2, L3, C6, R3, and C5. The remaining components are common to both of the circuits.

We shall first consider the operation of the circuit consisting of V1 and its associated components. With no audio signal applied to the grid of V1, the only

voltage present across the C2-R2 network is the voltage across the oscillator tank circuit. The values of C2 and R2 are chosen so that the reactance of C2 is large in comparison to the resistance of R2. This factor permits the capacitive reactance to be the current controlling component, and causes the voltage across it to lag the current through it by approximately 90 degrees. This same current flows through R2 and another voltage drop is produced which leads the applied voltage by 90 degrees. Actually, the current and voltage at the resistor are in phase, but since the current through the resistor leads the applied voltage (because of the capacitive reactance of C2), the voltage developed by this current also leads the applied voltage by the same amount. The reactance tube, VI, is effectively in shunt with the oscillator tank and the phase shift network. Capacitor C7 allows the ac component of current to pass through it, and at the same time, blocks the dc plate voltage from the phase-shift circuit and the tank.

The relationship of the currents and the voltages in the circuit can be best explained through the use of a vector diagram. Refer to the previous discussion of the Basic Reactance Tube Modulator (Electron Tube) in this section of the Handbook for this illustration.

Voltage ep is the alternating component of the plate to ground voltage which appears simultaneously across the reactance tube, the phase-shift network, and the oscillator tank circuit. The reactance tube receives its ac grid-input voltage, eg, across Rg. This voltage is the voltage drop across Rg and is in phase with the plate current ip and the grid current, ig. This relationship is characteristic of amplifier tubes.

Since both ip and ig are in phase with eg, and since eg leads ep by approximately 90 degrees, ip and ig also lead ep by 90 degrees. Both of these currents are supplied by the oscillator tank circuit, and since they lead the tank voltage, they are acting Iike the current in a capacitor. Thus the injection of these currents into the tank circuit accomplishes the same effect as placing a capacitor across the oscillator tank circuit. The frequency of the tank in this case is therefore decreased. With no audio modulation input, this frequency is the operating, or center frequency of the modulator.

Consider now the application of audio modulation to the grid of the tube. It is important to keep in mind that we are not speaking of actual capacitive reactance or capacitance changes. Our concern here is an effective capacitance produced by the leading currents in the R2-C2 combination. If the signal applied on the grid of V1 increases in a positive direction, the plate current of V1 also increases, and since this current is an effective capacitance shunt across the oscillator tank circuit, the frequency of the oscillator is decreased. Conversely, when the grid signal shifts in a negative direction under audio modulation, V1 plate current decreases, and since this current is an effective capacitance across (shunting) the oscillator tank circuit, the frequency of the oscillator is increased.

Before attempting to explain the operation of the circuit made up of V2, it should be pointed out that there are several minor circuit variations of the previously discussed circuit. Most of these variations concern differences in the phase shifting circuit (the R2-C2 combination in the previous example). There is no particular advantage to any one of them over any of the others. Refer to the circuit variations illustrated in the previous discussion of the Basic Reactance Tube Modulator (Electron Tube) during the following discussion.

Part A of the figure has already been explained. In part B of the figure, R and C are connected in the opposite manner, and the reactance values are chosen so that the resistance of R is large in comparison to the reactance of C. (This is the manner in which operation of V2 yet to be explained is connected.) Since the resistive component is so much larger, the r-f voltage applied to the plate load by the tank circuit causes the current to be in phase with the r-f voltage. The current through C, however, leads the applied voltage by 90 degrees. The voltage across C, therefore, lags both the current and the applied voltage by 90 degrees. This voltage is coupled to the grid of the reactance tube, and causes an r-f variation in the plate current that is in phase with the grid voltage. This r-f current is coupled to the oscillator tank and since it is in phase with the grid voltage, it must lag the current in the tank by 90 degrees. This produces the same result as injecting inductance into the tank circuit.

By substituting a small inductor in the place of capacitor C in part C of the figure, it is also possible to inject an effective capacitance into the tank circuit. The oscillator voltage applied across the plate load of the reactance tube causes a current flow whose phase is controlled by the large resistance of R. This current is in phase with the applied voltage, since R is large with respect to L. Since the voltage across L

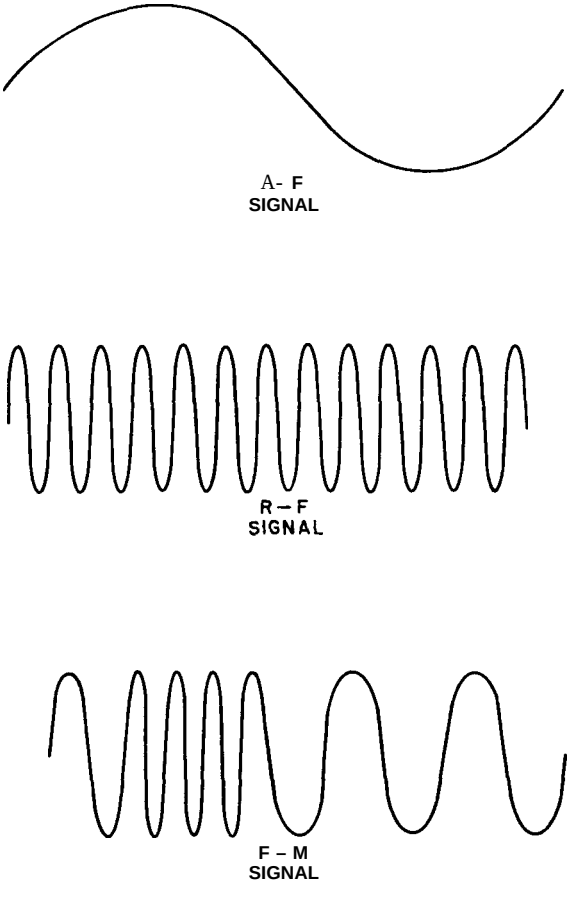
leads the current through it by 90 degrees, this voltage also leads the applied voltage by 90 degrees. This voltage is coupled to the grid of the reactance tube, and an r-f plate current flows which is in phase with the grid voltage and 90 degrees leading in respect to the oscillator tank voltage. The effect is, therefore, the same as injecting capacitance into the tank circuit, and the frequency is decreased.

By the same token, the reversing of R and L produces the same result as injecting inductance into the tank circuit, as shown in part D of the figure. The inductive reactance of L, of course, must be large in comparison to the resistance of R. The r-f voltage from the oscillator tank circuit causes a current to flow through the plate load which lags the applied voltage by 90 degrees. This voltage is then applied to the grid of the reactance tube, producing an r-f plate current which is lagging the current in the tank circuit by 90 degrees, producing the effect of injecting inductance into the tank circuit.

The V2 circuit operates in the same reamer as the VI circuit, only instead of injecting a capacitive reactance into the oscillator tank, it injects an inductive reactance. Upon close examination of the V2 circuit, it can be seen that the phase shifting circuit, R3 and C5, are connected in the opposite manner to the R2-C2 combination in the first example. By referring to the illustration of circuit variations, it can be seen that this type of connection (Part B of the figure) produces the effect of inductance in parallel with the tank circuit. It should be noted here that an increase in plate current in the first example caused an increase in the capacitive reactance injected into the tank, and hence the oscillator frequency decreased. In the V2 circuit, the inductive reactance is decreased with an increase in plate current, and thus produces an increase in the oscillator frequency. Now let us see what occurs when both circuits are connected as shown, and an audio signal is applied to the transformer Tl.

When the input signal is such that the grid of VI is positive, and the grid of V2 is negative, the following action results. The negative signal on the grid of V2 drives V2 into cut-off, and a further negative increase produces no further change. VI, however, conducts a greater as the signal on the grid becomes more positive, and thus additional capacitive reactance is injected into the oscillator tank circuit, resulting in a decreasing frequency. As the signal on the grid reaches its positive peak, and begins decreasing towards zero, the oscillator frequency begins increasing, and when the grid is returned to zero, the oscillator is again at the center frequency. The signal now continues in a negative direction and V1 is driven into cut-off. V2, the grid of which is connected to the opposite end of T1, is now brought into conduction, and begins to inject an inductive reactance into the tank circuit, resulting in an increasing frequency. As the "signal on the grid reaches its positive peak, and begins decreasing towards zero, the oscillator frequency begins decreasing and as the signal reaches zero the oscillator is again at the center frequency. The overall result of one cycle of audio modulation is shown in the following illustration.

Thus, it can be seen that the frequency of the audio modulation does not actually have an effect on



Effect of Modulation

the frequency of the output. The only effect is that it determines the number of times per second that the oscillator changes its frequency. The amount and direction of the frequency change is determined by the amplitude and the polarity of the modulation input.

Failure Analysis.

No Output. An open or shorted L2, an open or shorted C3, or an open C4 are the only components that can cause a no-output condition to exist. Check L2 for continuity and C3 and C4 for value with an in-circuit capacitor checker.

Distorted or Unmodulated Output. A defective V1 or V2, a defective T1, an open or shorted L1 or L3, an open or shorted C2 or C5, or an open R2 or R3 can cause a distorted output condition to exist. With an ohmmeter, check the continuity of L1 and L3, and check R2 and R3 for proper value. Also check C2, C5, C6, and C7 for opens or shorts with an ohmmeter. Check transformer T1 for continuity, as one half of the secondary may be open. If a distorted output still exists, check all capacitors with an in-circuit capacitor checker.

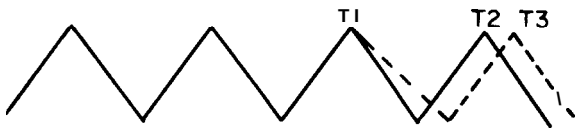
An unmodulated output can be caused by a defective Tl, an open or shorted RI, or an open or shorted Cl. With an ohmmeter, check the continuity of T1 and the value of RI. Check Cl for an open or short with an ohmmeter. An unmodulated output may also be caused by components being defective in pairs, that is, VI and V2, L] and L3, C6 and C7, etc. Check ail components in this case, in the manner described in the preceding paragraph.

PART 12-4. PHASE

PHASE MODULATION (PM)

General.

In phase modulation, sometimes referred to as indirect frequency modulation, the audio signal is used to shift the phase and the frequency of the carrier frequency, resulting in a frequency variation in the output. The amount of phase deviation is directly proportional to the amplitude of the audio signal, and the amount of frequency deviation is proportional to the frequency of the audio signal. An illustration of phase modulation follows.



Result of Phase Modulation.

The solid line represents the carrier frequency. If an audio signal is introduced at the beginning of time Tl, the next positive peak occurs, for example, at time T3, shown in dotted lines, instead of at a time T2, where it would normally occur. Since the peak following TI now occurs at a later time, the phase of the output is now lagging the carrier. By the same token, the phase can be changed to a leading one by the applications of a signal of opposite polarity. Thus the amount and direction of phase shift varies in accordance with the amplitude and polarity of the audio input. A frequency variation also occurs in the output, because the frequency of the modulating signal determines the rate at which the phase of the carrier deviates, and thus determines the amount of frequency deviation.

The frequency of the carrier before a phase shift occurs is called the center frequency, and is generated by a crystal controlled oscillator, which accounts for the excellent frequency stability of the phase modulator.

The phase variations, called modulation, are not applied until after the carrier frequency is generated and it is this peculiarity which allows the use of a crystal oscillator. With no audio signal applied, only the carrier frequency, is transmitted.

Since random noise usually consists of higher frequencies, the signrd to noise ratio at the higher audio frequencies may be lower. It is for this reason that the audio modulation is coupled through a pre-emphasis network before being applied to the modulator circuit. The pre-emphasis network increases the relative signal strength of the higher frequency components of the audio signal, and thereby compensates for any decrease in signrd-to-noise ratio as caused by random high frequency noise. This creates a state of unbalance between the amplitudes of the high and low frequency components, but is is compensated for in the receiver by the use of a de-emphasis circuit, which performs the opposite function of pre-emphasis.

The greatest advantage of the phase modulator is, as previously mentioned, its excellent frequency stability, which results from the use of a crystal oscillator.

The advantage of this type of modulation over a-m is its noise reducing capabilities. Most noise signals produce amplitude modulation of the carrier, or the carrier-plus-modulation signal, which is applied to the demodulating circuit in the receiver. If the receiver is responsive to amplitude variations, as in a-m receivers, this random noise is detected and amplified. If the receiver is responsive only to changes in frequency, as in an f-m receiver, phase modulation makes possible a considerable increase in the signal-to-noise ratio. Actually, phase modulation is a form of f-m, the difference being that whereas f-m is responsive only to changes in amplitude, p-m is responsive to both the amplitude and the frequency of the audio modulation.

A better understanding of phase modulation can be obtained from the following descriptions of specific phase modulator circuits.

BASIC PHASE MODULATOR (ELECTRON TUBE)

Application.

The phase modulator is used in transmitters to vary the frequency of an r-f signal in accordance with the intelligence to be transmitted.

Characteristics.

Carrier frequency is supplied by a crystal controlled oscillator.

Frequency stability is excellent.

Has a high signal-to-noise ratio.

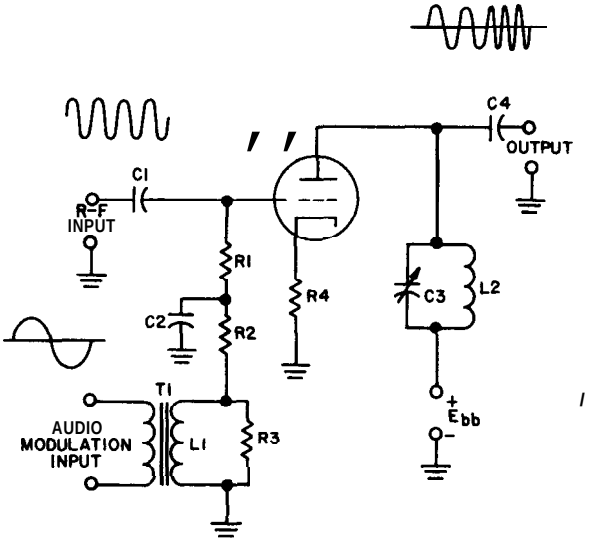
Operates over the linear portion of the Eg – Ip curve.

Circuit Analysis.

General. The purpose of the modulator stage is to convert an audio signal into a radio frequency containing the audio intelligence.

In the basic phase modulator, a crystal controlled oscillator supplies the desired basic frequency to the grid of a triode. A modulating (audio) signal is also applied to the grid of this modulator tube, and a phase shift occurs in the r-f output. The amount and direction of the phase shift is proportional to the amplitude and polarity as well as the frequency of the audio modulating signal.

Circuit Operation. A basic phase modulator is shown in the accompanying schematic diagram.



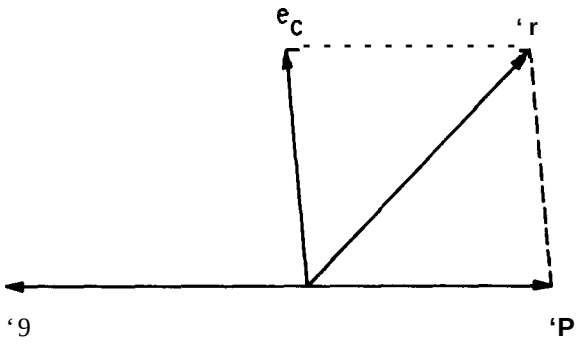
Basic Phasa Modulator.

The crystal oscillator r-f output is coupled through coupling capacitor Cl to the grid of VI, and it is this crystal oscillator frequency which is the center frequency of the phase modulated output. Resistors Rl, R2, and R3 forma voltage divider, across which both the oscillator r-f signal and the audio modulation is applied. R2, in conjunction with C2, also performs the function of a decoupling network, which bypasses the lower end of R1 to ground and prevents the r-f carrier frequency component from feeding back into the audio circuits through T1. In effect, it isolates the r-f from the audio, despite the apparent common connection. The audio modulation is applied through transformer T1 and through R2 and R1 to the grid of V1. Cathode resistor R4 provides degenerative feedback, and the plate tank circuit, consisting of L2 and C3, is tuned to a frequency below the lowest output r-f frequency. Because R4 is unbypassed and causes degenerative feedback, the tube gain is relatively low.

The r-f signal (the carrier) is of constant amplitude and frequency, and with both positive and negative cycles equal in amplitude, no bias change is produced

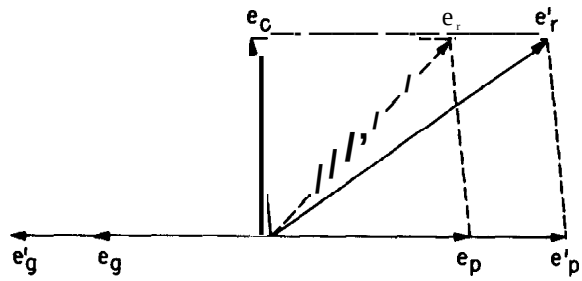
on VI grid. Thus an amplified r-f carrier appears as the reproduced output, with the normal 180 degree grid to plate phase shift. The audio modulation, however, applied through transformer T1, provides, in effect a changing bias on V1 grid as it varies in amplitude and polarity. As a result, the gain of the tube is varied in accordance with the audio signal bias. The manner in which this variation in the gain of the triode is converted into a phase shift of the carrier, can be better understood through the use of vector diagrams.

The voltage produced by normal amplifier action is represented as ep. Another r-f voltage is produced by the grid to plate capacitance of the tube, and is represented as ec, and the result of these two r-f plate voltages, which is the instantaneous plate voltage, is represented as er. Due to normal amplifier action, ep is 180 degrees out of phase with eg, the grid voltage and its amplitude is relatively low because of the degenerative effect of the unbypassed cathode resistor, R4. Since ec lags eg by some amount, er, which is the vector result of ec and ep it falls somewhere between these two voltages, as illustrated in the following diagram.



Vector Diagram Showing Effect of Modulation

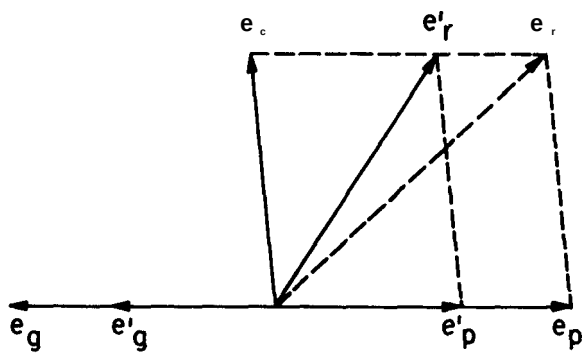
When the signal on the grid increases in a positive direction, the amplitude of the plate signal also increases, with the following result. The vectors which



Vector Diagram For Increasing Grid Voltage

change as a result of this increase in grid signal are designated as e’g, e’r, and e’p. ‘Voltages eg, er, and ep are shown in order to compare this example with the previous one. It can be seen therefore, that with a larger signal on the grid (e’g), the closer e’p and e’r become in phase.

Conversely, when the grid signal (e’g)”decreases in amplitude, the plate signal, e’p decreases, as illustrated in the following diagram.



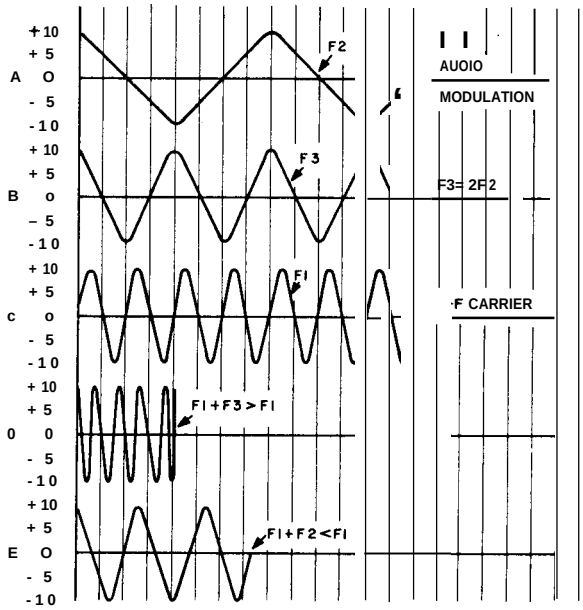
Vector Diagram For Decreasing Grid Voltage

As a result, the vector er shifts further out of phase with ep (to e’r) than it was under the first

condition illustrated. By comparing these three illustrated circumstances, it can be seen that the phase relationship between er and eg constantly changes in phase as eg varies in amplitude and polarity.

The overall effect is that the amplitude of the modulating signal determines the amount and direction of phase deviation of the carrier in the output. The frequency of the modulating signal determines the rate at which the phase of the carrier deviates, and thus determines the amount of frequency deviation. This effect can be more clearly seen by referring to the following illustration showing the different frequencies produced by adding F1 and F2, and F1 and F3.

The carrier (oscillator) frequency is represented by F1 in part C of the figure. F2 (shown in part A of the figure) represents the modulation frequency, and the result of adding or combining F1 + F2 is shown in part E of the figure. As shown in the figure, F2 starts at 10-volts positive. Assume, for ease of explanation, that this positive 10-volts modulation causes a full 90-degree phase shift in the carrier. Now, since the carrier frequency F1 is at O at the same instant, the sum value (Fl + F2) is at +10 volts and, by assumption, leads F1 by 90 degrees. As the modulation voltage (F2) decreases to +5 volts, the phase shift is reduced to one-half maximum or 45 degrees. At this point, F1 has completed 180 degrees of its cycle and is at O voltage, except that the 45 degree advance makes the sum of F1 and F2 a minus 5-volts instead, as shown in part E of the figure. As modulation Voltage F2 continues to decrease and reaches O voltage, no further phase shift occurs and the carrier and modulator voltages are again in-phase (at this point F1 has just completed 360 degrees of its cycle and by coincidence happens to be at O voltage also). The negative modulation cycle now continues, and, when F2 reaches –5 volts it also causes a 45 degree phase shift, but this time the shift is in a lagging direction. Therefore, although F1 is actually at O, the lagging sum produces a +5 volts combined signrd as shown at E. In this manner, the phase shift follows the modulating voltage, leading on the positive half cycle of modulation and lagging over the negative half cycle, with the amount of phase shift being proportional to the im.tantaneous amplitude of the modulating signal.



Effect of Frequency and Amplitude Changes of Modulating Signal

By following the relationship between F1 and F3 (part B of the figure) in the same manner as for F1 and F2 as just explained, we see that when a modulation frequency twice that of F2 is used, the sum shown in part D of the figure is an increasing frequency. Since frequency deviation increases with an increase in the modulation frequency, this is the result to be expected and proves our previous assumptions to be correct.

Failure Analysis.

No Output. A defect in nearly any component in the circuit can cause a no output condition to exist. Check with an oscilloscope to make sure that both the oscillator and the audio modulation are present at the inputs to the circuit. If either one is missing, the modulator is probably not defective, and the output will probably be restored with the restoration of the missing input. If both inputs are present, disable the oscillator, and check for the modulation input of the

491-044 0 73 73

grid. If not present, check transformer T1 for continuity with an ohmmeter. Check RI, R2 and R3 for a change in value, and C2 for a short. Disable the audio input, and check for the presence of oscillator frequency on the grid. If absent, check Cl for an open. If both signals are present on the grid, check R4 for value, and L2 for continuity. Check for the presence of plate voltage with an voltmeter. Check C3 for a short, and C4 for an open. If a no-output condition still exists, check all capacitors with an in-circuit capacitor checker.

Low or Distorted Output. A low or distorted output can also be caused by a defect in nearly any component in the circuit. Check for the proper amplitude of each input signal on the grid of tube VI with an oscilloscope. If low, determine whether it is low due to a defective oscillator or audio stage, or if it is a defect in the modulator circuit itself. If localized to the modulator, check transformer T1 continuity and resistors R1 and R3 with an ohmmeter. Check C2 for proper value with an in-circuit capacitor checker. Check R4 for value. Check plate voltage and determine whether or not the power supply is defective. Check C3 and C4 with an in-circuit capacitor checker, and check the continuity of L2 with an ohmmeter.

PHASITRON MODULATOR (ELECTRON TUBE)

Application.

The phasitron is used in transmitters to vary the frequency of an r-f signal in accordance with the intelligence to be transmitted.

Characteristics.

Utilizes a special phasitron tube.

Carrier frequency is supplied by a crystal controlled oscillator.

Has a high signal-to-noise ratio.

Operates Class A.

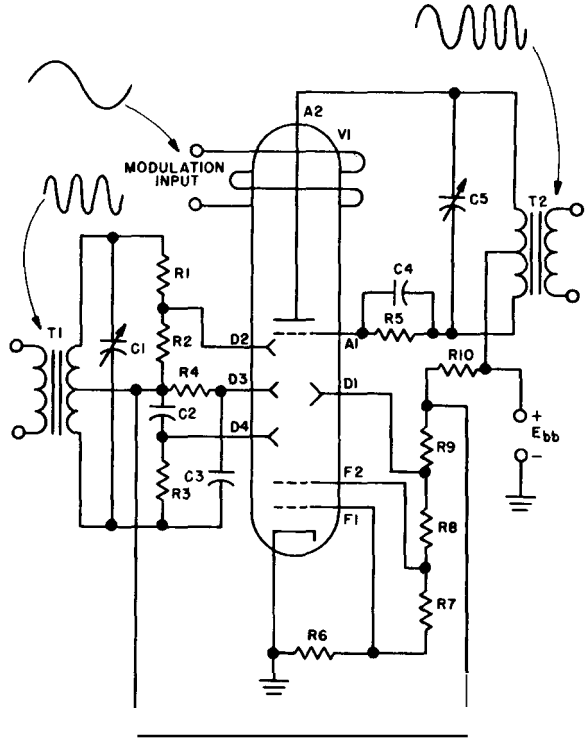
Frequency stability is excellent.

Output modulation proportional to both amplitude and the frequency of the audio modulation.

Circuit Analysis.

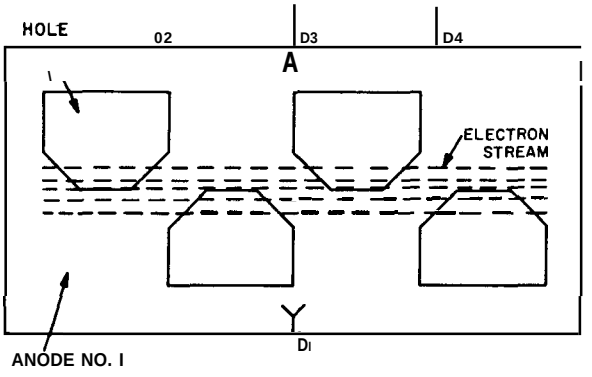
General. The phasitron performs the function of a phase modulator through the use of a special tube, called the phasitron tube. The carrier frequency is generated by a crystal controlled oscillator, and coupled through a phase splitting network to the tube. The modulation is applied inductively to the tube through a coil arranged around the outside of the tube, and the result in the output is a phase and frequency modulated carrier.

Circuit Operation. A schematic diagram of a Phasitron is illustrated.



Phasitron Modulator.

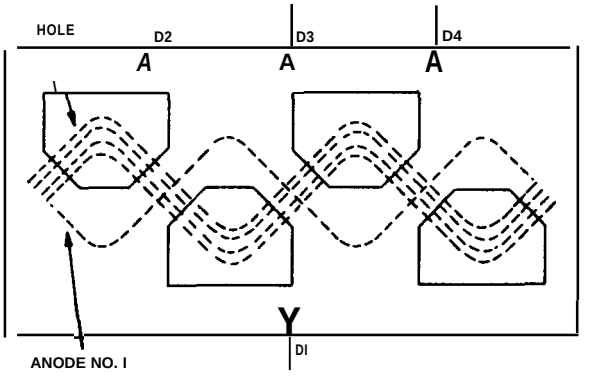
Before attempting to understand the operation of the phasitron circuit, a basic understanding of the special tube utilized is essential. The following illustration shows the basic configuration of the structure of anode number 1, the four deflection grids, Dl, D2, D3, D4, and the electron stream, with no potential applied to the deflection plates.



Phasitron Anode Structure and Electron-Beam Configuration with no Potential Applied to Deflector Grids

Anode number 1 has holes punched at regular intervals above and below a dividing line. The two focusing grids, F1 and F2, are such that it shapes the electron stream into a flat disc, which strikes anode number 1 as shown. Behind anode number 1“ is another anode, which receives the electrons which are permitted to pass through the holes in anode number 1. Thus, with no potential applied to the deflector grids, nearly equal current flows in each plate.

In operation, however, potentials are applied to these deflector grids, and they are each 120 degrees out of phase with each other. Upon re-examining the electron disc, but this time with the potentials applied to the deflector plates, the result is illustrated.



Phasitron Anode Structure and Electron-Beam Configuration with Potential Applied to Deflector Grids.

Now a greater portion of the stream passes through the holes in the first anode, and strike the second anode. Hence the plate current in anode number 2 is now greater than that of anode number 1. Since the potentials on D2, D3, and D4 are constantly changing (though always 120 degrees apart), the shape of the disc is also constantly changing, and shortly the disc is as shown by the dotted lines, resulting in maximum plate current in anode number 1, and minimum current in anode number 2. For any phase between these two extremes, each anode receives correspondingly more or less current. The modulation is applied to the coil around the outside of the tube, and the magnetic fields developed around this coil tends to increase or decrease the speed of rotation of the electron disc. By increasing or decreasing the speed of rotation, the frequency at which the anode current increases or decreases changes, and the output frequency is either increased or decreased.

In actual circuit operation, the carrier frequency is applied through transformer T1. The secondary of Tl, together with Cl, form a tank circuit tuned to this carrier frequency. Resistors Rl, R2, R3, and R4, together with capacitors C2 and C3, form a phase splitting network, and the result is that the signals applied to D2, D3, and D4 are 120 degrees out of phase with each other. Also applied to the phase shifting network is a constant potential, tapped from the common point of R9 and R1O. Resistors R6, R7, R8, R9, and R1O perform the function of voltage dividers in order to apply the proper voltages to the respective elements of the tube. R5 is a voltage dropping resistor, and C4 is an a-c bypass. The primary of T2, together with C5, form a tank circuit, tuned to the center frequency.

Referring to the construction of the first anode and the shape of the electron stream, it can be seen that there is a time during which all of the electrons strike the first anode, but never a time at which all of the electrons strike the second anode. This characteristic is overcome with R5, which causes a lower potential to be applied to the first anode than to the second anode. This same resistor would also cause degeneration of the ac component of plate current however, and for this reason C4, an a-c bypass, is placed in parallel with R5. The overall effect, with no modulation applied is that the plate current is constantly rdternating between the two anodes in such a

way that when one is maximum, the other is minimum, and conversely. The rate at which these currents rotate is equal to the crystal oscillator frequency, and it is to this frequency that the plate tank circuit is tuned.

When modulation is applied to the coil surrounding the tube, a magnetic field is developed, and this field advances or delays the rate of phase change of the electron stream. Thus the phase of the output leads or lags the oscillator frequency by an amount which is proportional to the amplitude and polarity of the modulation. The frequency of the modulation determines the rate at which the electron disc rotates. When the speed of disc rotation is increased, the output tank excitation frequency is higher, and when the speed of the disc rotation is decreased, the output frequency is lower.

The overall result in the output is therefore a signal which changes in phase and frequency as the audio modulation varies in amplitude and frequency.

Failure Analysis.

No Output. A no output condition can be caused by a defective Vl, an open R5, a shorted Cl or C5, a defective T1 or T2, or a loss of the plate supply voltage. Check for the proper plate supply voltage with a voltmeter. Check both transformers with an ohmmeter. Check R5 for value, and Cl and C5 for a possible short with an in-circuit capacitor checker. Do not overlook the possibility of either of the tank circuits being misaligned.

Low or Distorted Output. A low or distorted output can be caused by a defect in any component in the circuit. Check for the proper value of plate supply voltage with a voltmeter. With an oscilloscope, check the presence of both the carrier and modulation inputs on their respective elements of the tube, as the obsence of either input will produce a distorted output. Check the alignment of both tank circuits. With an in-circuit capacitor checker, check the value of all capacitors, especially for a distorted output condition. Check all resistors with an ohmmeter for proper value, and the transformer for partial shorts.

PART 12-5. PULSE

PULSE MODULATION

General

Radio frequency energy in radar is transmitted in short pulses whose time duration may vary from 1 to 50 microseconds or more. If the transmitter is turned off before the reflected energy returns from the target, the receiver can distinguish between the transmitted pulse and the reflected pulse. After all reflections have returned, the transmitter can again be turned on and the process repeated. The receiver output is applied to an indicator which measures the time interval between the transmission of energy and its return as a reflection. Since the energy travels at a constant velocity, the time interval becomes a measure of the distance traveled (range). Since this method does not depend on the relative frequency of the returned signal or on the motion of the target, difficulties experienced in cw and fm methods are not encountered. The pulse modulation method is used in practically all military and naval applications.

Since most radar oscillators operate at pulse voltages between 5 Kv and 20 Kv, and require currents of several amperes during the pulse, the requirements of the modulator are quite severe. The function of the high-vacuum tube modulator is to act as a switch to turn a pulse on and off at the transmitter in response to a control signal. The best device for this purpose is one which requires the least signal power for control and which allows the transfer of power from the transmitter power source to the oscillator with the least loss. The pulse modulator circuits discussed in this section are typical pulse modulators used in radar equipments.

SPARK GAP MODULATOR (ELECTRON TUBE)

Application.

The spark gap modulator is used in radar equipments to generate the pulse which controls the operation of the transmitter.

Characteristics.

Capable of handling high peak current and voltage.

Generated pulses have high peak power.

Generated pulses have low average power.

Generated pulses have a specific repetition rate.

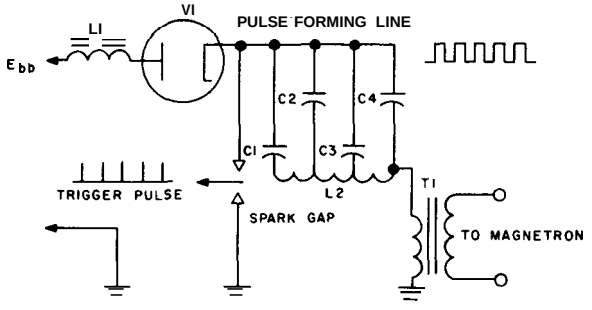
Generated pukes have controlled duration and shape.

Output pulse is somewhat erratic in timing.

Circuit Analysis.

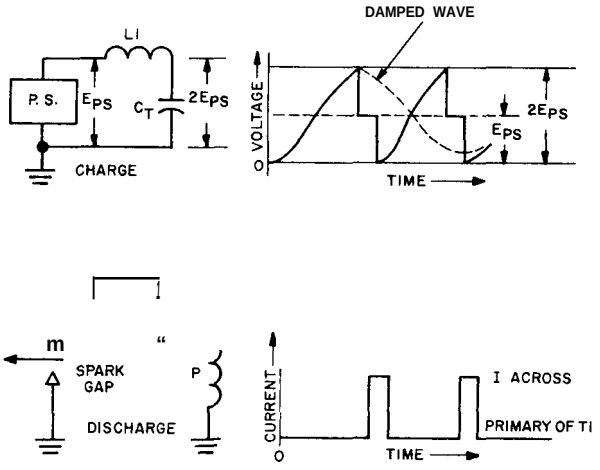
General. Different types of pulse modulators are used for triggering radar transmitters, depending on the particular requirements of the system. Each type contains a circuit for storing energy, a circuit for rapidly discharging the storage circuit, a pulse transformer, and an ac power source. The circuit for storing energy is essentially a short section of artificial transmission line which is known as the pulse forming line. In the spark gap modulator, the pulse forming line is discharged by a spark gap. Two types of spark gaps are in use: fixed gaps and rotary gaps. The fixed gap, discussed in this section, uses a trigger pulse to ionize the air between the contacts of the spark gap and initiate the discharge of the pulse forming line. The rotary gap is similar to a mechanically driven switch.

Circuit Operation. A typical freed spark gap modulator circuit is shown in the accompanying illustration.



Fixed Spark Gap Modulator Circuit

Between trigger pulses the spark gap is an open circuit, and current flows through the pulse transformer Tl, the pulse forming line L2, the diode Vl, and inductor LI to the plate supply voltage Ebb. These components form the charging circuit for the pulse forming line, and the entire circuit may be reduced to a series resonant circuit as shown in the accompanying illustration.



Equivalent Pulse-Modulator Circuits, With Wavaforms

The impedance of the primary of T1 is negligible as far as the charging circuit is concerned, the inductance of the pulse forming line may be considered to be short circuited because of the slow charging rate, and the diode, when conducting, is effectively a short circuit; therefore, these components are omitted from the figure. In effect, then, the total capacitance (Ct) of the pulse forming line is in series with the inductor L1 across the power supply. Assuming that diode V1 and the spark gap were not present, this circuit, when shock-excited by the sudden application of voltage would produce a damped-wave oscillation. On the first peak, the voltage across the entire pulse forming line approaches twice the value of the supply voltage as shown in the illustration, and at this time the current in the inductor L1 is zero since the diode stops conducting at full charge. As the peak voltage is reached, the spark gap is triggered by a synchronous separate trigger placing the pulse-forming network in series with the primary of T1 to ground. At this time approximately half the voltage (Eps) appears across the pulse-forming network (PFN) and the other half appears across TI, since the network impedance is equal to that of T1 in this instance because of the

rapidity of discharge. The action of the pulse-forming line is such as to cause voltage Eps to continue at the same amplitude until the complete discharge of the circuit by a time interval depending upon twice its delay period. The waveforms and time relationships of the circuit action are shown in the illustration. The pulse waveform is coupled through transformer T1 to the magnetron.

The spark gap is actually triggered (ionized) by the combined action of the charging voltage across the pulse-forming line and the trigger pulse. The air between the trigger-pulse injection point and ground is ionized by the trigger voltage, and this in turn initiates the ionization of the complete gap by the charging voltage.

Coincidence between the peak of the voltage swing across Ct and the trigger pulse used to fire the spark gap is required, in order that maximum power output may be obtained from the circuit. In order to ensure correct timing diode V1 is used and the design of the charging circuit is such that its resomnt frequency is higher than half the repetition rate of the spark-gap trigger pulse. Since the diode is nonconductive when maximum charge is reached on Ct, the maximum charge is retained until the spark gap is triggered.

Inductor L1 prevents current surge through V1 when the spark gap is triggered. Where humidity or pressure may affect the ionization of the spark gap, it is enclosed in a waled container.

In some circuits a resistor and capacitor in series are comected across the primary of T1. The function of these components is to eliminate the spike (sometimes encountered on the magnetron pulse) which is caused by delay between the time the pulse is presented to the magnetron and the time the magnetron conducts.

Failure Analysis

No Output. A no output condition can be caused by one of the following; an open Ll, a defective VI, an open L2, or a defective T1. Determine that the plate supply voltage (Ebb) and the trigger pulse are present. If they are not present, the trouble is in the preceding stages and the circuit is probably not at fault. If the plate supply voltage is not present on the anode of Vl, L1 is defective. If plate voltage is present on the anode of VI and no output appears, the tube is defective. Check L2 and the windings of T1 with an ohmmeter for an open or short.

Low Output. A low output can be caused by a low plate supply voltage, a weak Vl, leaky or shorted capacitors, shorted windings on L1, L2, or transformer T1. Check the plate supply voltage with a VTVM, if it is not the proper value the trouble is in the preceding stages and the modulator circuit is probably not at fault. Check the capacitors in the circuit with an in-circuit capacitor checker. Inductors Ll and L2 and transformer T1 can be checked with an ohmmeter for shorted turns.

Distorted Output. A distorted output could occur if the pulse-forming line had shorted or leaky capacitors or if the inductor windings became shorted or open. Check the capacitors with a capacitance checker and the inductor for continuity with an ohmmeter.

THYRATRON (GAS-TUBE) MODULATOR

Application.

The thyratron modulator is used in radar equipment to generate the pulse which controls the operation of the transmitter.

Characteristics.

Possesses heavy current handling capacity.
Is relatively independent of ambient temperatures.
Has positive grid control.
Has stable timing.
Can be triggered with a low amplitude pulse.
Operates over a wide range of anode voltages without readjustment.

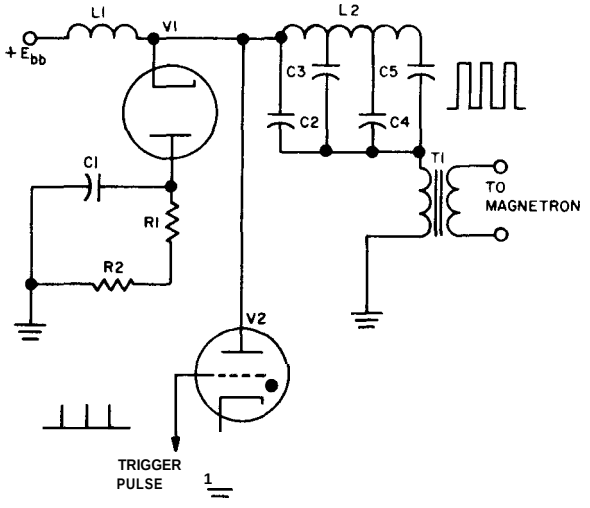
Circuit Analysis.

General. The hydrogen thyratron is a versatile electronic switch which requires a positive trigger of only 150 volts rising at the rate of 100 volts per microsecond. In contrast to spark devices, the hydrogen thyratron operates over a wide range of anode voltages and repetition rates. Its grid has complete control of initiation of cathode emission over a wide range of voltages. The anode is completely shielded from the cathode by the grid. Thus, effective grid action results in very smooth firing over a wide range of anode voltages and repetition frequencies. Unlike most other thyratrons, the positive grid control characteristic ensures stable operation. In addition, the deionization time is reduced by using the hydrogen filled tube. This makes the performance of the

tube relatively independent of ambient temperature so false triggering is avoided.

The hydrogen thyratron modulator provides improved timing because the synchronized trigger pulse is applied to the control grid of the thyratron and instantaneous firing is obtained. In addition, only one gas tube is required to discharge the pulse forming line, and a low amplitude trigger pulse is sufficient to initiate discharge. A damping diode is used to prevent breakdown of the thyratron by reverse voltage transients. The thyratron requires, for a driver pulse, a sharp leading edge and depends on a sudden drop in anode voltage (controlled by the pulse-forming line) to terminate the pulse and turn off the tube.

Circuit Operation. The schematic of a typical thyratron gas tube modulator circuit is shown in the accompanying illustration.



Typical Thyratron Gas Tube Modulator Circuit

L1 is a charging inductance. The damping circuit consists of damping diode Vl, current limiting resistors R1 and R2, together with r-f bypass capacitor Cl, which hold the plate of V2 at ground level during each negative half cycle of operation, thus eliminating the possibility of a negative overshoot and the production of damped oscillations. Inductor L2 with capacitors C2, C3, C4 and C5 form the pulse-forming line which develops and shapes the output pulse. Transformer T1 couples the shaped pulse output of the circuit inductively to the magnetron.

With no trigger pulse applied, as the circuit is turned on, the pulse forming line charges through the primary of Tl, the pulse forming line, charging inductor L1, and the power supply to ground. When the pulse-forming line reaches maximum charge, a synchronized trigger pulse is applied to the grid of thyratron V2, ionizing the tube (which acts like a closed switch) and provides a discharge path for the primary of T1 and the pulse-forming network to discharge to ground, through V2. As the voltage across the pulse forming network discharges and falls below the ionization level of the thyratron tube, the tube shuts off like opening a switch. However, there is a tendency for the positive discharge voltage to swing negative as it is abruptly stopped and cause negative overshoot because of the inductive properties of the discharging circuit. This negative overshoot is prevented from affecting the output of the circuit by the insertion of damping diode VI and the damping circuit consisting of Rl, R2, and Cl. This damping circuit provides a path for the overshoot transient through Vl, and it is dissipated by RI, and R2. Cl is a high frequency bypass to ground to preserve the sharp leading and trailing edge of the rectangularly shaped pulse.

Failure Analysis.

No Output. The following defects can cause a no-output condition. Low plate supply voltage, an open charging choke L1, or pulse-forming line choke L2, the windings of T1 being shorted or open, a defective tube V2, or a trigger pulse of insufficient voltage to ionize V2.

Check the plate supply voltage, if it is not normal, the trouble is probably in the power supply and the modulator circuit is probably not at fault. If plate voltage is normal, check the voltage on the cathode of V1. If no voltage is present, L1 is open.

If no voltage is present on the primary of Tl, pulse-forming line inductor L2 is open.

Make a point to point check with dc voltmeter (make certain you observe all high-voltage safety regulations) for the proper voltages in the charging circuit. Should no voltage be present at any of the points, the component or components associated with that portion of the circuit is defective; check the inductors with an ohmmeter (be careful to use a shorting stick to make certain the line is discharged)

and the capacitors with an in-circuit capacitor checker. With an oscilloscope, check for the proper trigger pulse (both arn'plitude and repetition rate).

Low Output. Insufficient plate voltage, an improper trigger pulse, a defective pulse-forming network, or a defective magnatron transformer, T1, can cause a low output. Use an ohmmeter for checking the inductors and transformer T1 (make certain the pulse network is discharged first), and an in-circuit capacitor checker for checking the capacitors in the pulse-forming line.

Distorted Output. With the proper trigger signal and plate supply voltage, a distorted output can be caused by shorted turns on inductors L1, and L2 or on the windings of T1. Use an ohmmeter to check for proper values. The pulse-forming line components, if defective, can also cause the output to become distorted. These can be roughly checked with an ohmmeter and an in-circuit capacitor checker.

HARD-TUBE MOD ULATOR

Application.

The hard-tube pulse modulator is used in radar equipments to develop the pulse which controls the operation of the transmitter.

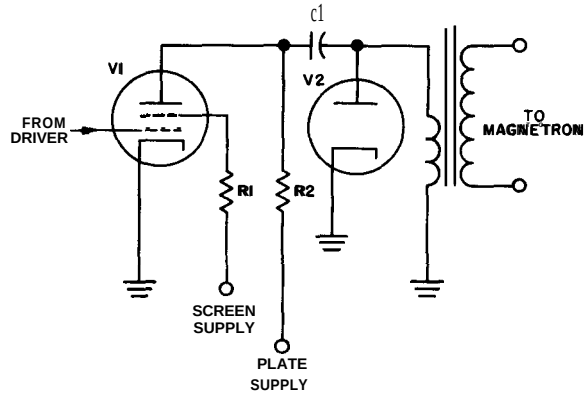
Charactaristk

Needs a shaped high-voltage pulse for operation.
Biased to cutoff.
Has gain of about 10.

Circuit Analysis

General. The hard-tube pulse modulator operates as an amplifier tube with a gain of about 10. The modulator tube is normally biased to cutoff. The application of a positive pulse of about 1300 volts to the grid is necessary to overcome the bias, causing VI to conduct and dropping the plate-to-cathode potential from the plate supply value established by the cutoff condition. Because of the large resistance of the plate load resistor, the negative voltage pulse developed by this action is effectively applied to the output transformer and the modulator tube in series. Since the impedance of the modulator tube is about one-tenth that of the output transformer, about nineteenths of the voltage pulse appears across the output transformer. The time between pulses is known as the charging time. A damping diode is in the circuit to damp out the oscillations produced by a negative overshoot when the positive pulse applied to the grid of the modulator is terminated. The damping is accomplished on the first oscillatory swing by shorting it to ground (the negative pulse on the cathode causes the diode to conduct).

Circuit Operation. The schematic of a typical hard-tube modulator is shown in the accompanying illustration.



Typical Hard-Tube Pulse Modulator

V1 is the modulator tube, R1 is the screen voltage dropping resistor, and R2 is the plate load resistor for VI. Capacitor Cl couples the output of the modulator to output transformer T1. Tube V2 is the damping diode, and T1 is the step-up output (magnetron) transformer.

With no trigger pulse applied from the driver, coupling capacitor Cl charges to the plate supply voltage through the primary of T1, R2, the power supply and ground. Tube V1 is biased at cutoff and the plate-to-cathode potential is established by the cutoff condition. A synchronized trigger pulse from the driver circuit is applied to the grid of V1 taking the tube out of cutoff and causing it to conduct. This is similar to closing a switch, and provides a path for Cl to discharge through both the primary of T1 and V1 to ground. This discharge occurs only for the duration of the trigger pulse applied to the grid of VI. When the trigger pulse terminates, the modulator is again cutoff and the magnetic field in the primary of T1 collapses, causing a reverse flow of electrons in the circuit. This reverse flow of electrons is prevented from causing negative oscillations by diode V2, which

conducts as soon as the plate goes in a positive direction (when a negative pulse appears on the cathode). Thus, diode V2 dampens any oscillations which would effect the output pulse of the modulator circuit.

Failure Analysis.

No Output. Should plate load resistor R2 open, coupling capacitor Cl open, damping diode V2 short, or the windings of transformer T1 be open or shorted, no output would appear on the secondary winding of T1. First check for plate supply voltage at the source. If the supply voltage is present, a drop should appear across R1. At the junction of R2, Cl, if no voltage is present, R2 is open. Check the windings of T1 for continuity or a short, with an ohmmeter.

Low Output. An incorrect plate or screen supply voltage, a weak VI, shorted turns on transformer Tl, or any of the components in the circuit changing value could cause a low output. Check all supply voltages and the trigger voltage from the driver. If any of these voltages are incorrect, the trouble is in that stage and the modulator circuit is probably not at fault. Check screen and plate load resistors R1 and R2, respectively, with an ohmmeter. Check coupling capacitor Cl with an in-circuit capacitor checker, and transformer T1 with an ohmmeter.

Distorted Output. Distortion can occur from any of the following: an improper trigger pulse, a change in screen or plate supply voltage, a defective VI or Tl, a leaky coupling capacitor Cl, or load resistors R1 or R2 changing value. If the driver output puke applied to the grid of the modulator is not the proper pulse repetition rate or amplitude, the trouble is in the preceding stages and the modulator is probably not at fault. If the screen and plate voltages are correct, and the output is stiU distorted, determine that Cl is not leaky by using an in-circuit capacitor checker. Determine that load resistors R1 and R2 are the correct value and that output transformer T1 has no shorted windings.

SECTION 13
SPECIAL CIRCUITS

PART 13-1. SPECIAL PURPOSE TRANSISTORS AND CIRCUITS

TETRODE, POWER, AND SPECIAL PURPOSE TRANSISTORSAND CIRCUITS

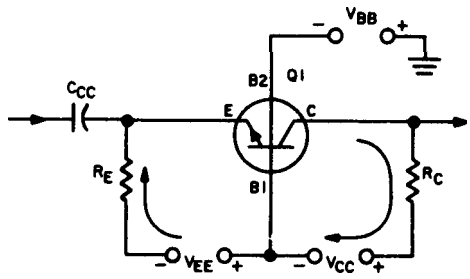
General.

In this section, various types oftetrodes, power considerations, power transistors, special purpose transistors, and their basic circuitry are presented. For general information on transistors and transistor biasing, refer to the Amplifier Section of this Handbook.

Tetrodes.

The addition of a fourth element to a transistor produces a tetrode transistor. Both junction and point-contact transistors can be formed into tetrodes. In the junction transistor the fourth electrode is essentially another base electrode (B2), whereas in the point+ ontact type it is essentially another emitter (E2).

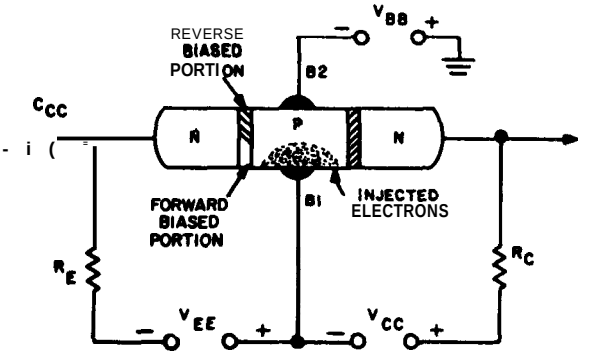
Junction Tetrode (Double-Besed Transistor). The junction tetrode consists of a conventional junction transistor with another base electrode (B2) added on the side opposite the BI connection. The addition of proper bias between the base electrodes decreases the collector capacitance and the base resistance, and thus improves the high-frequency response, As compared to a conventional junction transistor which has a high-frequency cutoff of approximately 30 MHz, a tetrode will have good response up to 200 MHz. A basic junction tetrode circuit is shown.



Junction Tetrode Circuit

The NPN transistor is used as an illustration for ease of explaining the operation. The tetrode is connected in the same manner as a triode, with forward emitter-junction bias and reverse collector-junction bias. Between base 1 and base 2, however, a large value of voltage is connected (on the order of volts as compared with tenths of a volt), usually about 6 volts. Since the base material is a semiconductor and the points of application are on opposite sides, there is a definite resistivity between B1 and B2 which produces a uniform drop across the base (if the base were ohmic, a short circuit would ensue). Since the applied base bias is negative and large, it blocks electron current flow through all parts of the base region, except for a small volume near the B1 connection. Thus the current is restricted to the small controlled space around the B1 terminal as shown in the following illustration. This effective reduction of the volume of the base region reduces the resistance to base current and also the base-collector capacitance through the collector junction. The over-all result

is to improve the high-frequency response of the transistor.

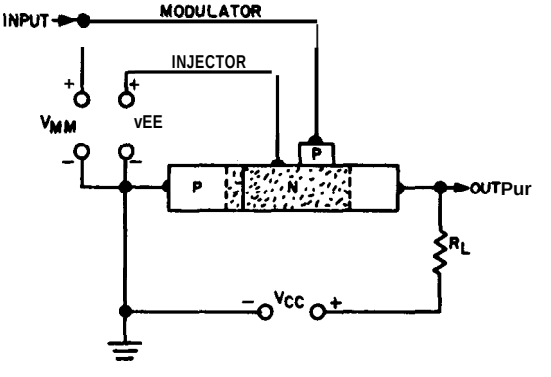


Tetrode Action

Since the entire base area is not available for current passage, the over-all current gain of the tetrode transistor is less than that of the triode type. At the higher frequencies (above 30 MHz) the performance of the tetrode is superior to that of the triode, and the improvement in frequency response offsets the slight loss of stage gain.

Spacistor Tetrode. The spacistor tetrode provides a high input impedance (up to 30 megohms) and a high output impedance (on the order of megohms), with reduced input and output capacitance and a very short transit time. It is capable of power amplification of 70 dB and a voltage gain as high as 3000. Operation is possible up to several thousand MHz, as compared to an upper limit of 300 to 400 MHz for the other types of high-frequency transistors.

A basic spacistor circuit is shown in the following illustration. The spacistor basic PN junction is reverse biased, and is manufactured so that the P-region contains a smaller depletion area than that of the N-region. The P-region acts as the base and the N-region as the collector. By the use of a large reverse bias (on the order of 100 volts), a strong electric field is produced across the junction, but because of the reverse bias only a small reverse current flows. An emitter connection (called the injector) is made on the large N-depletion area of the junction, and it is also reverse-biased. The emitter bias is chosen so that it is less than the collector bias, and an electron current flows from the emitter to the collector electrode. The magnitude of this electron current is proportional to the difference of voltage between the emitter and collector, and, because of the intense electric field through which it flows, the transit time is very small. A fourth electrode (called the modulator) is connected to a small piece of P-type which forms another PN junction with the large Ndepletion area, and is located very close to the emitter connection. While the modulator is positively biased, it is less than the collector bias, so that the modulator is effectively reverse-biased with respect to the collector. Therefore, practically no modulator current flows, and a high input resistance (several megohms) is obtained. When the modulator bias is varied, as by an input signal, the current flow between the emitter and collector is varied accordingly. Thus the modulator electrode acts similarly to the grid of an electron tube, and the emitter acts similarly to the cathode.



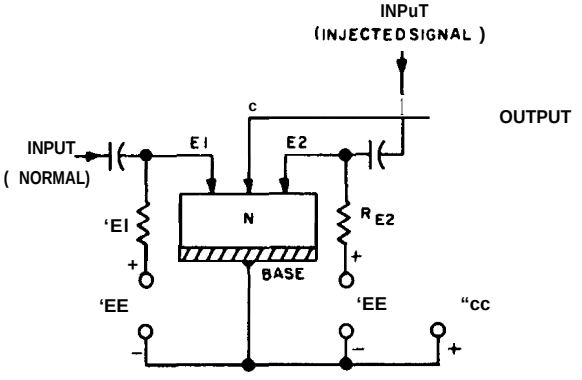
Spacistor Circuit

Because the emitter and modulator electrodes cover only a small area, the input capacitance is low. The collector-to-base (output) capacitance is also low because of the effect of the large N-depletion area, which reduces the total capacitance by effectively providing greater separation between the collector and base. As a result of the reduction of capacitance and the short transit time from emitter to collector, the high-frequency response is greatly improved.

Crystal-Mixer Tetrode. The crystal-mixer tetrode is a special four+ lement, point-contact device specially developed and constructed for use as a mixer. Although it has the same number of elements

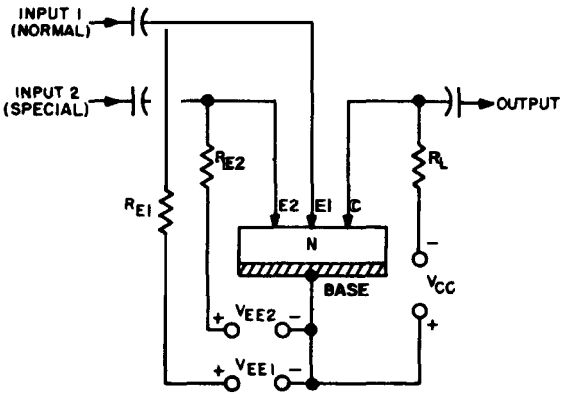
as the point-contact tetrode, it differs in construction and operation. This unit has approximately the same conversion gain as a conventional vacuum-tube mixer, but it operates better at high frequencies. It is superior to the conventional crystal-diode or triode mixer.

The mixer tetrode is constructed with two emitters and one collector as shown in the following illustration. The emitters are located at equal distances on opposite sides of the collector so that both emitters have the same effect on the collector. The collector output is equal to the sum of the outputs it would have if each emitter were operated separately, provided that the collector is not given into saturation.



crystal Mixer Tetrode

Point-Contact Tetrode. The conventional point-contact four-element (tetrode) transistor differs from the specially constructed crystal-mixer tetrode discussed above in both operation and construction. (See the following illustration.) Emitter No. 2 in the point-contact tetrode is spaced a greater distance from the collector than emitter No. 1. Both emitters are forward-biased and the collector is reverse-biased, as in a junction transistor. When emitter No. 1 is connected and emitter No. 2 is left open, the transistor operates like a conventional triode with a current gain of 1.5" to 3. When emitter No. 2 alone is used, because of the greater spacing from the collector, the current gain is small (about 0.2). When both emitters are used together, the current gain of emitter No. 1 is enhanced considerably, from 4 to 8, which is roughly 2-1/2 times the original value. Emitter No. 2 may be used as an input control element, if desired, and the current gain will vary according to the input signal.



Basic Point-Contact Tetrode Circuit

The increase in current gain when both emitters are properly biased and operated simultaneously results from the fact that the concentration of holes injected by the first emitter attracts electrons away from the base region, between the second emitter and the collector. This reduces the possibility of electron-hole recombination and enables many of the second-emitter injected holes to reach the collector, thereby increasing the flow of collector current.

Power Transistors and Considerations.

Power transistors use special construction and design considerations to achieve rated output. The conventional transistor is usually operated at low voltages and low values of current, whereas the power transistor is operated at relatively high voltages and high currents to produce power outputs. The classification of power transistors, however, is somewhat arbitrary, and does not include the same order of values as used for electron tubes. For example, transistors of from 2 to 50 milliwatts are classed as non-power types, from 50 milliwatts to 500 milliwatts (1/2 watt) as low-power types, from 500 to 1000 milliwatts (l-watt) as medium-power types, and all over 1 watt as high-power types.

Because the transistor is a nonlinear device, it does not respond to large signals (where variations in collector voltage and current are a significant fraction of the total range of operation) in the same manner as it

responds to small signals; hence, small-signal parameters are used to define nonpower (linear) operation, and large-signal parameters are used to define power (nonlinear) operation. Small signals can arbitrarily be defined as those which are less than 1 volt, and large signals as those which are greater than 1 volt. Since it is possible to have a small signal driving a power amplifier, it can be seen that sometimes either parameter can be used to predict circuit performance with good approximations.

While both point+ ontact and junction transistors can be used as power amplifiers, the point-contact type is usually limited to values not greater than 1 watt. This limitation is due to the fact that the point contact is unable to carry a heavy current without excessive heating and consequent damage to the transistor.

The power transistor must be able to dissipate the internally generated heat while operating at the increased temperature resulting from its own heat. It must also be able to operate at high currents and voltages without breaking down or causing excessive non-linearity (distortion). Since the junction transistor does not concentrate the heat around a point source, but spreads it throughout the junction, it has a definite advantage for power use. Both NPN and PNP junctions may be used, and they operate fundamentally the same regardless of the method of manufacture (grown junction, diffused-junction, alloy junction, etc.).

The current rating of a power transistor is the maximum collector current that can safely be carried by the transistor, without exceeding the power rating, causing internal damage, or producing an excessive loss of current gain at higher emitter currents.

The voltage rating of a power transistor is the voltage for which a specific leakage current occurs for a specific circuit configuration and operating current.

The power rating of the transistor is the maximum permissible power which may be safely dissipated by the unit without exceeding the maximum junction temperature and causing damage instantaneously or over a period of time.

The saturation voltage is the value below which the collector voltage cannot be further reduced, even by increasing the input current.

The thermal resistance of a transistor is the ratio of the difference in actual power rating with respect to the rise of temperature of the transistor. It is commonly expressed in degrees centigrade/milliwatt, or watt.

Thermal runaway is the condition whereby a small increase of collector leakage current occurs, because of an increase in the ambient temperature of the junction, and causes an increase in junction temperature, which, in turn, causes another increase of leakage current. This action builds up in an exponential manner, until complete thermal runaway occurs, permanently damaging the transistor. The power transistor is most sensitive to thermal runaway when it is operating near its maximum collector dissipation value and no thermal compensation circuitry is used. Thermal compensation is discussed later in this section of the handbook.

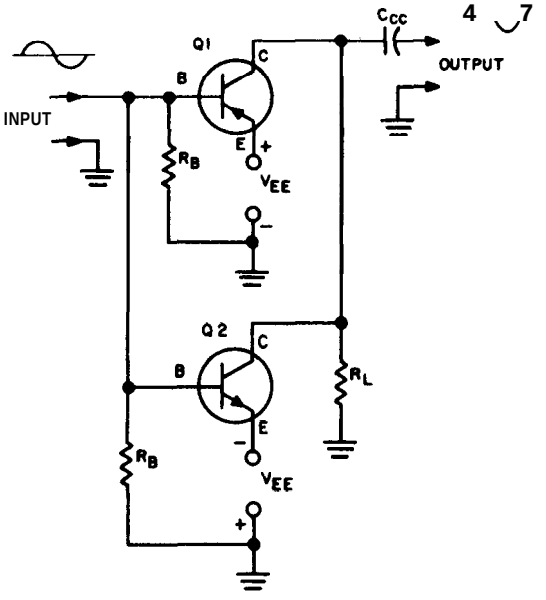
Either of two general methods is used to provide for heat dissipation and improve the power-handling capability of a power transistor-the use of a so-called infinite heat sink or liquid cooling of the transistor. The heat sink consists of an integrally constructed base mount, usually made of copper, plus a physical connection from the transistor shell to the collector. The base mount usually is directly connected to the chassis, which serves as the infinite heat sink. In cases involving high power, a special heat sink is provided, including fins for heat radiation into the surrounding air, and sometimes the transistor shell is provided with fins. Where the transistor cannot be grounded directly to the chassis, it is usually insulated from the chassis by a thin mica sheet. Liquid cooling is accomplished by sealing a cooling agent in the transistor case and allowing liquid convection to the metal case to provide the transfer of the heat to the air. In extreme cases, a circulating system is provided and the transistor is immersed in the cooling liquid similar to a water-cooled electron tube.

Medium power transistors usually employ Class A amplification, whereas higher-powered units use Class AB or B amplification because of its increased efficiency. See the introduction to the Amplifier Section of this handbook for an explanation of classes of operation. Class C is seldom employed because of the distortion produced, except for transmitting circuits which use the flywheel effect of the tank circuit to overcome the distortion, as in electron tube operation.

Complementary-symmetry circuits are also used to provide additional power output with a reduction in the number of components required and the over-all

4

circuit cost. The following figure shows a typical complementary-symmetry, push-pull circuit using an NPN transistor for one half of the circuit and a PNP transistor for the other half. Since the polarities and currents in these transistors are opposite and equal (for matched units), it is evident that one transistor works on one half of the input cycle and that the other transistor works on the other half of the cycle. The out-of-phase outputs are added at the proper time (in-phase) to produce an output from the load resistor which is equal to the continued effect of the collector currents.



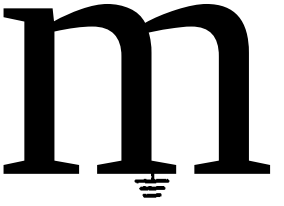
Complementary-Symmetry Push-Pull Circuit

Power transistors are used in audio, video, and r-f applications where outputs are required to operate electromagnetic or electrostatic output devices, in switching circuits, and in power circuits as substitutes for relays. They are especially advantageous when used as power converters to supply high voltage dc or ac from low-voltage d-c supplies to mobile, aircraft, or marine equipment. They provide increased efficiency of conversion and eliminate maintenance, mechanical, and interference problems encountered with vibrators, generators, or dynamotors.

Special-Purpose Transistors and Circuits.

The special-purpose transistors and circuits discussed in the following paragraphs are representative of the present state of the art, Discussion is limited to the salient points considered necessary for the user of this technical manual in the event some of the special-purpose devices are encountered. Emphasis has been placed on presenting functionally different types, rather than manufacturer's claims for proprietary construction and materials.

PNPN Triode (Hook Collector). The PNPN triode transistor is a four-layer semiconductor device with three junctions, and exhibits a high current gain in the common-base connection. It is illustrated in the following figure. This transistor has been used more in switching circuits than in other applications because of its higher noise level, leakage currents, and limited frequency response. The transistor essentially consists of a conventional triode two-junction PNP unit with an added N-layer at the collector end. The emitter P-area (Jl) and the collector N-area (J3) are forward-biased, the base N-area is gounded, and the second P-area is left floating between the base and the collector. As a result, the middle NP junction (J2) is effectively reverse-biased. Hence, the Pl, N1, and P2 sections are comparable in action to an ordinary triode transistor. The floating P2 region, however, causes a few unusual effects. The potential hill due to the depletion region at junction J3 has a great retarding effect on the holes from the emitter, causing a "space charge" of holes to build up on the P2 side of J3. The result of this is a reduction of the J3 junction resistance, thereby allowing increased electron movement from the N2 section into the P2 section. The complete path for this current (except the small part which recombines with some of the holes) is from the negative terminal of V_{cc} to N2, P2, N1, base lead, and back to V_{cc}.



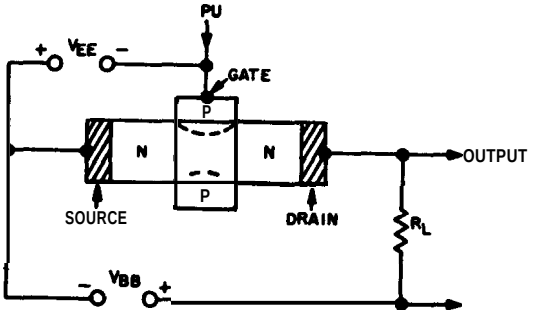
PNPN Triode

Large values of current amplification may be obtained since a relatively small accumulation of holes in the P2 section gives rise to a much larger number of electrons from the N2 region. Control of the collector current is obtained since it is determined by the number of "trapped" holes in the P2 region, which in turn is controlled by the emitter current; the emitter current, of course, is determined by the input signal to the transistor. The name hook collector is derived from the transistor energy diagram, which resembles a hook. NPNP transistors have also been manufactured.

The hook transistor operates as an amplifier and should not be confused with the PNPN switch or with the silicon-controlled rectifier which operates similarly to a thyratron tube. In the PNPN triode switch or controlled rectifier, the second P-area is always the gated region, whereas in the hook collector it is left floating.

Unipolar (Fieid-Effect Transistor). The unipolar transistor uses a unique construction to utilize the effect of an electric field to control the passage of current carriers through the basic semiconductor bar. It offers a high input resistance (about one megohm) with a relatively high output resistance and good high-frequency response.

The basic unipolar circuit is shown in the following figure. The basic N-germanium bar has a potential applied between the source-end and drain-end in series with load resistor R_L. The circular P-alloy (called the gate) which encircles the bar is reverse-biased to the source-end of the bar. The field effect produced by the reverse bias depletes the area beneath the P-electrode of current carriers. The input signal varies the basic conductivity of the N-bar and effectively controls the current supplied by the source. Thus, current flow through the load resistor produces a corresponding but amplified output voltage.

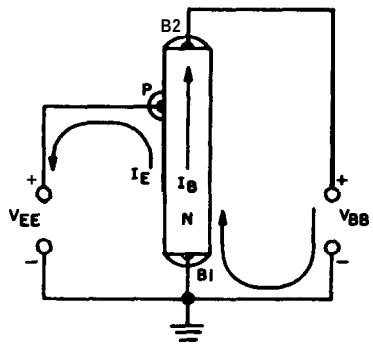


Unipolar (Field-Effect) Transistor

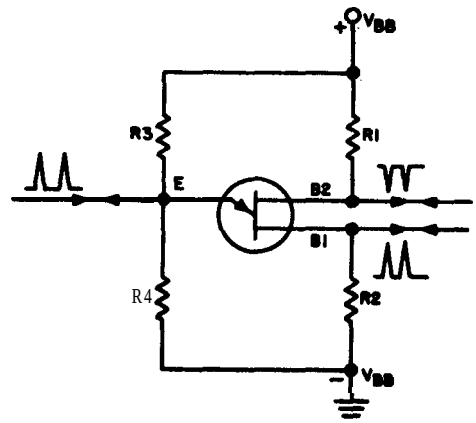
Since the predominant carrier in N-type material is electrons and they are controlled by the electric field between the gate and source-end of the bar, and since holes are not involved, the term unipolar was derived to indicate that only one carrier is involved.

The advantage of this type of device is that a small signal controls a much greater output, which is limited essentirdly only by the size of the source supply and the resistivity of the basic bar material. Applications are somewhat limited by a rather high noise figure.

Unijunction Transistor (Double-Based Diode). The silicon unijunction transistor is a three-terminal semiconductor device, sometimes called a double-based diode, which is unique in that it can be triggered on by, or an output can be taken from, each of the three terminals. Once the unit is triggered, the emitter current increases regeneratively until it is limited by the power supply, thus, the action of the transistor is similar to that of the gas thyratron tube. It can be employed in a variety of circuits, but it finds its greatest usefulness in the switching and pulse fields. The basic unijunction bias connections are shown.



Unijunction Transistor



Unijunction Input and Output Points

The unijunction transistor consists of an N-type silicon bar with two ohmic base contacts at the ends and a P-type emitter (PN junction) near base No. 2 (B2). A base biasing potential, applied between the two base contacts, establishes a voltage gradient along the bar; the emitter is located nearer B2, so that more than half of the base bias along the bar appears between the emitter and base No. 1. If an external potential is applied between base No. 1 and the emitter greater than the internal voltage gradient between the same points, the junction is forward-biased; if the external potential is less than the internal voltage a reverse-bias is produced. Normally, reverse bias is applied between the emitter and base No. 1 (B1) so that in the off condition the emitter current is at cutoff. When a positive trigger pulse of voltage is applied to the emitter (or a negative trigger to B1 or B2), the emitter is forward-biased. An increased hole current causes a reduction in the resistance, and a reduction in the internal voltage drop between the emitter and base one. As a result, the emitter current increases regenerativdy until it is limited by the power supply. This action is spoken of as conductivity modulation of the interbase current. The unijunction is returned to the off state by a negative trigger at the emitter. A typical circuit showing input and output points is shown in the following illustration.

Resistor R3 and R4 forma bias voltage divider for the emitter, which normally holds the circuit at cutoff. An input applied across R4 will produce a relatively high-voltage output across R1 and a relatively low-voltage output across R2. An input across R2 will produce an output across R1 and R4. Likewise, an input applied across R1 will produce outputs across R2 and R4.

Since the silicon base bar is temperature sensitive, this device can also be used in temperature-sensitive control applications by utilizing the variation of resistivity of the base with temperature. The interbase resistance increases with temperature at a practically constant rate. A typical value is 0.8 percent per degree C.

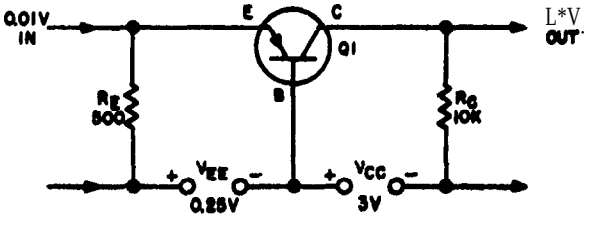
Surface-Barrier Transistor. The surface-barrier transistor is a specially constructed germanium device which is quite similar to the PNP junction transistor in operation. It has a lower noise figure, an excellent high-frequency response (about 50 times that of the alloy junction), and will operate at extremely low currents.

Manufacturing is by the chemical (electrolytic) etching process, which produces cavities on opposite sides of a thin, pure N-type germanium wafer. Then the same process is reversed to electro-deposit metallic electrodes in these cavities. The thin base region (about .0002 inch) helps produce the excellent high-frequency response, and the etching and plating processes provide excellent control of transistor characteristics. Junction alloy transistors use ohmic

4s1.044 0 73 74

non-rectifying contacts to the semiconductor. The surface-barrier transistor uses metal electrodes which are excellent rectifiers and operate efficiently as collectors or emitters for the minority carriers. The collector electrode is made larger than the emitter electrode to provide a high current gain. Operation depends upon the surface-barrier effect; that is, the electric field which exists at the surface of the germanium excludes both holes and electrons from a thin region near the surface. The addition of the metal electrode to the germanium produces a concentration of holes (minority carriers) directly under the surface. Forward-biasing of the emitter attracts the holes to the region between the electrodes, and reverse-biasing of the collector provides a means of collecting the holes as they diffuse across the thin base region.

The following illustration shows a typical CB amplifier arrangement using SBT transistor and indicates the operating voltages and gains. A voltage gain of 190 is realized, with an overall power gain of 159.

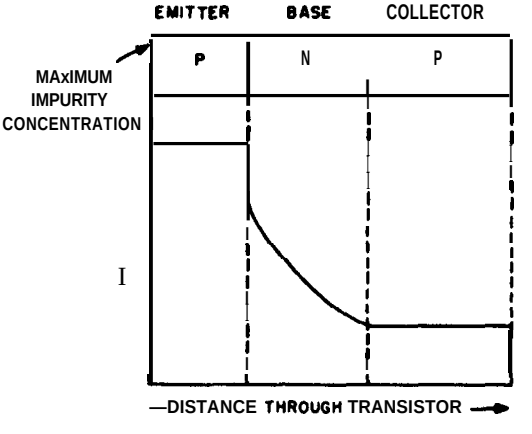


Typical SBT Common-Base Circuit

PNIP-NPIN Transistors. These transistors operate and are connected similarly to the conventional type transistor. Their basic difference is in construction; an intrinsic area is inserted between the base and collector areas. The over-all result is to reduce the base-to-collector capacitance and permit higher-frequency operation (on the order of 900 MHz maximum).

Drift Transistor. This transistor uses a construction which gradually changes the resistivity of the semiconductor from a highly conducting material at the emitter to a more resistive material (nearly pure germanium) at the collector. When a potential is applied between the emitter and collector, an electric field effect is produced which causes the internal carriers to drift across the junctions at high velocity, instead of relying upon diffusion effects. Thus, the drift transistor can be operated at higher frequencies than the normal junction transistor.

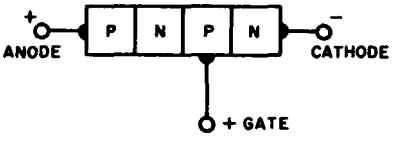
The impurity concentration gradient for a typical drift transistor is shown in the following figure. It is also representative of the resistivity gradient and the electric field produced, which vary in the same manner. Because of the variable impurity distribution in the base region,less of the depletion area extends into the base, and the total effect is that of widening the depletion area. Shorting of the transistor by punch-through effect as the collector voltage is raised is eliminated, because the depletion area will gradually extend into the base and collector areas and be blocked by the heavy impurity concentration near the emitter region, limiting further spread to the collector region. At the same time, the strong electric field produced, by the varying resistivity gradient from one end to the other of the transistor causes an attraction for the minority carriers and thus urges injected holes across the base region in the same direction as the diffusion currents. The result is to provide a shorter transit time for the injected carriers than would normally occur for the same base width if only the diffusion process were acting as a transport medium. With a shorter transit time, the high-frequency response is extended above that of the normal transistor.



Drift Transistor Construction

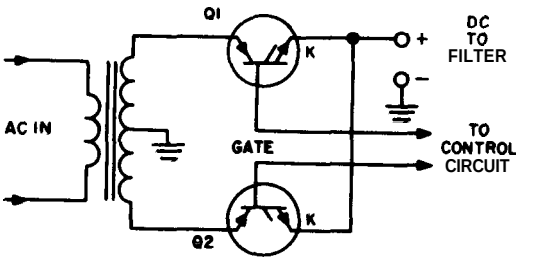
Diffused-Base (MESA) Transistor. The diffused-base transistor utilizes manufacturing processes to produce a physically thin diffused-base alloy on a basic germanium bar. Thus the collector-base capacitance is reduced, and the slowness of the diffusion process through the base region is minimized. Better high-frequency response results.

Silicon Controlled Rectifier, The silicon controlled rectifier is a silicon 3-junction, 3-terminal device. It is the semiconductor equivalent of the thyratron tube. It can be either a PNPN or a NPNP unit. In the PNPN unit, the anode is the P terminal and the cathode is the N terminal. The internal N region is not connected externally, but floats between the anode and the second P region or external gate terminal (see the following figure).



Silicon Controlled Rectifier

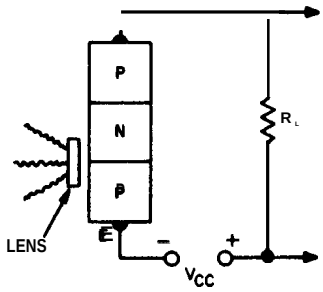
The controlled rectifier is connected as a conventional rectifier with anode to positive and cathode to negative. In this condition, both end junctions are forward-biased, but the middle junction is reversed-biased, and only a small reverse current flows (conduction is effectively blocked). When a positive gate, is applied to the gate electrode, the middle junction is forward-biased and heavy current flows; or, when a specific blocking voltage is exceeded, the silicon controlled rectifier also breaks down and operates exactly as if gated. Once conduction is initiated, it continues until either the current or the voltage drops below a small holding value or until the external circuit is interrupted. Following is a typical circuit utilizing two controlled rectifiers in a full-wave rectifier circuit. The output level is determined by the control circuit. These units are operable over ranges of from 20 to 600 volts blocking and currents of 1 to over 100 amperes, under control of gates from less than 1 volt at 1/4 milliampere to 3 to 4 volts at 10 milliamperes, with turn-on time of 1 to 5 microseconds and turn-off times of 10 to 20 microseconds.



Controlled Rectifier Circuit

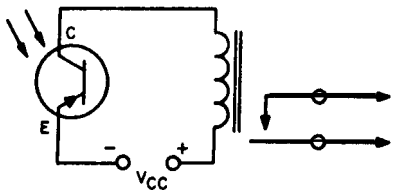
Phototransistors. The phototransistor is a combination of two junction diodes arranged as a conventional transistor, for example, in a PNP configuration, with only the two end leads brought out. The mechanical arrangement is such that light is focused on either one or both junctions to vary the conductivity of the unit. This unit is identical in operation to the photodiode, except that it is much more sensitive, from 50 to 500 times, because of transistor action.

The following figure shows that the connections are the same as for the photodiode and that the emitter junction is reverse-biased, with the collector junction forward biased and the base floating. Biasing is achieved through the internal resistance of the junctions. The emitter is more negative than the collector, and the base floats somewhere in between, being at a lower positive potential than the collector, so that it is effectively reverse-biased (assuming a PNP unit). Since the base is truly floating (it is not connected to any input or returned to ground except through the internal base-emitter resistance), it is extremely susceptible to any light impinging on the junction. Variations in light intensity cause the junction conductivity to vary, and thus act similarly to an input signal applied to a conventional emitter-base junction. Since the collector junction is forward-biased, the changing emitter conductance causes corresponding and amplified changes of collector current, developing an output across load resistor R_L.



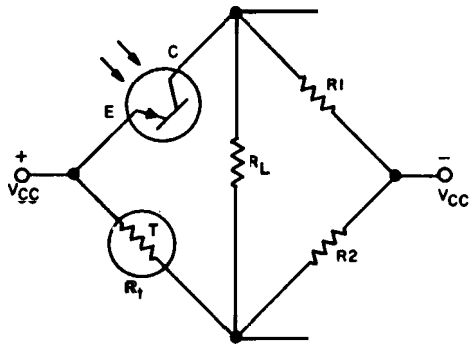
Phototransistor Circuit

Because of the large collector current control offered by the phototransistor, it may be used directly to control a relay connected to turn power on or off, or to operate a switching circuit; see the following figure.



Phototransistor Relay

The phototransistor is subject to humidity and temperature changes like the photodiode. Humidity effects are dependent upon the construction and encapsulation processes, but temperature variations may be compensated for by the use of a bridge circuit and a thermistor of equal but opposite characteristics. See the following illustration.



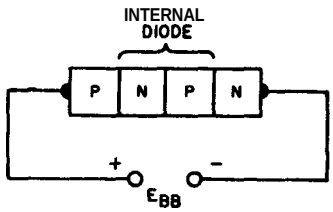
Thermistor-Compensated Bridge Circuit

Thermistor. A thermistor is a special semiconductor device which functions as a thermally sensitive resistor whose resistance varies with temperature. Thermistors have large negative temperature coefficients; that is, as the temperature rises their resistance decreases, and as the temperature drops their resistance increases. The resistance of a thermistor is varied not only by ambient temperature changes but also by heat generated internally by the passage of current.

Since the thermistor is basically a variable resistor, it is usually constructed from semiconductor material of greater resistivity than is used in transistors or semiconductor diodes. Therefore, its response to ambient temperature variations does not track equally with that of the transistor semiconductor, so that compensation is achieved only at a few points of correspondence. As a result, its greatest usage is in the field of temperature controls and measurements, and power-measuring equipment based on heating effect, such as r-f measuring microwave equipment. Although it is a semiconductor, it has no intrinsic amplification capability like the transistor, and is mentioned in this technical manual only because it is used in thermal compensating circuits for transistor stabilization.

PNPN Switching (Four-Layer Diode). The four-layer diode is a two-terminal device which operates in either of two states; an open, or high-resistance, state or a closed, or low-resistance, state. It is effectively an on-off switch which can be employed as such in switching circuits, or it may be used as a relaxation oscillator or multivibrator. In the non-conducting

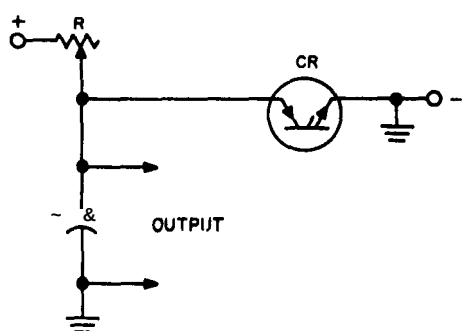
state it presents a resistance on the order of megohms, and in the conducting state it presents a low resistance of about 200hms. The following figure shows typical biasing polarity with the P_{-end} connected to positive and the N_{-end} connected to negative, a



PNPN Diode Bias Conditions

forward-biased condition. The internal NP junction, then, is reverse-biased and held in an almost nonconducting condition; this is the resting open-circuit, or high-resistance, condition. As the bias voltage is increased, it reaches a point which produces a condition similar to avalanche breakdown in the internal junction, and heavy current flows. Since there is no connection to the internal junction except through the other semiconductor material, there is a small minimum resistance at full current flow; this is the closed-circuit, or low-resistance, condition.

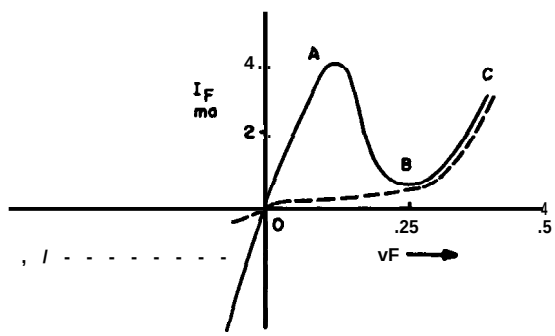
A basic switching diode circuit is shown in the following illustration.



Basic Switching Diode Circuit

Tunnel Diodes. Basically the tunnel diode is a PN junction formed of a semiconductor mixture which is impregnated with more than the normal amount of impurities. The resulting crystrd has current-voltage transfer properties which are different from those of the normal diode junction.

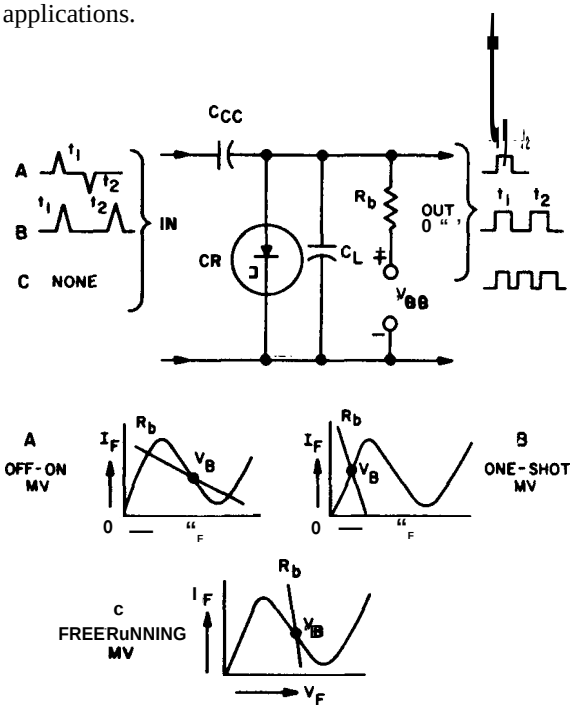
The following figure shows a typical diode transfer characteristic plotted as a dashed line, with the tunnel diode characteristic superimposed in the form of a solid line. Note that diode forward current increases with applied forward-bias voltage until point A is reached, then it reverses itself and decreases with increase of applied voltage to point B; between points B and C the curve is similar to that between O and point A. The region of operation between points A and B is a negative-resistance region over which the diode may be used on an amplifier or oscillator, since negative-resistance devices are capable of supplying power to the source instead of absorbing power from it.



Tunnel Diode Transfer Characteristics

The tunnel diode is also of value in switching circuits. Because three or more regions of operation are possible, it is only necessary to select the proper bias and load line to achieve different types of operation with the same circuit. A basic switching circuit utilizing the tunnel diode for three different functions is shown in the following illustration. Under condition A the load line is adjusted so that it intersects the characteristic curve at three points; two are in the positive-resistance region and the third is in the negative-resistance region. Application of a positive pulse turns the diode on, and application of a negative pulse turns it off; thus the circuit operates as an off-on multivibrator. Under condition B the diode

is operated in the positive-resistance region and functions as a one-shot multivibrator, producing a rectangular puke for each trigger pulse. Under condition C the diode load line is set so that it never intersects the positive regions of the characteristic curve, and the circuit operates in an eatable condition as a free-running multivibrator. The tunnel diode can operate at frequencies up to 1000 MHz at high switching speeds and appears particularly adapted for computer applications.



Tunnel Diode Operating Characteristics

Transistor Junction Symmetry. The low conduction resistance and low leakage currents of the fused junction transistor permit many applications using the transistor as a controlled switch. In the conducting condition these switches present a resistance of only a few ohms, and when cut off they offer impedances or resistances of hundreds of thousands of ohms to many megohms. Where the voltages and currents to be controlled are small, the inverted transistor connection offers slightly improved 'but different operating conditions. To provide the inverted comection the emitter and collector connections are interchanged (inverted), Thus, the element which normally functions as the collector now functions as the emitter, and the element which normally functions as the emitter now operates as the collector. The changes in characteristics provided by these changes in circuit connections make it necessary to consider the inverted transistor as a special device. Such devices are especially useful in circuits where a reversal of normal current flow is desired by merely changing the applied emitter and collector polarities.

Normal transistors are manufactured with a collector of larger size than the emitter to obtain a high value of current gain (alpha). The larger collector makes certain that most of the minority carriers diffused through the base region are collected despite any radial spreading, thereby improving the overall gain. On the other hand, either the collector or the emitter can emit minority carriers into the base region, while the other electrode functions to collect these carriers (both P-elements are composed of the same material). Because of the differences in area, when the normal collector operates as an emitter and the normal emitter operates as a collector a different value of converted current gain is obtained over that of the normal current gain. While it is possible to construct transistors with symmetrical or equal current gains in either direction, the maximum normal gain would be reduced. When the emitter of a normal transistor is reverse biased, the emitter leakage current with the collector open is usually lower than the collector leakage current with the emitter open because of the smaller size of the emitter.

Thus, we can define the two types of gain possible with the normal and inverted connection (normal alpha and inverted alpha). Most commercial transistors have a normal rdpha of 0.9 to 0.999 but the inverted alpha is only from 0.3 to 0.6. Since the collector leakage current and the emitter leakage current are not independent, but are related by the alpha gain times the leakage current, the emitter leakage current can vary over a range of from 0.3 to 0.699 the value of the collector leakage current. Consequently, as the normal alpha gain is higher than the inverted alpha gain, we find that higher current gains and power handling capabilities are available from the normal transistor connection. Any advantage of the inverted connection is mainly obtained when the inverted connection is used to control low power levels. That is much lower spurious signrds are generated due to the switching action than at the higher normal levels; also higher ambient temperature levels (up to 30 degrees centigrade) are possible

because of the lower operating temperatures. Another advantage is that reversed current flow may be obtained from the same transistor by simultaneously reversing the emitter and collector polarities. The inverted connection will also provide extremely linear detection in the millivolt region.

When analyzing the operation of switching transistor circuits, it is helpful to bear in mind that a transistor will conduct in either direction as long as the base voltage is such that either junction is biased in the forward direction. The transistor will always be cut off when the base voltage reverse-biases both junctions. Hence, if the P-materials at each end of a PNP transistor were equal in physical area, the current flow in either direction through the transistor would be equal if the emitter and collector polarities were reversed. Since, however, the physical areas are different, using the inverted connection results in different values of current flowing in opposite directions, but the general statement still holds. As long as the bias on one element is reversed, the base bias controls current flow through that element, since the other element is always forward biased. This is the normal condition of operation for a transistor. When emitter and collector leads are interchanged, or their polarities are reversed, the physical construction governs the maximum current flow, and the collector then becomes the emitter, with the emitter operating as the collector. Consequently, reduced gain is obtained and the characteristics are different than normal.

PART 13-2. LIMITERS

SERIES, POSITIVE OR NEGATIVE LOBE DIODE LIMITER (ELECTRON TUBE)

Application.

The series limiter is used in communications equipment as a speech clipper, in electronic equipment where amplitude limiting is desired (such as FM receivers or transmitters) and in waveshaping circuits where all or a portion of the positive half-cycle of a waveform is to be clipped off. This circuit is particularly suited for squaring off a peaked waveform. It is used universally in display circuits for modifying waveforms and determining the levels at which they are clipped or limited.

Characteristics.

Input signal waveform contains both positive and negative signals.

Output amplitude is lower than input amplitude; no amplification is realized in the circuit.

Output amplitude is lower than input amplitude; no amplification is realized in the circuit.

Output signal is taken across a load resistor.

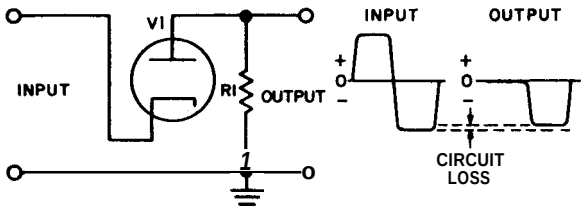
Output signal is in phase with input signal.

Circuit Analysis.

General. The series, positive or negative lobe diode limiter consists essentially of a diode connected in the signal line, in series with the signal source and the load, and polarized so that either the negative portion or the positive portion of the input signal will pass through the diode without being affected. A load resistor is connected on the load side of the diode, and the output signal is taken across this resistor. Due to the similarity between the positive lobe limiter and the negative lobe limiter, only the positive lobe limiter will be discussed in detail, with the differences being noted at the end of the discussion.

Circuit Operation. A simplified series, positive lobe diode limiter is shown in the following illustration. In this circuit, the diode conducts during the negative portion of the input signal. Conduction is accomplished' by driving the cathode negative with respect to the plate, which has the same effect from the viewpoint of the tube electrodes as driving the plate positive with respect to the cathode. When the input signrd goes negative, the diode conducts, and it presents a low value of resistance to the signal. The total resistance in the circuit, connected across the input terminals, then consists of diode VI, which has a low resistance, in series with load resistor R1, which has a comparatively high resistance. Since the voltage drop across each individual resistance in a series circuit is in direct proportion to its resistance divided by the sum of the resistances, according to Kirchhoffs laws, most of the input signal voltage will appear across load resistor R1, while a small amount will drop across diode VI and be lost insofar as the circuit output is concerned. For this reason the value of the load resistor, R1 should be many times greater than the forward resistance of the diode, VI. When the input signrd goes positive, the diode cuts off and thus limits the flow of current in the series circuit.

The voltage across load resistor RI then falls suddenly to zero, and remains at zero until the input signal goes negative on the following half cycle.



Simplified Series, positive Lobe Diode Limiter and Input-Output Waveforms

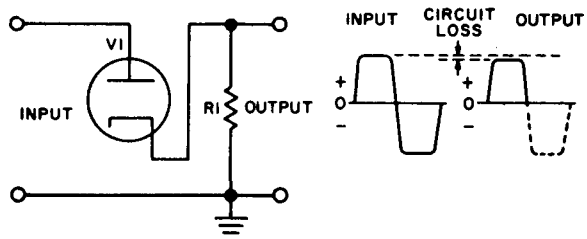
The value of load resistor R1 affects the output of the circuit in several ways. First, for the best frequency response characteristic, RI should be as low as practicable. But in order for the circuit to function to the best advantage as a limiter, the load resistor must be severrd times the value of the forward, or conduction, resistance of the diode. The effect of various values of load resistance on the output voltage, for three characteristic tube types at V1 in the previous circuit, are shown in the following table. The three tube types are all twin-diodes, and have different values of forward resistance. The forward resistance, or resistance during the period of conduction, of a single section of each of the tubes is as follows: 6AL5, 250 ohms; 6X5, 500 ohms; 6H6, 750 ohms. The values of output voltage are listed, assuming an input voltage of 10 volts to the circuit, with the polarity of the voltage such that the diode V1 conducts to the maximum value (10 volts) on the negative half cycles.

Value of R1	Tube Type 6AL5 (250 ohms fwd res)	Tube Type 6X5 (500 ohms fwd res)	Tube Type 6H6 (750 ohms fwd res)
IK	8.0	6.66	5.71
5K	9.52	9.08	8.69
10K	9.75	9.52	9.30
50K	9.95	9.90	9.85
100K	9.97	9.95	9.92

Output Voltage of Diode Limiter Using Various Tubes and Load Resistances, at 10 Volts Input

It can be seen, from the table above, that with a load resistance of lOOK, which is 400 times the value of the forward resistance of a type 6AL5 tube, practically the entire input voltage is available at the output of the limiter, with only 0.3 volt circuit loss occurring within the tube.

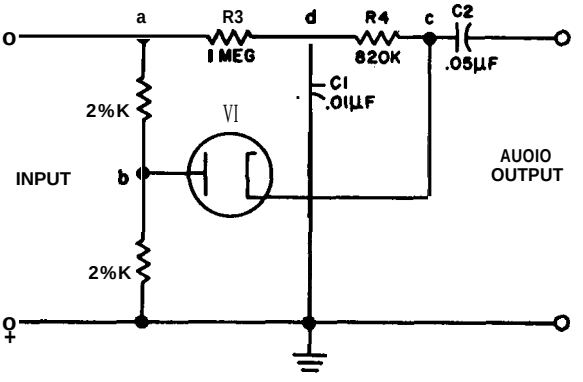
A simplified series, negative lobe diode limiter is shown in the following illustration. In this circuit, the diode conducts during the positive portion of the input signal. When the input signal goes positive, the diode presents a low vrdue of resistance (called the forward resistance) to the signal, and passes the signal through the circuit to the output. The remainder of the circuit operation is essentially the same as the description given above for the positive lobe limiter.



Simplified Series, Negative Lobe Diode Limjter and Input-Output Waveforms

One application of the series, negative lobe diode limiter is given in the following illustration, which shows a series-connected peak noise limiter for use in an AM receiver. This circuit operates as follows: Assume that an input audio level (rectified dc from a diode rectifier applied between point ***a*** and ground of –10 volts is applied to the input terminals of the circuit. The cathode of diode VI is connected to point c and assumes a potential through resistors R3 and R4 of –10 volts with respect to ground. (Since no appreciable current flows through R3 and R4 there is no appreciable voltage drop across them.) The plate of diode VI is connected to point ***b*** and, with no current flowing, assumes a potential —5 volts with respect to ground, through the voltage-divider effect of resistors R1 and R2. The plate of the diode (point ***b)*** is thereby momentarily 5 volts positive with respect to its cathode (point c); under these conditions the diode conducts, and its resistance becomes approximately 2000 ohms. Capacitor Cl is connected to

point *d* and charges through resistor R3 to a potential of approximately –7 volts with respect to ground when the diode resistance is 2000 ohms. Any considerable change in this potential would require approximately 0.1 second, because of the time constant of R3 and Cl.



Series, Negative Lobe Dioda Limiter Used in a Noise Limiter Circuit

If a noise voltage of –100 volts suddenly appears at the input to the circuit (point a) across R1 and R2, the plate of the diode (point b) will assume a potential of –50 volts instantaneously, while its cathode (point c) remains at –7 volts due to the time delay of the R-C circuit R3C1. This makes the plate of the diode 43 volts more negative than its cathode, and the resistance of the diode becomes almost infinite. This effectively disconnects point c and audio output capacitor C2 from point b, and the circuit momentarily has no output except that small value which passes through R3 and R4, shunted to ground at their junction point by Cl, and also shunted by the capacitance of the diode. By the time the momentary noise pulse has decayed, the cathode of the diode will have assumed a potential considerably more negative than its plate (due to its connection to point a, through R4 and R3), and will again conduct the audio input signal from point *b* to point c and the output capacitor, C2.

The time period during which the circuit limits a noise pulse depends upon the R-C time constant of R3 and Cl, while the percentage of the audio input voltage which is available at the output of the circuit depends upon the relationship of RI and R2. The actual values of these components that may be encountered in a particular circuit depend upon the intended use and application of the circuit.

Failure Analysis.

No Output. Because of the relative simplicity of the series, positive or negative lobe diode limiters, the analysis of failure is likewise simple. The failure of either component will cause trouble, but only the failure of the diode would be responsible for a no-output condition. Obviously, the failure of the applied signal at the input to the limiter should be suspected if no output is obtained from the limiter.

When the series, negative lobe diode limiter is used in a more complicated circuit, such as the noise limiter shown in the illustration, a few additional components could be responsible for no output. If RI became open-circuited or if output coupling capacitor C2 became open-circuited no output would be realized from the circuit. (If R1 became open-circuited, there is a possibility that some small value of the input signal, without limiting, would be obtained through R3 and R4, depending upon the particular input waveform.) If capacitor Cl became shorted, the cathode of the diode would be at ground potential and, since the plate of the diode is at a negative potential, the diode would be cut off; thus, no output would be obtained from the circuit. In any case, an analysis of the particular circuit would be necessary in order to isolate the faulty component.

Reduced or Unstable Output. In a series, positive or negative lobe diode limiter, a reduced value of output would most likely be due to a diode which has poor cathode emission, and therefore has a high internal, or forward, resistance. It is also possible, although less likely, that the load resistor may have decreased in ohmic value because of age or overload. If, however, the cathode emission of the diode falls off, its internal resistance will increase, and the end result will be a decrease in the output voltage. This can be seen from the previous table, which shows the dependence of the output voltage upon both the load resistance and the diode used. Consulting the table, suppose that the circuit comprised one section of a type 6AL5 diode and a IK load resistor. With a 10-volt input, the output may be expected to be on the order of 8 volts, since the 6AL5 has approximately 250 ohms forward resistance. If, however, the cathode emission decreased to the extent that the

forward resistance increased to 500 ohms (comparable to that of the type 6X5 diode), the output will also have decreased to approximately 6.66 volts, comparable to the output of the 6X5 under its normal operating conditions.

In the application of the series, negative lobe diode limiter shown in the illustration, a leaky capacitor Cl could cause both a reduced and a distorted output, while a substantial change in the value of either R3 or R4 could be the cause of distorted output, as could also a shorted coupling capacitor C2. Since the output voltage is dependent upon the comparative vahres of RI and R2, a change in the value of either R1 or R2 will affect the circuit output. If RI should increase in value, the output voltage will decrease, while if R2 should increase in value, output voltage will increase. An open capacitor Cl will prevent the circuit from limiting and, as a result, noise pukes will be present in the output; furthermore, some slight increase in output may be noticed.

SERIES, POSITIVE OR NEGATIVE LOBE DIODE LIMITER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

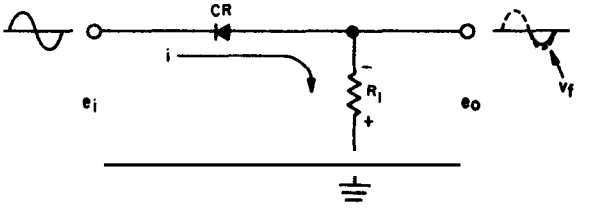
Characteristics.

Same characteristics as electron tube version.

Circuit Analysis.

General. A limiter circuit is used to accomplish any of the following functions: to square off the peaks of an applied signal, to obtain a rectangular waveform from a sine-wave signal, to eliminate the positive (or negative) portion of a waveform, or to keep the input amplitude to an FM detector at a constant value. The positive-lobe limiter is designed to effectively eliminate or reduce the positive portion of the input signal. The negative-lobe limiter eliminates or reduces the negative portion of the input signal. Due to the similarity between these two circuits, the following discussion will pertain primarily to the positive-lobe limiter. A short discussion of the negative-lobe limiter will be made at the conclusion, explaining the differences.

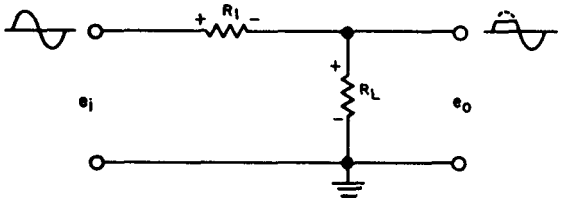
Circuit Operation. A schematic diagram of a typical series-diode positive-lobe limiter is shown in the accompanying figure.



Series-Diode Positive-Lobe Limiter

As can be seen, diode CR is connected in series between the input and output, with R1 serving as the load resistor, When a positive input is applied between the cathode and ground, the cathode is made more positive than the anode, and the diode does not conduct. Thus, for this condition only the reverse resistance of the diode (which will be discussed later) will allow any signal to pass to the load. When the input signal is negatively polarized, the cathode is more negative than the anode and the diode conducts. When the diode conducts, electrons flow opposite the direction of the arrow through R1 to ground, and the polarity of the voltage developed across R1 is negative with respect to ground, as shown in the illustration. The amount of current flow and the resistance value determine the output voltage produced. Since the forward resistance of the diode is in series with R1 to ground, together they form a voltage divider and the output voltage taken across R1 is always less than the input voltage. (The loss (voltage drop) produced by the forward resistance is shown in dotted lines on the negative portion of the waveform and identified by the symbol $\mathbf{v_f}$ in the illustration.) Also since the load resistor is not frequency-selective, the waveform of that portion of the signal produced by forward current flow through the resistor is the same as the waveform of the original signal (except where clipped) and of the same phase. The polarity, of course, is rdways negative. In forward conduction, the diode can be considered as a switch which connects the output to the input. Since the diode is a semiconductor, it introduces a slight amount of resistance, usually not more than 10 ohms, in series with the circuit. When the diode is nonconducting, its reverse resistance is relatively high (50K to 1 megohm, or greater), but finite (unlike the electron-tube reverse resistance which is usually infinite). In most applications, the reverse-resistance

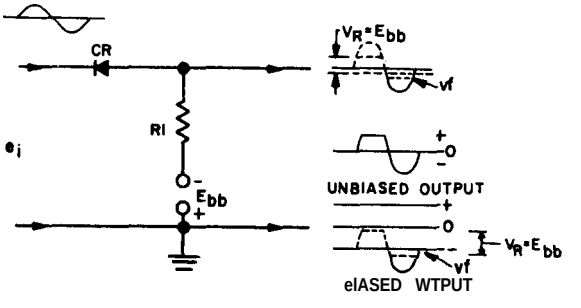
vrdue is high enough to have little effect on circuit operation, but in a series limiter its effect may be important. The following figure shows the equivalent circuit for a diode limiter with a back resistance of 50K, plus a load resistance of 50K. As is clearly evident from the figure, the diode resistance, R1, and the load resistor, R_L, form a voltage divider across the input. Even though the diode is not conducting, in the forward direction, the small leakage current which flows through the diode reverse resistance causes it to act as a voltage divider with R1. As a result, half the applied input voltage appears in the output circuit. This illustrates the serious disadvantage of semiconductor limiters. As shown in the figure, the positive portion of the waveform is only partially clipped, whereas in a vacuum-tube circuit the entire positive waveform would have been eliminated. One of the practical results of this reverse-resistance effect is that diodes of one type cannot be replaced with those of another type (even though voltage and current ratings may be adequate) unless their reverse resistances are similar. Otherwise, the amount of limiting or clipping will be different from the amount selected by the designer, and improper functioning of following circuits can occur.



Reverse-Resistance Equivalent Circuit

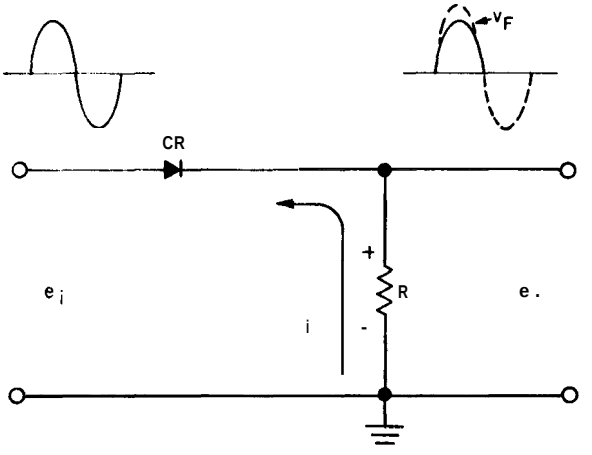
Consideration of the equivalent circuit, in the preceding figure, during forward-resistance conditions reveals why the output waveform can never have the same value as the input signal. If the forward diode resistance is assumed to be 5 ohms and the load resistance 50K, then the input signal will be diminished by an amount equal to the ratio of the resistance of the diode and the load resistor, or one ten-thousandth. It is clear from this example that the forward resistance of the semiconductor diode is low enough to produce even less loss than that of the electron tube diode, which is never less than 100 ohms and is usually more. (Practically speaking, 250 ohms is the average low value with the high value being on the order of 500 to 700 ohms.)

The amount of clipping of the input waveform can be selected by using a diode which has the proper value of reverse resistance, or by placing a negative potential (E_{bb}) in series with RI, as shown in the following figure. In the latter case, the diode will not conduct until the input signal is more negative than the applied bias (V_R). Thus the reverse resistance loading of the diode on the input circuit is effectively nullified (the reverse resistance voltage divider action with R1 is eliminated). The complete positive lobe, in this case, is eliminated. Note, however, that the voltage divider action produced by the forward resistance and RI still remains, as indicated by v_f in the figure. The total negative signal amplitude is reduced by the amount of forward voltage drop and the effective negative bias.



Bias Control of Clipping

A schematic diagram of a typical series-diode negative-lobe limiter is shown in the accompanying illustration.



Series-Diode Negative-Lobe Limiter

The circuit operation is the same as that of the positive-lobe limiter described above, except that all signal polarities are reversed due to the reversal of the diode in the circuit.

Failure Analysis.

No Output. A no-output condition can be the result of either an open-circuit condition (a defective diode, or open connection) or a short-circuit condition (RI shorted). A resistance check of the diode and load resistor will quickly reveal the defective component.

Low Output. Lack of sufficient input signal, as well as a defective diode, can cause low output. A change in value of the load resistor with age, although not very likely to occur, can also cause a reduction of output. If the diode is biased, a change of bias voltage can cause improper output. In either case, a resistance check will determine whether the components are defective, and a voltage check will determine whether the bias is correct. Be certain to observe the proper polarity when checking the diode with an ohmmeter; otherwise misleading results will be obtained.

Distortion. Except for the clipping effect, a diode limiter produces no inherent distortion. If a distorted waveform is obtained, check the input with an oscilloscope to determine whether the input signal is distorted. The negative portion of the output waveform should be identical to the negative portion of the input signal; if it is not, the diode is defective. Another possibility is that the circuit following the limiter introduces distortion by feeding back an out-of-phase signal. In some cases, it may be necessary to disconnect the limiter output to determine whether such feedback exists.

PARALLEL, POSITIVE OR NEGATIVE LOBE DIODE LIMITER (ELECTRON TUBE)

Application.

The parallel limiter is used in communications equipment as a speech clipper, in electronic equipment where amplitude limiting is desired (such as FM receivers or transmitters) and in waveshaping circuits were all or a portion of the positive half-cycle of a waveform is to be clipped off. This circuit is particularly suited for squaring off a peaked waveform. It is used universally in display circuits for modifying waveforms and determining the levels at which they are clipped or limited.

Characteristics.

Input signal may contain both positive and negative signals. In special cases “it may contain only positive or negative signals, in which case only those of higher amplitude will be limited, or clipped.

Output waveform contains only negative or positive signals, or signals which are less positive or less negative than a predetermined limiting level.

Output amplitude is lower than input amplitude; no amplification is realized in the circuit.

Output is taken across a diode.

Output signal is limited when the diode conducts.

Circuit Analysis.

General. The parallel, positive or negative lobe diode limiter circuit consists of a diode and a resistor connected in series with each other across the input signal. The diode is polarized so that it will conduct during the positive or negative portions of the input signal. The output signal is taken across the diode tube and is produced during the period that the diode does not conduct. Due to the similarity between the positive and negative-lobe limiters, only the positive-lobe limiter will be discussed in detail. The negative-Iobe limiter will be discussed only briefly at the end of the discussion.

Circuit Operation. A simplified parallel, positive lobe diode limiter is shown in the following illustration. In this circuit, the diode, VI, conducts only during the positive portion of the input signal. When

the input signal goes positive, the diode conducts, and its internal (or conduction) resistance drops from an infinite resistance, when nonconducting, to a vahre of approximately 500 ohms. Since the resistance value of resistor R1 is very large compared to the conduction resistance of the diode, practically the entire value of the input voltage drops across load resistor R1, while only a very small voltage drops across diode V1. This voltage may become negligible when the ratio of the load resistance RI to the diode resistance is very high. Some value of voltage, however small, will still exist across diode VI, because any diode has some measurable amount of resistance. This value of voltage is shown in the output waveform as E_{vl}, on the positive side of the zero-voltage baseline, and represents a loss in the circuit because the output contains this unwanted amount of positive signal. When the input signal goes negative, the diode does not conduct, and the current flow through R1 is interrupted (except for that infinitesimal current which flows through RI because of the high resistance of the load connected to the output terminals). With no (or almost no) current flowing through RI there is no voltage drop across Rl; hence, the output voltage is equal to the input voltage. It should now be obvious that the load impedance connected to the output terminals should be as high as possible in order to obtain the highest possible voltage at the output terminals. The actual value of the output voltage in the previously illustrated circuit during the negative half cycle of the input signal (neglecting the source impedance of the input signal, and assuming that the resistance of the diode when nonconducting is infinite) may be calculated by applying Ohm's law according to the proportion:

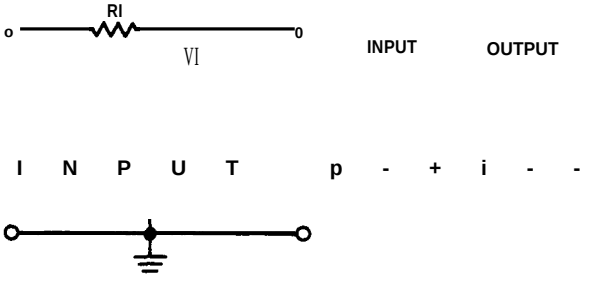
$$E_o : E_1 = R_o : R. + R1$$

where: E_o = output voltage of circuit
E_1 = input voltage to circuit
R. = output load resistance (impedance)
R1 = limiter load resistor

The proportion above can be restated and solved for E_o, as follows:

$$E_o = \frac{E_1 R.}{R. + R_1}$$

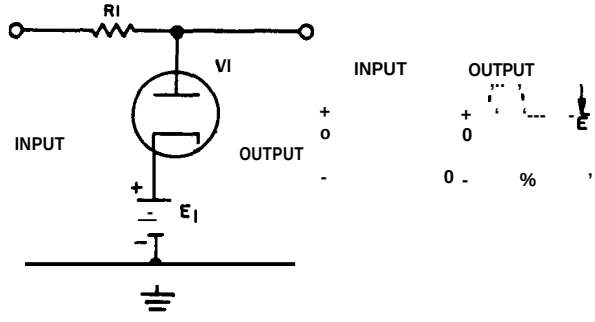
It can be seen from the above formula that the output voltage (E_o) will be approximately equal to the input voltage (El) when the output load resistance (R_o) is very large compared to the resistance of the limiter load resistor, (R1).



Simplified Parallel, Positive Lobe Diode Limiter and Input-Output Waveforms

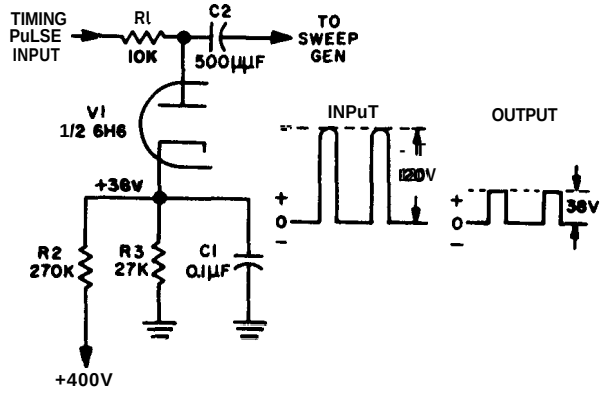
A parallel, positive lobe diode limiter maybe used to limit only the peaks of the positive waveform, while allowing a given value of the positive signal to pass through the circuit to the output. This may be accomplished by applying a biasing voltage, having a value equrd to the value of the positive signal to be passed by the circuit, to the cathode of the diode, as shown in the following illustration. The biasing, or limiting, voltage may be obtained from a battery, as shown in the illustration, or from a tap on a bleeder resistor connected in the output circuit of a d-c power supply. When connected as shown in the illustration, with the cathode of V1 connected to the positive terminal of the d-c source, the cathode of the diode is held more positive than the plate by the value of E_i in the absence of an input signal. As long as the positive cycles of the input voltage remain less positive than El, the bias voltage of the battery, the diode remains nonconducting, and the output voltage is approximately equal to the input voltage. Since all of the negative cycles of the input voltage are less positive than E_i, these too cause the diode to remain nonconducting, with the result that the output voltage is approximately equal to the input voltage. When the input signal increases to a value which exceeds the voltage of E_i, the diode conducts during that portion of the positive cycle when the input voltage is greater than El. During this period of conduction, the output voltage of the circuit is equal to the value of E_i (on the positive cycle), while the peak of the positive input cycle which exceeds the value of E_i is clipped,

or limited, appearing as a voltage drop across the diode load resistor R1.



Parallel, Positive Lobe Diode Limiter Used as a Positive Peak Limiter

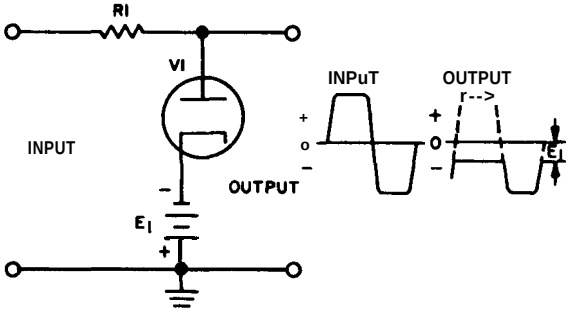
An application of the positive peak limiter is shown in the following illustration. In this circuit an input timing pulse having a pulse duration of approximately 5 microseconds and an amplitude of +120 volts, from a radar transmitter, is applied through a diode limiter to a sweep generator circuit, to produce the sweep presentation on an indicator scope. The diode limiter, which is a parallel, positive lobe diode limiter, is used to provide a fixed pulse amplitude of +38 volts output to the sweep generator circuit. This is accomplished by applying a fixed bias potential of +38 volts to the cathode of diode V1, from a voltage divider composed of R2 and R3 connected to a +400-volt power supply. When the input signal rises to a potential more positive than +38 volts, V1 conducts, and its resistance (conduction resistance) drops to a very low vrdue. Since the cathode is held at a potential of +38 volts and the resistance of V1 is negligible, the potential at the plate of V1 is also +38 volts, while the remainder of the +120-volt input pulse appears as a voltage drop across the plate load resistor, R1. The +38-volt pulse, which comprises the output of the limiter stage, is coupled through capacitor C2 to the following (sweep generator) stage. The output potential is thus held, or limited, to a maximum of +38 volts, regardless of how large the value of the pulse is at the input to the limiter circuit. If, however, the input pulse decreased to a value less than +38 volts, the entire pulse would be passed through the circuit to the output, and no limiting would occur. In this event the voltage at the plate of the diode would be less positive than the voltage at the cathode, and the diode would not conduct.



Typical Application of Parallel, Positive Lobe Diode Limiter in a Radar Indicator Circuit

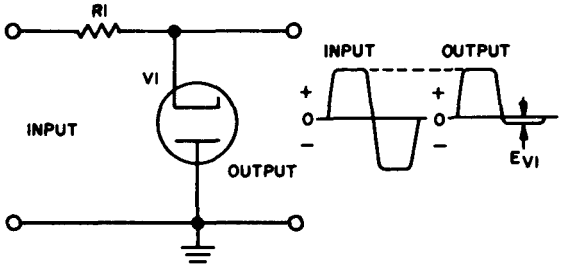
A parallel, positive lobe diode limiter may also be used where it is desired to limit not only the entire positive peaks of the input signal, but also a predetermined level of the negative peaks, in order to furnish an output only when the negative peaks exceed this predetermined level. This may be accomplished by applying a biasing voltage to the cathode of the diode, equal to the value of the predetermined level, but of opposite polarity to that of the preceding circuit, as shown in the following illustration. In this circuit a negative potential E_1 is applied to the cathode of diode V1, from a battery or power supply. With the cathode negative with respect to the plate, the diode is maintained in a conducting state in the absence of an input signal, and the output voltage is held at a steady (negative) dc level equal to E_1. With an input signal applied to the circuit, the output voltage will continue to be held at this steady dc level, with the input signal appearing across the diode load resistor, RI, until the input signal becomes more

negative than E_i. When this point is reached, the diode will no longer conduct; its resistance will then have increased to an infinite value. As a result, the input signal, which previously appeared across R1 because RI was much greater in resistance than diode Vl, now will appear across VI and the output terminals of the circuit, since V1 is now much greater in resistance than RI. The output signal, therefore, contains ordy the negative peaks of the input signal which are more negative than the biasing voltage, E_i.



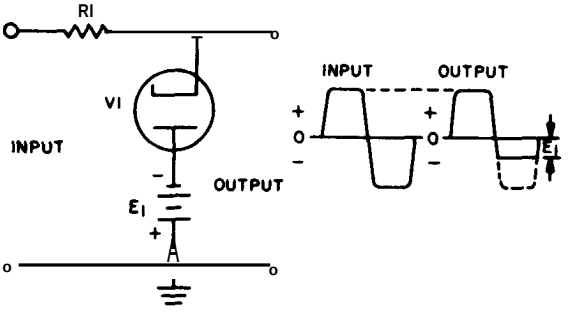
Parallel, Positive Lobe Diode Limiter Used to Pass Negative Peaks

The circuit of a simplified parallel, negative lobe diode limiter is shown in the following illustration. The circuit operation is the same as that of the previously discussed positive-lobe diode limiter, except that the polarities at the output are reversed due to reversal of the diode in the circuit.



Simplified Parallel, Negative Lobe Diode Limited and Input-Output Waveforms

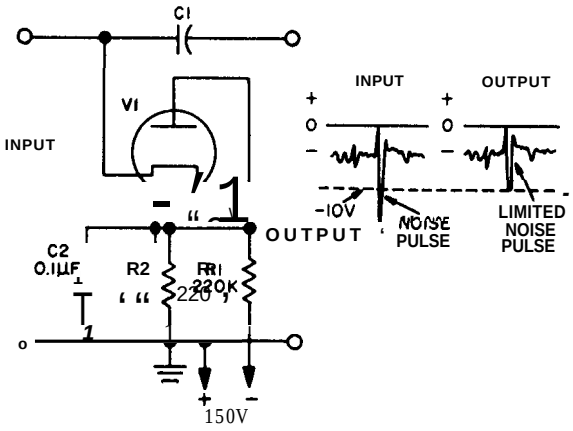
When it is desired to limit only the negative peaks of the input signal and allow the remainder of the negative portion and all of the positive portion (if any is included) of the input signal to pass, unmodified, to the output of the limiter, the circuit shown in the following illustration may be used. Once again, the circuit operation is the same as that of the previously discussed positive-lobe diode limiter, except that the polarities at the output are reversed due to the reversal of the diode and the battery voltage in this circuit.



Parallel, Negative Lobe Diode Limiter Used es a Negative Peak Limiter

An application of the negative peak limiter is shown in the following illustration. This circuit is used as a noise limiter following the diode detector stage in an AM receiver. The output of the detector is a negative audio signal having a maximum value of 0.2 volt rms, and this signal is applied to the input of the peak noise limiter. The resistors, R1 and R2, are connected as a bleeder to a negative 150-volt power source. The –10 volts obtained at the junction of R1 and R2 due to the voltage divider action is applied as a fixed bias to the plate of the parallel diode limiter, V1. Under normal conditions the input signal is passed through coupling capacitor Cl to the output terminals, unaffected by V1 and its associated circuit. When a noise pulse having a peak amplitude exceeding –10 volts (the value of the fixed bias applied to Vl) appears at the input terminals, diode VI conducts, placing an effective short circuit across the output terminals for the duration of the noise pulse. The noise pulse is conducted to ground through the

low resistance of V1 (when in a conducting state) and the low reactance offered by C2 to a sharp noise pulse. Since the noise pulse is shorted to ground, the pulse is prevented from activating the agc circuit, which would in turn block the i-f amplifiers and interrupt the output signal for a much longer time interval than the actual time duration of the noise pulse.



Parallel, Negative Lobe Diode Limiter Used as a Peak Noise Limiter

Failure Analysis.

No Output. In a parallel, positive lobe diode limiter circuit similar to those shown in the first two illustrations, the analysis of failure is as simple as the circuit itself. Either the failure of the diode by shorting, or the failure of diode load resistor RI or coupling capacitor C2 by open-circuiting, or the failure of the applied signal are the only possible causes of a no-output condition.

When the parallel, positive lobe diode limiter is used in a more extensive circuit, such as in the radar indicator circuit shown in third illustration, some of the additional components could be responsible for no output. In this particular circuit, which is intended to limit positive pulses to a level of +38 volts and not to completely limit positive pulses to zero potential, a shorted cathode bypass capacitor Cl would cause complete limiting to zero (ground) potential. Since the" input contained only positive pulses, complete limiting would produce no output.

The analysis of failure which results in no output from a parallel, negative lobe limiter should also be relatively simple, because of the small number of components comprising the circuit. In the first two illustrations, for example, only three conditions could be the cause of no output. Either the diode load resistor R1 may be open-circuited, the diode V1 may be shorted, or the input signal may have failed. One other condition could contribute to no output in the second circuit illustrated, but the possibility that this condition will occur is remote. If the input signal to this circuit contained only negative pulses, the peaks of which were to be limited, and the biasing voltage E_1 was removed (because of battery or power supply failure) or the polarity of the voltage was inadvertently reversed, then the entire negative input signal would be conducted to ground through diode V1, and no output from the circuit would be obtained. In a more complicated circuit, such as that shown in the third illustration, additional causes of no output may be an open coupling capacitor Cl, a shorted bypass capacitor C2, or failure of the biasing voltage due to either power supply failure or an open resistor R1 in the voltage divider circuit.

Reduced or Unstable Output. In a parallel, positive lobe diode limiter, a reduced value of output may be due to either an increased value of the diode load resistor R1, or the result of a change in the parallel portion of the circuit, which consists of the diode itself and its cathode biasing components when applicable. In the first two illustrations, an increased value of RI due to overheating or aging or an improper value of biasing voltage E_1 could be the cause of reduced output. In the circuit shown in the third illustration, the failure of the applied voltage to the cathode circuit or an open-circuited resistor R2 would allow the diode to almost completely limit the input pulses (assuming they are positive pulses, as shown in the illustration), and would thus cause a substantially reduced output. If, however, the low end of the cathode voltage divider, resistor R3, became open-circuited or resistor R2 becomes shorted, the full value of the bias voltage from the power supply (+400 volts) would be applied to the cathode of V1. With a +400-volt potential on the cathode, the diode would be completely cut off, and no limiting would be realized. In this case, the output signal would be the same as the input signal.

A reduced or an unstable output from a parallel, negative lobe diode limiter may be due to a substantially increased value of the diode load resistor, RI,

resulting from overheating or aging; an intermittently shorting diode, VI; or an erratic output from the biasing voltage supply, E_b, when used. In a more extensive circuit, such as that shown in the third illustration, a leaky coupling capacitor, Cl, would contribute to an unstable or erratic output. In addition, if the resistor at the low end of the bleeder supplying the biasing voltage became open-circuited (R2 in the circuit illustrated), the output of the circuit would be distorted from the normal output, in that the output would contain negative signals up to a possible negative 150-volt value, and no limiting would be obtained. If, on the other hand, bypass capacitor C2 became open-circuited, a sharp negative increment of a noise pulse applied to the input to the circuit would encounter a much greater impedance to ground through R2 than would normally be offered by C2. As a result, the decay time of the noise pulse would be increased because of R2, resulting in distortion of the output waveform.

PARALLEL, POSITIVE OR NEGATIVE LOBE DIODE LIMITER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

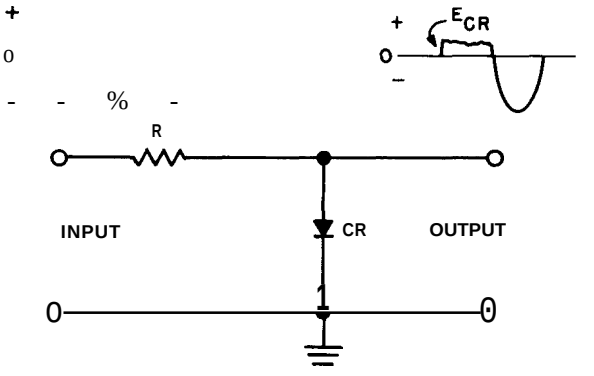
Characteristics.

Same characteristics as electron tube version.

Circuit Analysis.

General. The positive or negative lobe limiter circuit is used to accomplish any of the following functions: to square off the peaks of an applied signal, to obtain a rectangular waveform from a sine-wave signal, to eliminate the positive or negative portion of a waveform, or to keep the input amplitude to an FM detector at a constant value. The positive-lobe limiter is designed primarily to eliminate or reduce the positive portion of the input signal, whereas the negative-lobe limiter is intended primarily to eliminate or reduce the negative portion of the input signal. Due to the similarity between the positive-lobe and the negative-lobe limiters, only the positive-lobe limiter will be discussed in detail here. The negative-lobe limiter will be discussed only briefly at the end of the discussion.

Circuit Operation. A parallel, positive-lobe diode limiter is shown in the following illustration. In

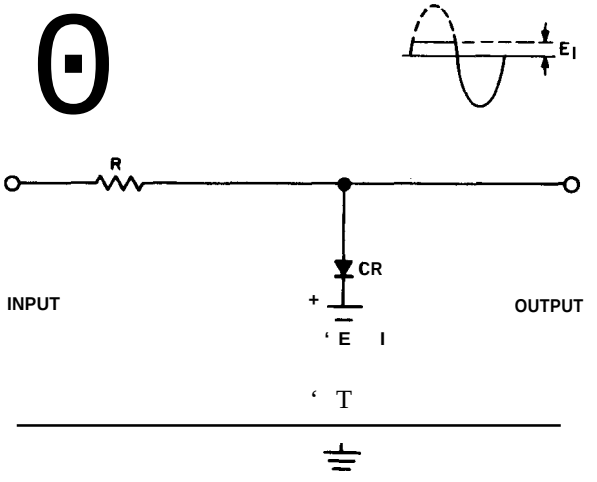


Positive-Diode Positive-Lobe Limiter

this circuit, diode CR conducts only during the positive portion of the input signal. When the input signal goes positive, the diode conducts, and its resistance drops from a very high reverse resistance to a very low forward resistance. The amount of resistance of the diode in the conducting (or the nonconducting state) is determined by the internal characteristics of the particular diode selected for the circuit. Since the resistance value of R is very large compared to the conducting resistance of the diode, practically the entire value of the input voltage drops across load resistor R, while only a very small voltage drops across diode CR. This voltage may become negligible when the ratio of the load resistance R to the diode resistance is very high. Some value of voltage, however, will still exist across CR, because of its conducting resistance, called the forward resistance and is shown on the illustration as E_{cr}. When the input signal goes negative, the diode does not conduct, and current flow through R almost ceases. A small reverse current still flows through CR, because of the reverse resistance of the diode and thus a small portion of the input voltage is dropped across R. The amount of reverse resistance of the diode depends upon the characteristics of the diode selected. Thus, this is one of the disadvantages of the semiconductor diode over the vacuum tube. The vacuum tube reverse resistance is considered to be infinite, whereas the semiconductor is finite. The voltage dropped across R subtracts from the output, and thus the gain of the limiter is less than unity. On the other hand, the forward resistance of the semiconductor is less than that

491-044 0 7375

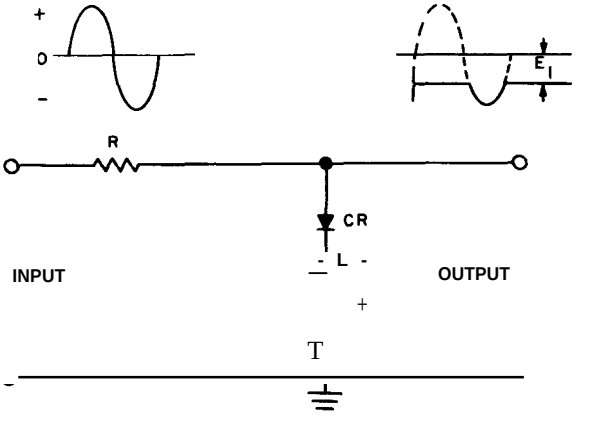
of the vacuum tube, making the semiconductor better in some applications.



Parallel, Positive Lobe Diode Limiter Used as a Positive Peak Limiter

A parallel, positive-lobe limiter may also be used to limit only the peaks of the positive waveform, whiie allowing a given value of the positive signal to pass through the circuit to the output. This may be accomplished by applying a biasing voltage, having a value equal to the value of the positive signal to be passed by the circuit, to the cathode of the diode, as shown in the following illustration. The biasing, or limiting, voltage may be obtained from a battery, as shown in the illustration, or from a tap on a bleeder resistor connected in the output circuit of a dc power supply. When connected as shown in the illustration, with the cathode of CR connected to the positive terminal of the dc source, the cathode of the diode is held more positive than the anode by the value of E_i in the absence of an input signal. As long as the positive cycles of the input voltage remain less positive than El, the battery bias voltage, the diode remains essentially nonconducting, because its cathode is positive with respect to the anode and the output voltage is equal to the input voltage minus the voltage developed by the reverse resistance of the diode. Since all of the negative cycles of the input voltage are less positive than El, these too cause the diode to remain essentially nonconducting, with the result that the output voltage is again equal to the input voltage minus the voltage developed by the reverse resistance of the diode. When the input signal increases to a value which exceeds the voltage of E_i, the anode becomes positive with respect to the cathode and the diode conducts, and continues conducting as long as the input remains more positive than E_i. During this period of conduction, the output voltage of the circuit is equal to the value of E_i, and that portion of the input signal which exceeds the bias voltage is clipped, or limited, appearing as a voltage drop across the diode load resistor, R.

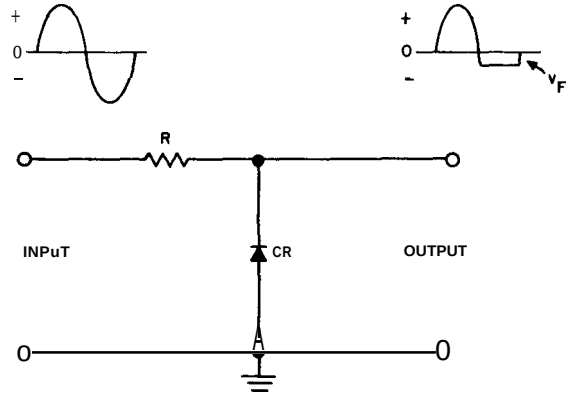
By reversing the polarity of El, the parallel, positive lobe diode limiter may also be used where it is desired to limit not only the entire positive peaks of the input signal, but also a predetermined level of the negative peaks, in order to furnish an output only when the negative peaks exceed this predetermined level. (See the following illustration.) With the cathode negative. with respect to the anode, the diode is maintained in a conducting state in the absence of an input signal, and the output voltage is held at a steady (negative) dc level equal to El. With an input signal applied to the circuit, the output voltage continues to be held at this steady dc level, the input signal appearing across the diode load resistor, R, until the input signal becomes more negative than El. When this point is reached, the diode no longer conducts; and its forward resistance increases



Parallel, Positive Lobe Diode Limiter Used to Pass Negative Peaks

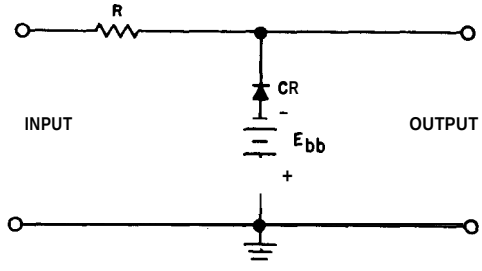
to a very high value. As a result, the input signal, which previously appeared across R because R was much greater in resistance than CR, now appears across CR and the output terminals of the circuit, since CR is now much greater in resistance than R. The output signal, therefore, contains only the negative peaks of the input signal which are more negative than biasing voltage E_1.

The circuit of a parallel, negative-lobe diode limiter is shown in the accompanying illustration. In this circuit, diode CR conducts only during the negative portion of the input signal. As long as the input signal remains positive, the diode remains in a nonconducting state, and current flow through R almost ceases. A small reverse current still flows through R and CR, because of the reverse resistance of the diode, and thus a small portion of the input voltage is dropped across the resistor. The amount of reverse resistance of the diode, just as in the positive-lobe limiter, depends upon the characteristics of the diode selected. The remainder of the circuit operation is essentially the same as the positive-lobe limiter described above.



A-949
Parallel-Diode Negative-Lobe Limiter

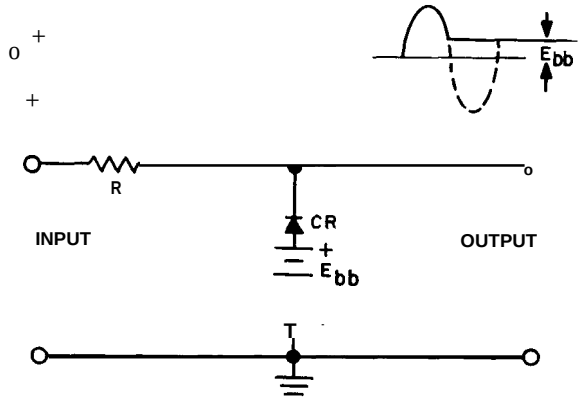
A parallel, negative-lobe diode limiter may be also used to limit only the negative waveform peak, while allowing a given value of negative signal to pass through the circuit to the output. This may be accomplished by applying a negative biasing voltage, having a value equal to the value of the negative signal to be passed by the circuit, to the anode of the diode, as shown in the accompanying illustration. The circuit operation is essentially the same as the parallel, positive-lobe diode limiter used as a negative peak limiter (described previously), only with opposite polarities.



Parallel, Negative Lobe Diode Limiter Used as a Negative Peak Limiter

By reversing the polarity of E_{bb}, the parallel, negative-lobe diode limiter may also be used where it is desired to limit not only the entire negative peaks of the input signal, but also a predetermined level of the positive peaks, in order to furnish an output ordy when the positive peaks exceed this predetermined level. This circuit is illustrated below. The operation is essentially the same as the parallel, positive-lobe

diode limiter used to pass negative peaks (described previously), only with opposite polarities.



Parallel, Negative Lobe Diode Limiter Used to Pass Positive Peaks

Failure Analysis.

No Output. A shorted diode or an open load resistor will cause a no-output condition to exist. The only other likely possibility is the absence of the input signal. Check the diode and the resistor with an ohmmeter, making certain to observe the polarities of the diode, since an erroneous indication may be obtained if the proper polarity is not observed. If both components check good, check for the presence of the input signal, making sure that it is of proper amplitude.

For the special case where the diode is not completely shorted, but reads a very low resistance of, say 200-ohms or less, the diode maybe considered defective.

In the case of the biased limiter, check the bias for proper voltage with a voltmeter. In the case of a battery bias supply the voltage will be either weak or absent, but in the case of the bias supply being a power supply, it could also be high.

Reduced or Unstable Output. A defective load resistor, R, or a defect in the parallel branch of the circuit, consisting of CR and the bias supply, E_i, can produce a reduced or unstable output. The only other likely possibility is a decrease in the amplitude of the input signal. The trouble can be localized in the same manner as described above for a no-output condition.

TWO-DIODE, POSITIVE AND NEGATIVE LOBE DIOOE LIMITER (ELECTRON TUBE)

Application.

The two-diode, positive and negative lobe diode limiter is used where it is required to limit both the positive and negative peaks of an input signal waveform, in order to prevent the output signal from exceeding predetermined maximum values for both the positive and negative peaks. With the elimination of both peaks, the remaining signal is generally of square-wave shape; therefore, this circuit is often used as a square wave generator.

Characteristics.

Input signal contains both positive and negative signals.

Output waveform contains both positive and negative signals, both of which do not exceed values which are preset limits in the initial design of the circuit.

Output amplitude is lower than the input amplitude; no amplification is afforded by the circuit.

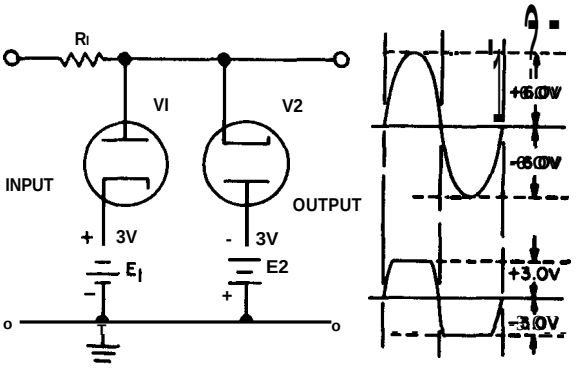
Output is taken across two reverse-connected diode tubes.

Circuit Analysis.

General. The two-diode, positive and negative lobe diode limiter consists of two diodes, a source of both positive and negative voltage, and a load resistor. The load resistor is connected on the input side of the two diodes, and the diodes with their source of (bias) voltage are connected in parallel with each other and in parallel with the output terminals of the circuit. The output signal is produced as a repetition of the input signal during the interval that either diode does not conduct, and is limited at the point where either diode conducts.

Circuit Operation. The circuit of a simplified two-diode, positive and negative lobe diode limiter is shown in the following illustration. In this circuit the two diodes, VI and V2, each have a de voltage connected in series with them. The cathode of diode V1 has a positive potential applied which, for the purpose of illustration, has a value of +3.0 volts, as indicated in the associated waveform. The plate of V2 has a negative potential applied, which for illustration has a value of –3.0 volts. A load resistor, R1, is connected between the input terminals and the two diodes. Under conditions of no input signal, both diodes are in a nonconducting state, since the voltages

that are applied to them are of such polarity as to oppose the flow of current through the diodes. These voltages are often termed bias voltages, since they establish the level of potential at which the diode will switch from a nonconducting to a conducting state. Now assume that an input signal, having a sine waveform with positive and negative peaks of +6.0 and –6.0 volts, respectively, is applied to the input to the circuit, as shown by the input waveform in the illustration. When the voltage on the positive cycle of the input signal reaches +3 volts, this same value of voltage appears at the plate of VI, since, with no current flow, there is no voltage drop across the load resistor RI. At this point the plate voltage is equal to the voltage applied to the cathode from the bias battery, E_1. As soon as the positive cycle of input signal exceeds +3 volts, diode VI conducts, and a current flows through V1 and load resistor R1. If the voltage drop across V1 is assumed to be negligible, any value of input voltage which exceeds +3 volts will appear as a voltage drop across R1, resulting from the current flow due to the conduction of VI. This is in accordance with Kirchhoff's laws, in that the algebraic sum of the voltage drops and the applied voltage around any closed circuit equals zero. (At this moment–during the positive input cycle–the parallel path consisting of diode V2 and battery E_2 is effectively out of the circuit, since it is in a nonconducting state.) The signal at the output terminals, during the positive half of the cycle, will then rise in sine-wave fashion to a value of +3 volts, at which point the voltage will be limited, or held, until the input signal passes through its peak of +6 volts and falls to +3 volts again, when it will follow the sine waveform during the decay of the positive cycle down to zero volts. Thus the positive half cycle of the output waveform will have a flat top at +3 volts. When the input signal passes through zero volts and increases in a negative direction, the output signal retains the sine waveform until the input signal reaches a value of –3 volts. At this point the cathode voltage of V2 is equal to the negative voltage (–3 volts) applied to the plate of V2 from bias battery E_2. As soon as the negative cycle of the input signal exceeds (negatively) the –3 volts bias, diode V2 conducts, causing a current to flow through V2 and load resistor R1. In a similar manner to that described for diode V1 and the positive cycle, any value of input voltage which is more negative than –3 volts will appear as a voltage drop across R1, as a result of the current flow when V2 conducts. The output signal, during the negative half cycle, will then follow the sine waveform of the input signal to a point at –3 volts, when the voltage will be limited until the input signal passes through its negative peak of –6 volts and returns to the value of –3 volts again. Then V2 will stop conducting, and the output signal will again follow the sine waveform of the input signal as the negative half of the cycle is completed.



Simplified Two-Diode, Positive and Negative Lobe Diode Limiter and Waveforms

The point at which the positive portion of the input signal will be limited, or clipped, may be preset by applying a positive bias voltage of equal value to the cathode of diode Vl, which is the positive peak limiter diode. In like manner, the point of negative limiting may be preset by applying a negative bias voltage to the plate of the negative peak limiter diode, V2. In this way the output signal maybe held within any desired positive and negative limits. Such a circuit is sometimes referred to as a gate clipper, since it acts as a gate which allows the center portion of an input signal to pass through to the output. More infrequently it is known as a slicer.

When the applied bias voltages are equally positive and negative and of a low value, while the input signal is a sine wave of a relatively high value, most of the curved portions of the sine wave at its peaks will be clipped, and the remaining positive-going and negative-going portions of the waveform w-ill have steep sides which approach the vertical. Thus a fairly accurate square wave output may be obtained, and such a circuit is often used as a square wave generator.

Failure Analysis.

No Output. In a twodiode, positive and negative lobe diode limiter such as that previously illustrated, several conditions could be responsible for no output. Failure of diode load resistor Rl, due to an "open" resistor, or failure of the applied input signal would result in no output. Another possibility which should be investigated is the failure of both bias voltages. If individual batteries are used for both the negative and positive biases, the simultaneous failure of both is very urdikely, and thus some measure of output signal would be obtained. If, however, the bias voltages are obtained from a dc power supply operated from a power line, and the power supply failed, the diodes could then conduct through the circuit completed by the bleeder resistor in the output circuit of the power supply. Under these conditions the positive portion of the input signal would be clipped, or limited, by diode VI, and the negative portion would be limited by diode V2; thus no signal, or extremely little, would be present at the output terminals.

Reduced or Unstable Output. In a two-diode, positive and negative lobe diode limiter, a reduced or unstable output may be due to a defective load resistor, Rl, which may have suffered a considerable increase is resistance value. In addition, poor emission of the cathode in diode V1 or V2 may cause unstable output, as may also insufficient bias voltage E_1 or E_2 due to aging batteries or a defective power supply. Finally, the possibility of a reduced value of input signal, due to some defect in the preceding circuit, should not be overlooked.

TWO-DIODE, POSITIVE AND NEGATIVE LOBE LIMITER (SEMICONDUCTOR)

Application.

Same application as the electron tube version.

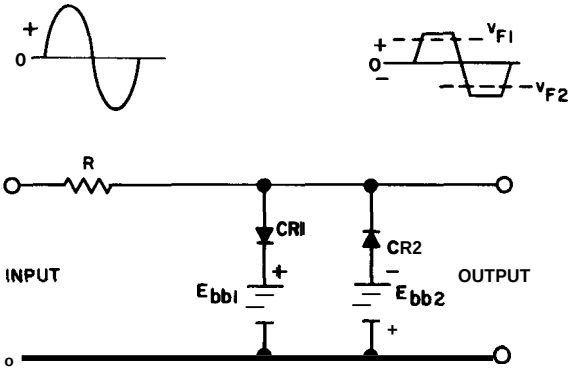
Characteristics.

Same characteristics as the electron tube version.

Circuit Analysis.

General. The positive and negative lobe diode limiter is used to accomplish any of the following functions: to square off the peaks of an applied signal, to obtain a rectangular waveform from a sine-wave signal, or to eliminate the negative or positive portion of a waveform and clip the other portion. Our discussion here will primarily concern the equal clipping of both the positive and negative portions of a sine-wave, that is, the conversion of a sine-wave into essentially a square-wave.

Circuit Operation. The circuit of a parallel, positive and negative lobe diode limiter is shown in the following illustration. Diode CRI limits the positive half cycle of the input and CR2 limits the negative half. E_{bb1} and E_{bb2} supply the bias for their respective diodes and the resistor, R, acts as the load resistor. Reverse biases are applied to the diodes so that the cathode of CR1 is positive with respect to its anode, and the anode of CR2 is negative with respect to its cathode.



Parallel, Positive and Negative Loba Diode Limiter

As the signal is applied at the input and begins increasing in a positive direction, both diodes remain cut off, due to the bias, and the input signrd is reproduced at the output. The output continues to follow the input signal, until a point is reached where the signal becomes more positive than the positive bias applied to the cathode of CR1. At this point, the anode becomes more positive than the cathode, and the diode conducts. When the diode conducts, it provides a low resistance path for forward current to ground, and shunts the output through the diode instead of the external load. It is at this point that the output waveform is flattened. Actually, even during its conducting period, the diode offers a slight opposition to current flow, and a small forward voltage drop adds to the load voltage. Thus, the output voltage is slightly higher than the diode bias by the amount shown as V_F**1** on the output waveform.

As the input signal reaches its positive peak and begins decreasing toward zero, it again reaches a level

which is less positive than E_{bb1}, diode CRI again cuts off and the input is again faithfully reproduced at the output. The input signal continues in the negative direction, and shortly becomes more negative than E_{bb2}. When this occurs, the cathode of CR2 is made more negative than the anode, and diode CR2 conducts, duplicating the action which occurred on the positive half cycle. The forward voltage drop of the conducting diode is shown as V_{F2} on the output waveform. The input then reaches the negative peak and begins decreasing towards zero. As it becomes less negative than E_{bb2}, CR2 ceases conducting, and the remainder of the input signal is reproduced at the output.

The amount of clipping which takes place at the output is dependent to a certain extent upon the type of diodes selected, but primarily upon the value of the bias. As E_{bb1} is made more positive, less clipping occurs on the positive half cycle, and as it is made less positive, more clipping occurs. By the same token, as E_{bb2} is made less positive, more clipping occurs. By the same token, as E_{bb2} is made more negative less clipping occurs on the negative half cycle, and as it becomes less negative, more clipping occurs.

Failure Analysis

No Output. An open load resistor R, or the absence of the input signal are the two most probable causes of a no-output condition. Check the value of R with an ohmmeter for proper value, and check for the presence of the input signal with an oscilloscope. Note that for the diodes to produce a no-output condition, both of them must be shorted, and that the loss of both bias supplies will produce an extremely low clipped output, caused by the voltage drops across the diodes.

Low or Distorted Output. Under most circumstances, the output will be either distorted or lost completely. Distortion may be caused by a change in the bias supply, by an open or shorted diode, or distortion of the input signal. Check both bias supplies for proper voltage with a voltmeter, and both diodes with an ohmmeter. Be sure to observe proper polarities when checking the diodes, as incorrect indications could be obtained by not doing so. The input signal should be checked with an oscilloscope to determine if the input waveform is at fault.

The possibility of both half cycles of the output being decreased by the same amount is unlikely. Both bias supplies must decrease by the same amount to cause this condition. If both supplies increase, the output will increase. The only other cause of decreased output is the load resistor increasing in value.

TRIOOE GRID LIMITER

Application.

The triode grid limiter is used to limit, or clip, the entire positive half cycle, or a portion thereof, of the input waveform.

Characteristics.

Input may be either a positive signal or a signal containing both positive and negative portions.

Output may be a negative signal with peaks clipped, or a signal having positive and negative portions in which all or a portion of the negative peaks are clipped.

Output signal is out of phase with input signal; therefore, the clipped positive half cycle of the input becomes a clipped negative half cycle of the output signal.

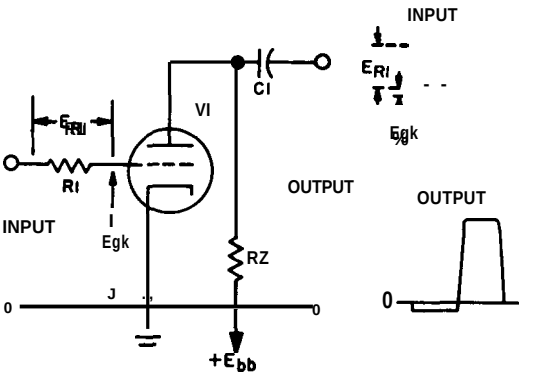
Output signal will contain a positive signal which is the amplified negative input signaL It may contain a negative portion, which is the result of a partially clipped positive input signal that has been amplified. The over-all output peak amplitude may be higher or lower than the input, depending upon the circuit application design.

Circuit Analysis.

General. The triode grid limiter is similar in its limiting action to that of the parallel, positive lobe diode limiter. An advantage of the triode grid limiter over the diode limiter, however, is that amplification of the negative portion (that part of the input signal which is not limited) is accomplished, in addition to the clipping action. In the triode grid limiter, the clipping is obtained as a result of the action of the cathode and control grid, in the same manner as the action of the cathode and plate of a diode limiter. Limiting action is obtained when conduction occurs i.e., when the grid is positive with respect to the cathode. When conduction of the "diode" (cathode to grid) does not occur, i.e., when the grid is negative with respect to the cathode, amplification and phase inversion of the input signal take place, in the manner which is characteristic of a regular triode amplifier.

Circuit Operation. A typical unbiased grid limiter circuit is shown in the following illustration. In this

circuit the input signal is applied to the grid of triode VI through grid resistor RI. In the circuit illustrated the no-signal plate current will be relatively high because the tube is unbiased; therefore, the plate voltage will be correspondingly low. For this reason, a positive input signal may have little effect upon the plate current. However, when the input signal goes positive, this positive voltage appears at the grid of Vl, and grid current begins to flow. Since the cathode of V1 is grounded, the only resistance to the flow of grid current in addition to R1 is that offered by the grid-to-cathode resistance of V1. If grid resistor R1 has a very high resistance in comparison to the grid-to-cathode resistance of V1 when grid current flows, practically the entire positive portion of the input signal will be clipped, or limited, to the voltage of the cathode (which in this particular circuit is zero voltage, or ground potential). In the same manner that the reverse resistance of a diode (the plate-to-cathode resistance when in a nonconducting state) is infiite, while the forward (or conduction) resistance is only 500 (approximately) ohms, so also is the grid-to-cathode resistance of a triode of an infinite value when in a nonconducting state (when the grid is negative with respect to the cathode); however, this resistance drops to a value of 500 to 1000 ohms when the grid becomes positive with respect to the cathode. Therefore, practically the entire value of the positive portion of the input voltage will drop across the very high resistance of R1 and is shown on the input waveform as E_{R1}. Only a very small part of the input voltage will drop across the grid-to-cathode (conduction) resistance of V1 which is a relatively low resistance; this voltage drop, although small, is shown on the input waveform as the value E_{gk}. As a result of the small positive bias on the grid of VI, a maximum value of plate current flows in the plate circuit. The high plate current, flowing through plate load resistor R2, causes a maximum voltage drop across R2, resulting in a minimum (nearly zero) voltage at the plate of V1. Because of the phase inversion within the triode, the effective grid voltage, which is the minimum positive voltage drop across the grid-to-cathode resistance of Vl, becomes an inverted (negative) and amplified voltage, although still minimum, at the plate of V1.

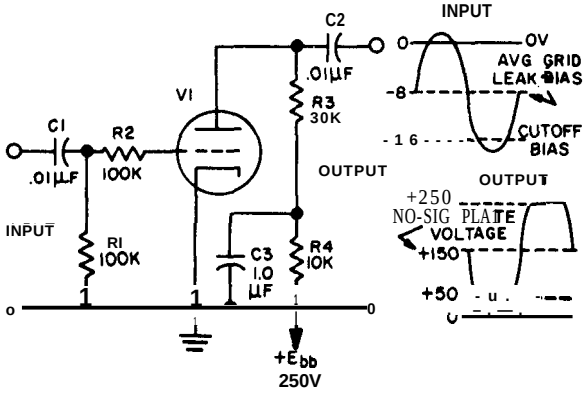


Typical Unbiased Triode Grid Limitar and Input-Output Waveform

When the positive half cycle of the input signal is completed and the input voltage falls to zero (the potential of the cathode), the grid current ceases to flow. As a result there is no longer a voltage drop across R1. Then, as the grid goes more negative during the negative half cycle, with no voltage drop across RI, the entire value of input voltage appears at the grid of VI, since it is applied across the (infinite) resistance between the grid and the cathode. Assuming that the negative input signrd does not drive the grid to cutoff, the negative half cycle is amplified by the triode and inverted, and this positive waveform appears at the output terminals of the circuit. In this manner, the positive portion of the input signal waveform is cut off, or limited, practically to zero, while the negative portion of the input signal is amplified without distortion and inverted, and passed through coupling capacitor Cl to the output terminals.

Another type of grid limiter circuit, which develops grid-leak bias to limit both the positive and negative peaks of the input signal, is the grid-leak biased grid limiter illustrated below. In this circuit, a sine wave from a master oscillator is applied to the input terminals, to produce a square wave which will be eventually used to produce trigger aud timing pulses in a radar circuit application. The triode, Vl, operates without fixed bias, but develops grid-leak

bias as a result of grid current flow. As the input voltage rises, during the positive portion of the input signal, the input coupling capacitor, Cl, charges because of the current which flows through grid return resistor RI and through grid resistor R2 in series with the grid-to-cathode resistance of V1. When the positive portion of the input cycle is completed and the input goes negative, the charge in capacitor Cl leaks off through resistor RI. During the charging cycle of Cl, the resistance in series with Cl consisted of R1 in parallel with R2 and VI. During discharge, V1 will not conduct when the grid is more negative than the cathode, and therefore the resistance in series with Cl is that of R1 alone. The resistance in series with Cl is thereby greater during discharge than it is during the charge cycle; as a result, a charge accumulates in capacitor Cl and becomes a negative bias, applied to the grid of VI (between grid and cathode).

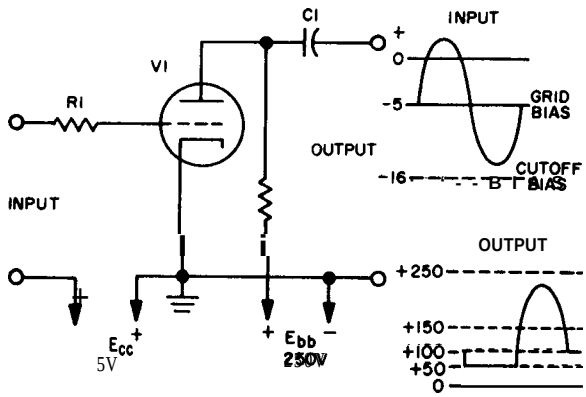


Typical Grid-Leak Biased Grid Limiter and Input-Output Waveforms

The negative bias on the grid, produced by the flow of grid current during the charging cycle of Cl, acts in opposition to the effect of the input signal in driving the grid positive. The bias therefore establishes the average value, or baseline, about which the input sine wave varies. In the previous illustration, this bias is shown as having a value of –8 volts. Now, when the input signal during the positive portion of the cycle swings from –8 volts to zero volts, or cathode potential, the flow of grid current through the high value of the grid resistance of R1 limits the signal of approximately zero volts at the grid of V1. The increased flow of plate current through the plate load resistors, R3 and R4, produces an increased voltage drop across them and a minimum voltage at the plate of V1. This is shown in the output waveform as the output signal falls from +150 volts to +50 volts, and is clipped at the level of +50 volts until the positive portion of the input signal, at the input terminals, passes through the crest of the waveform and falls back to zero volts. As the input signrd falls below zero volts, the plate current begins to fall, the voltage. drop in R3 and R4 decreases, and the voltage at the plate of Vi–which is the output voltage of the circuit-begins to rise. When the negative-going input signal falls toward the cutoff bias value, the plate current decreases toward zero, reaching zero when the combination of input signal and bias reaches cutoff. The plate voltage of V1, and therefore the output signal voltage, increases toward the B+ voltage, reaching this value of +250 volts at cutoff. Thus the top of the output waveform is limited, or clipped, at the level of +250 volts, as shown in the illustration.

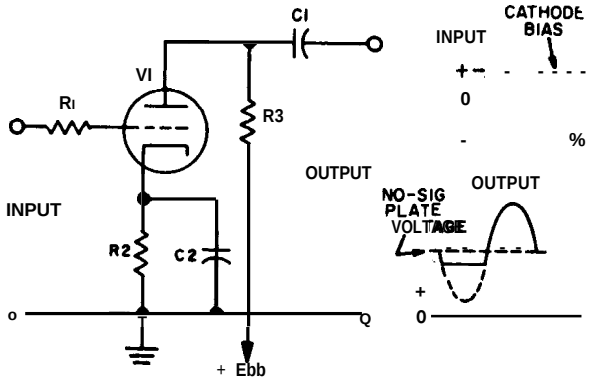
A third type of grid limiter circuit is that in which a freed negative bias is applied to the grid, from a battery or dc power supply. A typical circuit of this type of grid limiter is shown in the following illustration. In this circuit, a fixed bias of –5 volts, dc, is applied to the grid from a bias supply, along with the input signal. As the signal increases from the negative 5-volt bias value in a positive direction, the plate current increases in accordance with the signal input, with a consequent decrease in plate voltage, until the input signal reaches the cathode potential of zero volts. When this point is reached, any further rise in grid voltage drives the grid positive with respect to the cathode, and the resulting flow of grid current through grid resistor R1 limits the voltage at the grid to approximately zero volts (disregarding the voltage drop across the grid-to-cathode resistance of Vi). The plate voltage, now at its lowest value, is clipped, or limited, at a level determined by the circuit application, which for illustration is shown as +50 volts in the output waveform. As the input signal passes through its positive crest and fills, grid current ceases to flow when the input signal falls to zero volts. During the remainder of the positive half cycle of the input signal, and through the complete negative half cycle, the flow of plate current follows in accordance with the grid voltage, without distortion, and the amplified and inverted waveform of voltage is furnished to the output terminals of the circuit. (The

amplitude of the negative portion of the input signal is not sufficient to drive the tube to cutoff.)



Typical Fixed Bias Grid Limitar and Input-Output Waveforms

A fourth type of grid limiter circuit is the self-biased grid limiter, in which the bias is automatically developed by the flow of plate current through a bypassed cathode resistor. A typical circuit of this type of grid limiter is shown in the following illustration. In this circuit, the grid of VI is normally held at ground potential, and the grid bias is produced by the flow of plate current through cathode resistor R2. In order to maintain the bias at a relatively constant level, so that it does not vary with the input signal waveform, R2 is bypassed with capacitor C2, which has a large value of capacitance. The flow of plate current through R2 established the cathode of V1 at a positive voltage above ground potential, thus furnishing the bias to the grid, which is at ground potential and therefore negative with respect to the cathode. When the input signal rises at the start of the positive haIf cycle, the plate current in VI increases with the signal, and the waveform is not limited until the grid voltage reaches a value equally positive to that of the cathode. When this point is reached, a further rise of the input voltage produces grid current, which results in the limiting 'of the voltage at the grid. This is indicated by the input waveform in the illustration, at the point of cathode bias. Grid current ceases to flow, and thereby limiting is completed, when the input signal has fallen back to the point where the voltage is equal to that of the cathode. During the remainder of the positive hrdf cycle, and throughout the negative half cycle, the circuit operates as a Class-A amplifier, furnishing an output waveform which is an amplified and inverted reproduction of the input signal, without distortion. (The amplitude of the negative portion of the input signal is not sufficient to drive the tube to cutoff.)



Typical Cathode-Biasad Grid Limiter and Input-Output Waveforms

Failure Analysis.

No Output. The analysis of failure which results in no output from a triode grid limiter is somewhat similar to that of the parallel, positive lobe diode limiter. In the triode grid limiter, failure of triode VI, or an open-circuited grid resistor or plate load resistor, or failure of the plate supply voltage could each be responsible for a no-output condition. If the circuit utilizes cathode bias, an open cathode resistor would also be a cause of no output. If the circuit contains input and/or output coupling capacitors, an open-circuited' capacitor in either position would result in no output. Finally, failure of the applied signal, or an input signal of incorrect waveform or voltage level, could also be responsible for a no-output condition.

Radueed or Unstable Output. Assuming that an input signal of correct waveform and voltage level is being furnished to the input terminals of a grid limiter circuit, a reduced value of output is probably the result of either insufficient signal at the grid terminal of the triode, insufficient voltage at the plate terminal of the triode, or a leaky coupling capacitor

in the grid or plate circuit, when used. Insufficient signal at the grid may be due to a defective grid resistor which has increased in value or become open-circuited. Insufficient plate voltage may be due to a defective plate load resistor or insufficient plate supply voltage brought about by a defect in the power supply. A shorted plate output coupling capacitor may also be responsible for low plate voltage, with the following stage loading the plate circuit. A cathode resistor, if used, may be too low in value and cause excessive plate current, resulting in a low plate voltage. Leaky coupling capacitors, if used, may cause distortion of the waveform, in addition to placing an additional load on the circuit. Finally, a shorted or leaky decoupling capacitor in the plate supply decoupling circuit, when used, would be responsible for low, or absence of, plate voltage.

TRIODE SATURATION LIMITER (ELECTRON TUBE)

Application.

The triode saturation limiter is used to limit, or clip, the positive peaks of an input waveform. This limiter is useful when low amplitude input signals are used, at rather low plate supply voltages.

Characteristics.

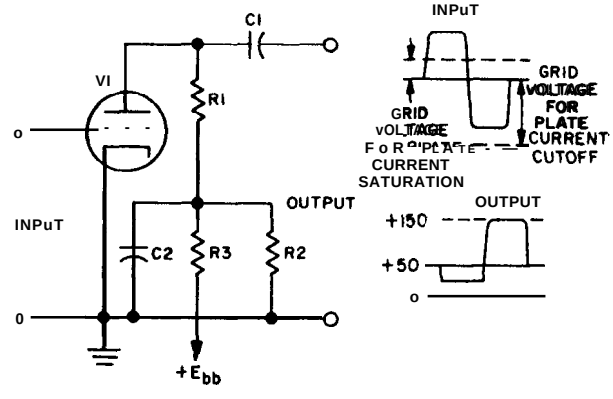
Same characteristics as the grid limiter circuit.

Circuit Analysis.

General. The triode saturation limiter differs from the triode grid limiter in its limiting action, in that the actual limiting is accomplished in the plate circuit, while in the grid limiter it is accomplished in the input, or grid circuit. In the saturation limiter the entire input signal is applied to the grid of the triode. Amplification of the entire signal is provided by the triode, up to its maximum capability insofar as its maximum plate current is concerned. When the input signal to the grid is such that maximum plate current flows, any additional vrdue of input signal has no further effect on the plate current; this additionrd value is thereby limited, or clipped, at the level of maximum current flow in the plate circuit.

The action of the triode saturation limiter is similar to that of the triode grid limiter in its end result; that is, in both cases the positive portion of the input waveform is the portion which is limited, or clipped. In the saturation' limiter, however, the output is generally of a higher amplitude, because the plate current is driven to its maximum value. On the other hand, since it is necessary to drive the plate circuit to its maximum conduction to produce limiting, this becomes a disadvantage because a higher input signal is required to drive the grid.

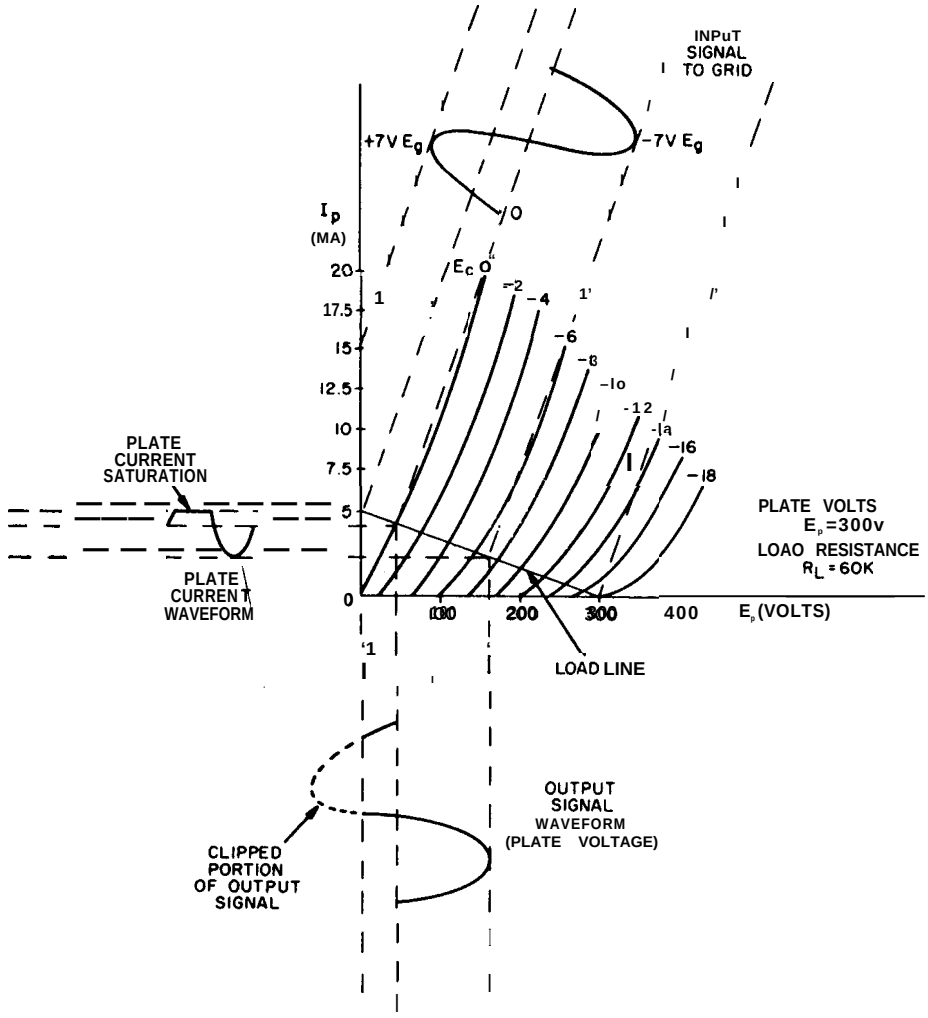
Circuit Operation. The circuit of a typical triode saturation limiter is shown in the accompanying illustration.



Typical Triode saturation Limiter and Input-Output Waveforms

In **this** circuit the input signal, which is obtained from a low-impedance source that is capable of a relatively high power output, is applied directly to the grid of triode V1, and no grid resistor is used. The cathode is connected directly to ground, and the triode is thereby operated at zero grid bias. A voltage divider, consisting of R3 and R2, is connected in the plate supply circuit, to obtain a lower value of voltage. Capacitor C2 acts as an additioml falter for the plate voltage supply, while resistor RI is the plate load resistor. If the resistance value of R1 is relatively high, and the relative resistance value of R3 and R2 are such that the voltage at their junction is relatively low, then a fairly low value of positive input signal will drive the grid to the point of plate current saturation, and limiting **will** occur. The reason for this is as follows: The following illustration shows the dynamic characteristics of a typical triode amplifier tube–a single section of a type 12AU7. Assume that this tube is used in the circuit previously illustrated,

with a plate voltage (at the junction of R3 and R2) of +300 volts, and a load resistance R1 of 60K. The triode is operated at zero bias, since the cathode is grounded, and the input signal to the grid is a sine wave of 14 volts peak-to-peak. From the illustration, it may be seen that the plate current flowing in the circuit, with no signal input, is approximately 4 ma. It is rdso evident that the maximum plate current that can flow, with the fixed values of plate voltage and load resistance given, is 5 milliamperes. When the input signal rises from zero toward +7.0 volts on its positive half cycle, plate current increases from 4 ma to 5 ma, reaching 5 ma when the input signal reaches approximately +2.5 volts. At this point the plate current is maximum, and limiting occurs. The output voltage at this point has decreased nearly to zero (there is always some value of voltage drop within the triode, because of its plate resistance). The output voltage waveform is thereby clipped on its negative half cycle, until the input signal has passed through its positive peak of +7.0 volts and fallen back to +2.5 volts. At this point limiting ceases, and the plate current begins to decrease in accordance with the input signal.



A-959

Operating Characteristics of a Typical Triode Saturation Limiter

It becomes evident, from the illustration, that the point at which saturation is reached, and thereby the positive limit at which clipping of the input signal occurs, may be adjusted by adjusting the slope of the load line, which in turn may be adjusted by varying the load resistance and/or the plate voltage. On the other hand, the percentage of the positive portion of the input waveform which is clipped may be adjusted by varying the peak voltage of the input signal. Referring again to the previous illustration, it can be seen that clipping of the positive portion of the input signal occurs at approximately +2.5 volts. This is approximately 30 percent of the positive peak input waveform. If the input signal is now increased to 25 volts peak-to-peak, clipping of the 12.5-volt positive peak still occurs at +2.5 volts. The positive portion of the input signal is now clipped at 20 percent of the peak input value.

Failure Analysis.

No Output. The cause of a no-output condition in a triode saturation limiter may be one of four possibilities. Either the input signal may have failed, the triode tube may be defective, the plate supply voltage may have failed, or the output coupling capacitor may be open-circuited. Failure of the plate supply voltage may be due not only to a defective power supply, but also to an "open" resistor RI or R3 or a shorted bypass capacitor C2, in the plate circuit.

Reduced or Unstable Output. A reduced or unstable output from a triode saturation limiter could result from almost any component of the circuit which has become defective. A weak or leaky (partially shorted) triode VI or a reduced value of plate voltage may be the cause of either condition, depending upon the extent of the defect. A reduced value of plate voltage may be due to a defective power supply, or it may be due to an increase in the value of resistor R1 or R3 or a decrease in the value of R2. A leaky coupling capacitor Cl may allow some of the d-c plate voltage at VI to appear at the input to the following stage, resulting in an improper bias to that stage and probable distortion therein. Finally, in the analysis of failure of a circuit it is often assumed that the proper input signal is being supplied. This fact will bear checking, however, because an input signal of incorrect value or waveform could well be responsible for a distorted or reduced value of output signal.

TRIODE CUTOFF LIMITER (ELECTRON TUBE)

Application.

The triode cutoff limiter is used to limit, or clip, the entire negative half-cycle, or the negative peaks, of the input waveform,

Characteristics.

Input may be either a negative signal or a signal containing both positive and negative portions.

Output may be positive signal with peaks which exceed a preset value clipped, or a signal having both positive and negative portions in which all or a portion of the positive peaks are clipped.

Output signal is out of phase with input signal; therefore, the clipped negative half-cycle of the input signal becomes a clipped positive half-cycle of the output signal.

Output signal will contain a negative signal which is the amplified positive portion of the input signal, if such is included in the input. It may contain a positive portion, which is the result of a partially clipped negative input signal that has been amplified. The peak amplitude of the output signal, including both positive and negative portions when applicable, may be higher or lower than the input peak amplitude, depending upon the circuit application design.

Circuit Analysis.

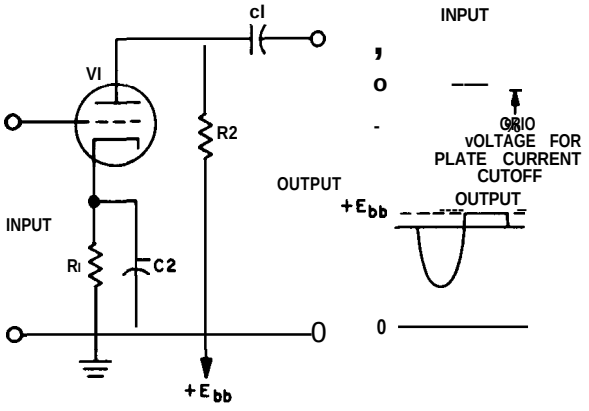
General. The triode cutoff limiter depends, for its limiting action, upon the fact that an electron current within a vacuum tube can flow only from the cathode to the plate, and not in the reverse direction. When the signal at the grid of the triode drives the grid to cutoff, the plate current is decreased to zero, and it remains at zero during the time that the grid is held at or below cutoff by the input signal. At cutoff the plate current is zero, and, regardless of how much farther the grid is driven negative, the plate current remains at zero, since the plate current cannot become a negative value. When the grid is at (or below) cutoff, since no current flows in the plate circuit, there is no voltage drop across the plate load resistor. The voltage at the plate, therefore, increases to, and is maintained at, its maximum value, which is the voltage of the plate power supply, E_{bb}. The limiting thus attained affects the positive peak of the output waveform, whereby the positive peak is cut off, or flattened, at the voltage level E_{bb} as a result of driving the grid in the negative direction to cutoff.

Cutoff voltage is that value of negative voltage, with respect to the cathode, which must be applied to the grid to reduce the plate current to zero. This value of voltage is dependent upon the value of the plate supply voltage, E_{bb}. In a triode the cutoff voltage, E_{co}, is approximately equal to the plate supply voltage, E_{bb}, divided by the amplification factor, μ, of the triode; thus:

$$(-)\,E_{co} = \frac{E_{bb}}{\mu}$$

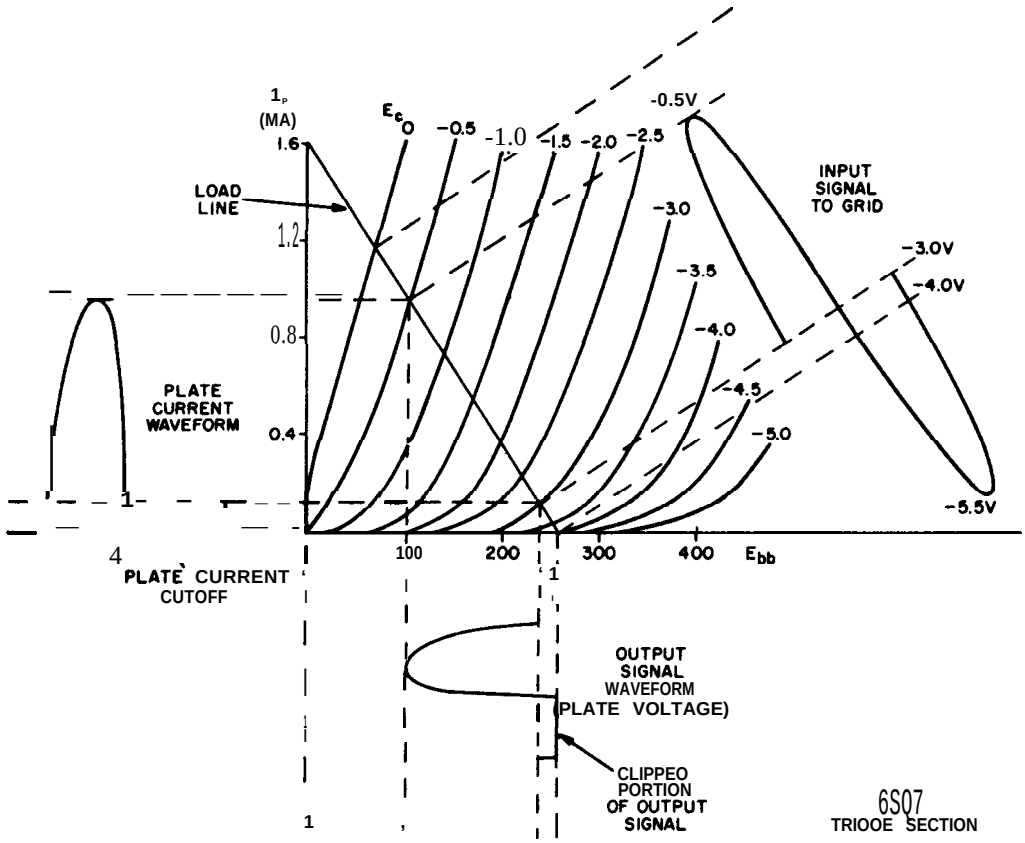
The relationship expressed above is valid only for a tnode; it does not apply to tetrodes or pentodes.

Circuit Operation. The circuit of a typical triode cutoff limiter is shown in the following illustration.



"Typical Triode Cutoff Limiter and Input-Output Waveforms."

In this circuit the input signal is applied directly to the grid of triode Vl, and no grid resistor is used. Cathode bias is supplied by resistor Rl, bypassed by C2 to hold the bias value constant with the average value of the plate current. If the value of the cathode resistor, RI, is suftlciently large the bias developed will set the operating point of the tube near cutoff. When the input signal rises on the positive half cycle, the plate current will increase and thus produce the resultant plate voltage waveform shown in the illustration. When the input signal begins to fall, this causes a corresponding positive excursion of plate voltage, and this action continues until cutoff is reached on the negative half cycle of the input signal. At this time the plate current is zero, thus limiting (clipping) the positive portion of the plate-voltage waveform. For the purpose of illustration, assume that the resistance value of R1 is such that the no-signal d-c bias is –3.0 volts at the grid. The plate supply voltage, E_{bb}, for this illustration is +250 volts, and the maximum amplitude of the input signal is 2.5 volts. The grid voltage, with input signal, therefore swings from -0.5 volt to –5.5 volts. The dynamic conditions existing in this example are shown in the following illustration, based on utilizing the triode section of a type 6SQ7 tube.



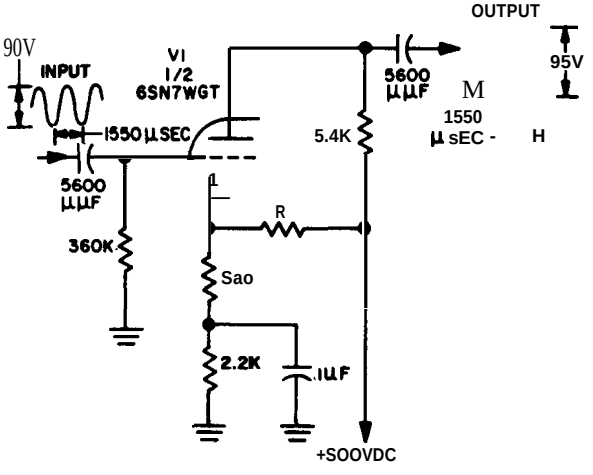
Operating Characteristics of a Typical Cutoff Limiter

From the illustration, it may be seen that the no-signal plate current is approximately 0.125 ma. When the input signal rises on its positive half-cycle, the plate current increases from 0.125 to 0.95 ma, reaching this maximum value when the input signal reaches its most positive (or least negative) value of -0.5 volt. The input signal then begins to fall, completing the positive half-cycle when the voltage at the grid is –3.0 volts. As the input signal begins its negative half-cycle, the voltage at the grid continues in its negative direction until it reaches –4.0 volts. At this point cutoff occurs, and the plate current has fallen to zero. The output voltage at this point, with no plate current flowing and therefore no voltage drop through plate load resistor R2, has increased to +250 volts, the value of E_{bb}. With the plate current cut off, the output voltage remains at this value until the input signal has fallen through its negative peak of –5.5 volts and increased to the cutoff point of –4.0 volts. As the input signrd continues to rise, the plate voltage (output signal) begins to fall; at the end of the negative half-cycle of input signal the output voltage has fallen to its no-signal value of approximately +235 volts, and the plate current has increased to 0.125 ma again.

From the preceding illustration it becomes evident that the point at which cutoff is reached, and thereby the negative limit at which clipping of the input signal occurs, may be changed by adjusting the slope of the load line and/or the no-signal grid bias. The slope of load line may be adjusted by changing the plate supply voltage, E_{bb}, and/or the load resistance; this adjustment, however, will affect the no-signal grid bias when cathode biasing is utilized. The grid bias may be further adjusted by changing the value of the cathode resistor. It should be noted that, with

cathode bias, cutoff cannot be maintained with a steady dc signal, because the bias is obtained by means of the plate current flowing through the cathode resistor. At cutoff, no plate current flows, and therefore no bias will be obtained. But with ac, and especially with pulsed signals and the use of a large capacitor bypassing the cathode resistor, the bias may be adjusted over a considerable range by changing the value of the cathode resistor, thereby adjusting the point at which cutoff is reached. When complete clipping of the negative portion of the input signal is not required, the percentage of the negative portion which is clipped may be adjusted by varying the peak voltage of the input signal. However, the maximum limit of the input signal must in no case be great enough to drive the grid into the positive region, where grid limiting would act to clip the positive peak of the input signal and thereby introduce distortion to that portion of the waveform. Refer to the previous illustration; the positive peak of the input signal is shown driving the grid to -0.5 volt, and the negative peak to –5.5 volts. Clipping occurs at -4.0 volts, and the no-signal bias is –3.0 volts. With the negative swing from –3.0 to –5.5 volts, or a total swing of 2.5 volts (of which the portion between 4.0 and –5.5 volts, or a total of 1.5 volts, is clipped), the percentage of the negative portion clipped is therefore 1.5/2.5, or 60 percent. Under the same circuit conditions, the percentage of the negative portion which is clipped may be increased, by increasing the input signal amplitude, only by the additional amount of 1.0 volt peak to peak. This increased input would drive the grid to –6.0 volts on the negative peak, and to zero volts on the positive peak, which is the absolute maximum limit without incurring grid limiting. With the additional drive on the negative swing, the percentage of the negative portion clipped would thereby be increased to 2.0/3.0, or 66 per cent.

The circuit of a triode cutoff limiter used in a specific application is shown in the following illustration. This cutoff limiter is used in the modulator circuit of Radar Set AN/SPS-10D, and in this application begins the shaping of a sine wave at a frequency of 650 Hz, obtained from a repetition rate oscillator, to a square wave. In the absence of an input signal, V1 is cut off by the positive voltage present at the cathode, obtained from the voltage divider composed of the two cathode resistors and resistor R returned to +300 volts, dc. Resistor R in this circuit represents the conduction through another triode tube. The 0.1 -μf capacitor across the 2.2K resistor in the cathode circuit acts to maintain the cathode bias at a constant average value. The input to the grid of VI is a sine wave of approximately 90 volts peak to peak. As the input voltage increases on the positive portion of the input signal, the grid voltage overcomes the positive bias voltage at the cathode from the voltage divider, and the triode conducts. The output signal, which had maintained a flat top at +300 volts, dc during the cutoff interval, now begins to fall in accordance with the rising sine wave input signat, because of phase inversion within VI. The output signal maintains the 1550-psec pulse width of the input signal, but has a waveform which is approximately a square wave, with the positive peaks cut off sharply, and a peak voltage of 95 volts, as shown in the illustration.



Triode Cutoff Limiter Used in Modulator of Radar Set AN/SPS-10D

Failure Analysis

No Output. Assuming that an input signal of correct polarity and sufficient voltage is being furnished to the triode cutoff limiter, the cause of a no-output condition could be one of several possibilities. The triode tube itself should be first suspected. If the tube is found to be capable of operation, the input 'signal may not be present at the grid of the tube, because of an open coupling capacitor. The

absence of voltage at the plate, due to an open plate load resistor, an inoperative power supply, or a shorted bypass capacitor across a plate load decoupling circuit, if such a circuit is used, may be responsible for no output, as may also an open cathode resistor. Finally, an open output coupling capacitor, if used, would prevent the output from the limiter from being furnished to the following stage.

Reduced or Unstable Output. Several conditions could contribute to a reduced or unstable output from the triode cutoff limiter. A reduced value of plate voltage, due to a defective power supply, or an aging triode tube due to low cathode emission, may be responsible for a reduced output. An open cathode bypass capacitor would be the cause of degeneration, and reduce the output signal. If a freed cathode bias is obtained from a voltage divider in the plate voltage supply line, such as shown in the second circuit illustrated herein, and if the resistor on the high side should become open-circuited, the operation of the circuit would be changed from fixed bias to self (cathode) bias, thereby changing the point of limiting, with the possibility of a distorted, or even excessive, output. An open grid resistor, if used, may cause grid "blocking" and severe distortion. In addition, the possibility of an input signal of incorrect waveform, or of insufficient amplitude, should not be overlooked in cases of reduced or otherwise faulty output.

TRIODE OVERORIVEN AMPLIFIER LIMITER (ELECTRON TUBE)

Application

The triode overdriven amplifier limiter is used to limit, or clip, both the positive and the negative peaks of an input signal waveform. It is also used to steepen the sides of an input signal having a waveform which is approximately a square wave.

Characteristics

Input is generally a sine wave, or a partially squared wave produced from a sine wave by a preceding limiter.

Output is usually a square wave having relatively steep sides.

Output signal is out of phase with input signal.

Amplitude of output signal may be higher or lower than input amplitude, depending upon the points at which the positive and negative peaks are clipped. Amplification is afforded by the circuit to the input signal, before the peaks are clipped.

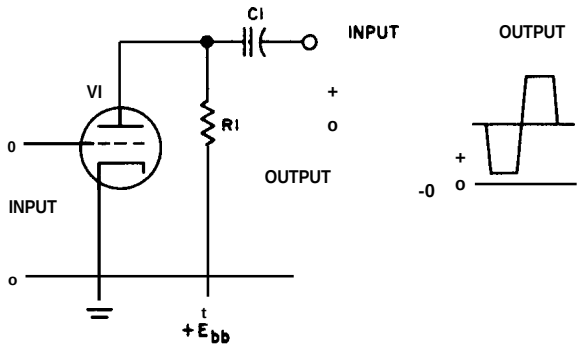
Circuit Analysis

General. The triode overdriven amplifier limiter accomplishes its limiting action by combining cutoff limiting with saturation limiting (or with grid limiting). The principal use of this type of limiter is to produce a square wave, having steep sides which are very close to true vertical, from an input signal whose waveform is only a rough approximation of a square wave, having sides which deviate at considerable angles from the vertical. The preceding circuit which furnishes the input signal should have an output impedance which is relatively low, and therefore be capable of delivering power, because a current of some degree is drawn by the grid of the triode when it is driven positive. The preceding circuit should rdso be capable of furnishing an input signal of considerable amplitude, so that the slope of the sides of the, waveform may be as nearly vertical as possible before amplification and limiting.

Circuit Operation. The circuit of a typical triode overdriven amplifier limiter is shown in the following illustration. In this circuit the input signal is applied directly to the grid of the triode, Vl, and no grid resistor is used. Since the source of the signal has a low impedance and thereby can furnish current to the grid of Vl, no limiting is performed in the grid circuit. No cathode resistor is used; hence the grid is operated at zero bias. The input is a very large amplitude signal, often ten times the value required to drive the tube to cutoff and to saturation. When the input signal rises, the plate current also rises until the point of plate current saturation is reached. The input signal continues to rise to its peak; however, the plate current cannot increase further because it is already at maximum. During this time, the plate voltage is limited to its minimum value. As the input signal passes through its positive peak and begins to fall, it drops below the saturation point, and at this time the plate current again follows the input signal. As the input signal continues to fall, the plate current decreases accordingly to cause the plate voltage to rise until the plate current is cut off by the input signal. The plate voltage is thus limited to its maximum positive value. When the input signal passes through its negative extreme and begins to rise, it

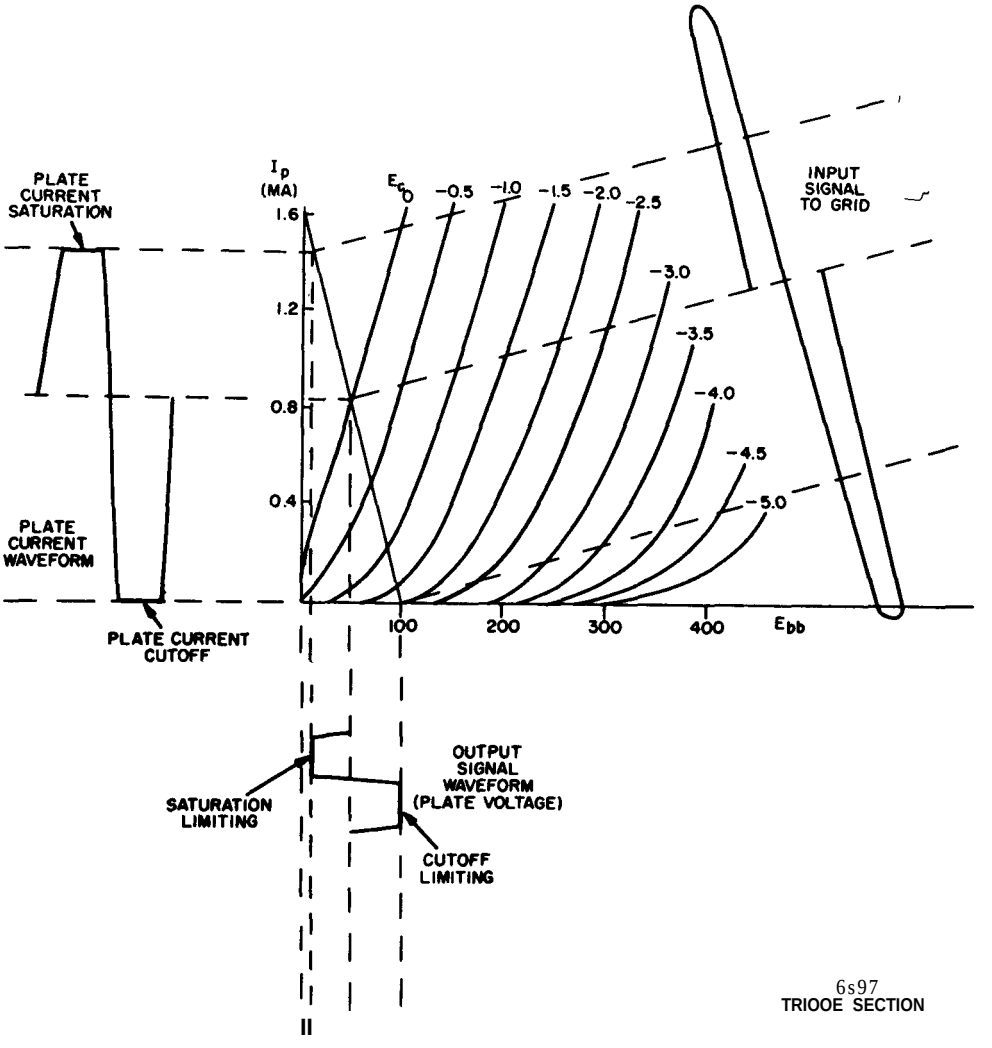
491-044 0 73 76

rises above the cutoff point and, once again, plate current begins to flow.



Typical Overdriven Amplifier Limiter and Input-Output Waveforms

The action of the triode overdriven amplifier with an input sine-wave signal of sufficient amplitude is shown in the following illustration. This illustration shows the dynamic conditions existing in the circuit, based on utilizing the triode section of a type 6SQ7 tube, with an input signal having an amplitude sufficient to drive the grid into plate current saturation on the positive swing, and beyond cutoff on the negative swing. It may be seen that the plate current flowing, in the absence of an input signal, is 0.8 ma. When the input signal rises on the positive portion of its cycle, the plate current increases from 0.8 ma to approximately 1.4 ma, at which point plate current saturation is reached. As the input signal continues to rise to its peak, the plate current cannot increase in accordance with the input signal, because it is already at its maximum value. The plate voltage at this time is at its lowest value, with nearly all of the plate supply voltage, E_{bb}, existing as a voltage drop across the plate load. (A small portion of the total voltage drop exists across the plate-to-cathode resistance of the triode itself.) The plate current is thereby limited at the saturation value, and the output voltage is limited at its lowest value, until the input signal passes through its positive peak and falls again below the saturation point. At that time the plate current begins to frdl in accordance with the input signal, and, consequently, the output signal begins to rise. The input signal continues to fall as the positive portion of the input cycle is completed and the negative portion begins.



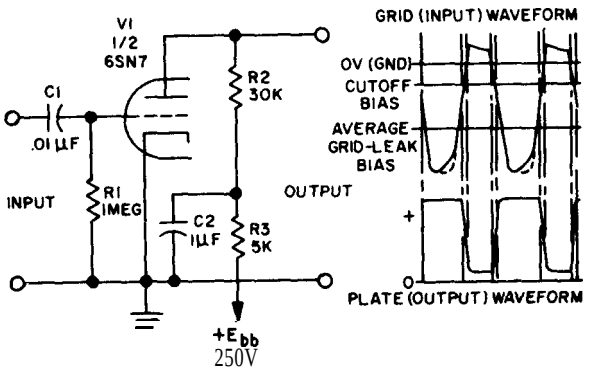
Operating Characteristics of a Typical Overdriven Amplifier Limiter

As the input signal continues to fall, the plate current continues to decrease until the grid voltage reaches -2.0 volts. At this point cutoff occurs, and the plate current has decreased to zero. The output voltage at this point, with no plate current flowing and therefore no voltage drop through the plate load resistor, has increased to maximum (the value of E_{bb}). The plate current is thereby limited at zero, and the output voltage is limited at its maximum value, until the input signal passes through its negative peak and rises again to the cutoff point. At that time plate current again begins to flow, and the output voltage begins to fall, until the plate current increases to 0.8 ma when the negative portion of the input cycle is completed.

It becomes evident, from the preceding illustration, that the point at which the positive portion of the input signal is clipped (plate current saturation), and the point at which the negative portion of the input signal is clipped (cutoff), may be adjusted by changing the slope of the load line and the plate load resistance. The slope of the load line may be

increased by increasing the plate supply voltage, E_{bb}, and at the same time increasing the plate load resistance. This will produce a larger positive output signal, because it increases the value of the negative input signal required to reach cutoff.

A practical application of a triode overdriven amplifier limiter is its use in the time circuitry of a radar transmitter. In this application the overdriven amplifier functions as one of the stages in a chain of circuits, which generate a sine wave in a master oscillator, and from it produce sync and timing pulses for the operation of the complete system. The overdrive amplifier follows after the master oscillator and a triode limiter in the chain, and it receives an input signal whose waveform is that of a sine wave which has been approximately squared by a triode limiter. The function of the overdriven amplifier is to steepen the sides of the square wave from the limiter, to produce a square wave having sides as nearly vertical as possible, which may be used in a following stage to produce a sharp trigger pulse. The circuit of the overdriven amplifier used in this application is shown in the following illustration. In this circuit, which utilizes cutoff limiting with grid limiting (instead of saturation limiting), the input signal waveform is somewhat like a square wave, and of large amplitude. As the input signal begins to rise toward its positive peak, the plate current remains at zero, since the grid voltage is below cutoff, until the grid voltage rises (becomes less negative) to the cutoff potential. The triode then conducts, as the grid voltage rises to zero (ground) potential. When the signal drives the grid to zero bias, grid current begins to flow, limiting any further rise of the grid voltage at this point. The grid current charges coupling capacitor Cl, through the relatively low grid-to-cathode resistance of triode V1, to an average voltage which serves as a highly negative bias for the grid of triode V1. During this time the plate (output) voltage has fallen abruptly, decreasing nearly to zero, and it remains at that value until the grid signal falls, from its positive peak, back to zero. At zero bias, the plate current begins to fall rapidly as the grid voltage becomes more negative, until cutoff is reached, when the plate current has fallen to zero. During this time the plate (output) voltage has risen sharply to its maximum value of E_{bb}. From the waveforms shown, it should be noted that the negative portion of the output waveform is narrower than the positive portion; this is due to the fact that the tube conducts only during a portion of the positive half-cycle of the input signal, while it remains nonconductive during the entire negative half-cycle.



Overdriven Amplifier Used in Radar Timing Circuitry, and Waveforms

Failure Analysis

No Output. The cause of a no-output condition in the triode overdriven amplifier limiter may be defective triode tube, failure of the plate supply voltage, an open input or output coupling capacitor (if either is used), or failure of the input signal. Assuming that the tube has been determined to be capable of operation, and that an input signal of proper amplitude and polarity is present at the input to the circuit, an open plate load resistor (or plate decoupling resistor if a decoupling circuit is used) would render the circuit inoperative, and no output would be available. A shorted decoupling bypass capacitor (C2 in the second circuit illustrated), if a decoupling circuit is used, may also be the cause of a no-output condition. An open coupling capacitor in the input grid circuit, if one is used, would likewise prevent any output from being produced.

Reduced or Unstable Output. When the output of the triode overdriven amplifier becomes unstable or is of reduced value, a low value of plate voltage, due to a defective power supply, or an increased value of plate load resistance, due to a defective or "aging" resistor, may be the cause of this condition. Either a leaky input or output coupling capacitor or an open grid resistor could be responsible for unstable operation. The tnode tube itself may have low cathode emission; this would produce a reduced output.

Finally, the input signal itself should be checked to ascertain whether it is of correct waveform and has sufficient amplitude, since any deficiency in the input signal would be evident in the output from the overdrive amplifier.

TRIO DE, BASIC COMMON-BASE LIMITER

Application.

A triode, basic common-base limiter is used in semiconductor circuits when it is desired to limit the amplitude of a relatively small input signal to a definite negative and positive output level.

Characteristics.

Cutoff and saturation limiting are used by this limiter.

Base to emitter bias and base to collector bias values determine the proper limiting level.

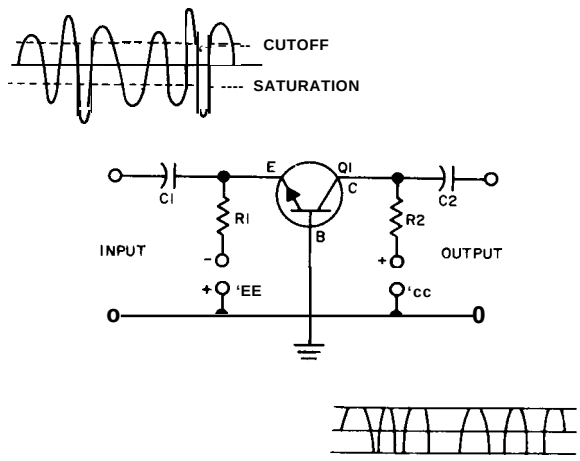
Low input impedance and high output impedance.

No phase inversion.

Circuit Analysis.

General. The triode, basic common-base limiter is essentially a transistor amplifier which is operated at a level which allows it to be cutoff and saturated at certain positive and negative amplitudes of the input signal. By using a specific emitter to base voltage a specific emitter current is obtained. This emitter current determines what signal level is required to cutoff and saturate the limiter. These cutoff and saturation values are the limiting levels.

Circuit Operation. A triode, basic NPN common-base limiter is shown in the accompanying illustration.



Triode, Basic Common Base Limiter (NPN)

Capacitor Cl and resistor R1 form a coupling network which couples the signal from the previous stage to the emitter of QI. Bias supply V_{EE} determines the emitter to base bias voltage. The value of base resistor R1 in conjunction with the bias supplied by V_{EE} determines the emitter current. Collector load resistor R2 and collector supply V_{CC} establish the collector current. Capacitor C2 couples the output of Q1 to the following stage. Q1 is an NPN transistor.

When the incoming signal is positive-going the positive signal voltage opposes the normal negative bias between the emitter and the base. This reduces the current flowing through the transistor. When the collector current of Q1 is reduced, the voltage drop across R2 is also reduced, and the collector voltage

approaches that of the collector supply which, in effect, makes the collector more positive. Thus, for a positive incoming signal a positive output voltage is obtained.

When the positive incoming signal becomes sufficiently large that it cancels the forward bias entirely the transistor cuts off and collector current ceases. The collector voltage of Q1 is now at the supply value and cannot increase further. Hence, for any further positive increase in signal voltage there is no change in output voltage, which stays constant for any variation of input signal voltage beyond the cut-off level.

When the incoming signal is negative-going the emitter is driven negative with respect to the base. This increases the forward bias and current flow (electron flow) from emitter to collector. An increase in voltage drop across the collector resistor R2 resuhs, which drives the collector more negative. Thus, a negative input results in a negative output.

If the incoming signal exceeds a certain negative value, the current from emitter to collector reaches its maximum (saturation) value and the collector voltage reaches a minimum value. Any further increase in amplitude of the negative input signal does not affect the collector current or the voltage at the collector, since the transistor has attained a saturated level.

It is at these levels of saturation and cutoff that the output voltage is limited. Thus, to achieve limiting it is necessary to supply a large amplitude signal. Between the limits of cutoff and saturation the circuit will act as a conventional amplifier. Beyond these limits the peaks are cut off and the waveform is effectively “squared off”.

Failure Analysis.

No Output. In a triode, basic common-base limiter a no-output condition may be caused by any of the following (provided the input signal is present and correct): An open coupling capacitor Cl, an open bias resistor RI, an open or shorted supply voltage V_{EE}, an open collector to base resistor R2, an open or shorted supply voltage V_{cc}, an open outPut coupling capacitor C2, or a faulty transistor Q].

To determine which of these components is at fault first use an oscilloscope to determine if the input signal is present at the input terminals of the circuit. Then determine if the input signal is present at the emitter of the transistor. If the signal is present at the input terminals but not at the emitter, first check Cl with an in-circuit capacitor checker. If C 1 is not open check RI with an ohmmeter (after disconnecting one end of the resistor from the circuit). If RI is not open, check bias voltage V by measuring it with a high resistance voltmeter. If V_{EE} is not zero or shorted, check R2 with an ohmmeter (after disconnecting one end of the resistor from the circuit). If R2 is not open, check the collector bias voltage V_{cc} with a high resistance voltmeter. Check C2 with an in-circuit capacitor checker. If C2 is not open and all other components check out, transistor Q1 must be at fault.

Low or Distorted Out. A low or distorted out may be caused by: input capacitor Cl being shorted, resistor R1 being shorted or beyond tolerance, voltage source V_{EE} being other than the required voltage, resistor R2 being shorted or beyond tolerance, voltage source V_{cc} being other than the required voltage, capacitor C2 being shorted, and transistor Q1 being defective.

To determine which of these components is at fault, first check the voltage between one plate of Cl and ground with a high resistance voltmeter, then check the voltage between the other plate of Cl and ground. If these voltage values are equal then capacitor Cl is shorted. Check the value of RI with an ohmmeter (after first disconnecting one end of R1 from the circuit) for the proper ohmic value. Check voltage source V_{EE} with a high resistance voltmeter. Check R2 with an ohmmeter (after first disconnecting one side of R2 from the circuit) for proper ohmic value. Check voltage source V_{cc} with a high resistance voltmeter. Check the voltage between one plate of C2 and ground with a high resistance voltmeter, then check the voltage between the other plate and ground. If all of these components are good and the trouble still persists, the fault must be in transistor Q1.

VIDEO LIMITER (ELECTRON TUBE)

Application.

The video limiter is used to amplify and limit to a specific amplitude low level video input signal voltages in radar and television equipment.

Characteristics.

Constant output is obtained once the limiting level is reached. Linear amplification occurs up to limiting level.

Screen grid and plate voltages determine limiting level for a specific bias.

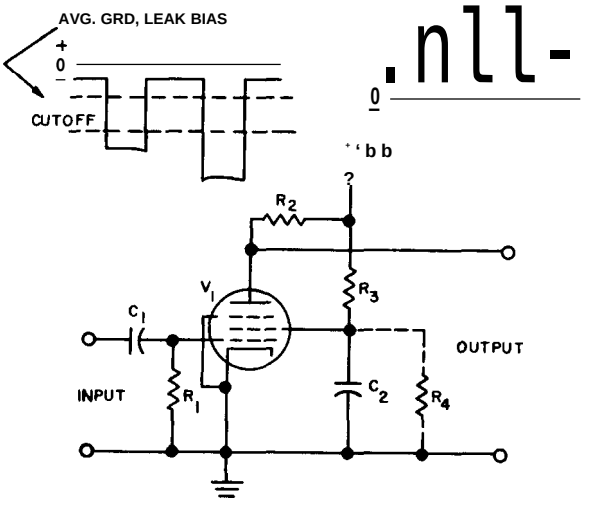
Best performance is obtained with sharp cutoff pentode-has rapid rise time, has little droop.

Circuit Analysis.

General. The pentode video limiter is located between the video detector and the low level cathode follower output stage in radar and TV receivers. Cutoff type limiting, rather than grid current or plate saturation limiting, is preferred in video limiter operation. Cutoff limiting occurs when the limiting level is determined solely by the cutoff bias level. Grid current limiting occurs when sufficient grid current is drawn to produce the desired limiting bias. Plate saturation limiting occurs when the grid bias is low or at zero and the signal drives the plate current into the saturation (no current change) level at which limiting occurs.

The limiter is supplied with a negative signal from the video detector. The signal is restricted in its negative amplitude direction by biasing the limiter tube so that cutoff occurs at the point where the desired negative voltage amplitude is attained. As the negative voltage is applied to the grid of the pentode it is inverted and amplified at the plate and coupled to the cathode follower following the limiter stage.

A pentode tube is preferred in limiter applications for several reasons. The primary reason is that the pentode inherently has sharp cutoff capabilities. This allows the tube to reach cutoff bias with a less negative-going (smaller) signal than normally would be required, and thus performs better for smaller input signals.



PentOde Video Limiter

Circuit Operation. The schematic of a typical video limiter circuit using a pentode type of electron tube is shown in the accompanying illustration.

The input signal is capacitively coupled through coupling capacitor C_1 to the grid of V_1. The combination of capacitor C_1 and grid leak resistor R_1 establish the bias potential. Plate load resistor R_2 is used to develop the plate output voltage. The screen grid dropping resistor R3 drops the screen grid voltage to the proper value and bypass capacitor C_2 places the screen at ground potential for video.

Without a signal applied, only contact bias is developed and the tube operates near zero bias. At this point the plate and screen grid voltages largely control the amount of plate current flowing.

With the application of the negative input signal (obtained from the video detector) to Cl, grid leak bias is established by the combination of C_1 and R_1. This is somewhat different than the grid leak bias explained in the Amplifier Section of this Handbook, since in this application only negative pulses are used.

When the input signal used is first applied, the current through C_1 is maximum and the total input voltage is dropped across R_1, with electron flow through R_1, placing the control grid at a negative potential with respect to the cathode. C_1 charges through R_1 for the duration of the pulse. The capacitor then discharges through R_1 for the period between pulses. Before completely discharging, however, C_1 begins to charge again with the application of a new pulse. After a few cycles of operation, an average negative voltage (bias) is, established at the control grid of the tube because of the relation of the time constant of C_1R_1 to the duty cycle of the input signal. This negative voltage (bias) establishes the cutoff point for limiting, which is determined from the plate current versus grid voltage characteristic curve of the particular pentode used for V_1. This average negative bias voltage determines where the input signal causes cutoff to occur, and thus, which portion of the input signal will be reproduced.

With the application of the input pulse, plate current flows for that portion of the pulse above cutoff. Once the tube reaches cutoff the current is at zero and remains at this point for all portions of the negative signal beyond cutoff regardless of whether or not the input signal increases. At cutoff, the plate voltage is at its maximum and, likewise, will remain at this limited amplitude for all portions of the input signal beyond cutoff. The plate voltage then decreases to a minimum value when the plate current is brought back to its maximum value by the trailing edge of the negative input pulse. Note that during the entire time the signal is less than the cutoff bias value, no limiting occurs. Thus, in the region from zero bias to cutoff, normal tube amplification action occurs. Hence, limiting occurs only for those input signals which are larger in amplitude than the value of cutoff bias. The larger the input signal, the more effective the cutoff action.

The limited voltage output level is also controlled slightly by the plate and screen grid voltages of the tube since these voltages in addition to the biasing level affect the tube characteristics and control the total amount of plate current flowing. The approximate magnitude of the limited output can be obtained from the product of load resistor R_2 and the plate current (in milliamperes) with no signal applied.

Circuit Variations. If the plate current changes between pulses because of a duty cycle change, the effective limiter output voltage is altered accordingly. This plate current change occurs if the duty ratio of the input signal is increased.

$$\text{Duty Ratio} = \frac{\text{Avg Power}}{\text{Peak Power}}$$

$$\frac{\text{Pulse Width}}{\text{Pulse Time Period}} = \text{Duty cycle}$$

This increase in duty ratio decreases the amount of screen grid current flowing, thereby increasing the screen grid voltage. This results in greater plate current flow during the invervals between signals because of the increased voltage on the plate. An additional screen resistor R_4 placed in parallel with C_2 (as illustrated in the dotted lines in the schematic) reduces the effect of any change in plate current by voltage divider action. There will be little shift of screen voltage with increased duty ratio when the current taken by R_1 and R_2 is relatively large compared to the screen current, since the voltage division is fixed at that developed across R_2.

Failure Analysis.

No Output. In a pentode video limiter, a no-output condition may be caused by any of the following (provided the input signal is the proper value and polarity): an open coupling capacitor C_1, an open bias resistor R_1 or plate resistor R_2, or by absence of plate or screen voltage, or by a defective tube V_1. To determine the component at fault first check the supply voltage and then the plate and screen voltages with a high resistance voltmeter. If the supply voltage is low or zero the trouble is in the power supply or primary fuse. If the supply voltage is normal but the plate voltage is low or zero plate load resistor R_2 may have increased in value or is open. Likewise, if the screen voltage is low or zero, screen resistor R_2 may have increased in value or is open. Check R_2 and R_3 for value with an ohmmeter Note that zero screen voltage will also occur if screen capacitor C_2 is shorted. Meanwhile the excessive current drain through R_2 will cause it to heat, smoke, and eventually burn out. Check for a shorted C_2 by

measuring the resistance to ground from the screen terminal. If both plate and screen circuits are satisfactory, check for a signal on the grid of V_1 using a vacuum tube voltmeter or an oscilloscope. If the signal appears on the grid but no output is obtained, check R_2 for proper value and continuity, since an open grid resistance will cause grid-blocking. The blocked grid will be indicated by no output and a large negative grid bias which reduces as the meter is connected from grid to ground substituting for the grid resistor. As the meter is left across the circuit unblocking will occur, and when the meter is removed the grid will again block. This indicates R_1 is either open or so large in value as to be useless. If coupling capacitor C_1 is shorted the plate voltage from the preceding stage will drive V_1 into plate current saturation. Such a condition will be indicated by obtaining identical voltage readings to ground from either side of C_1, or by checking for a short with an incircuit capacitance checker. If all tests are normal and the trouble persists the tube is most probably at fault.

Reduced or Distorted Output. This condition may exist because capacitor C_1 is shorted, resistor R_1 is open, screen grid bypass capacitor C_2 is shorted, plate and/or screen voltage is reduced, or tube V_1 is defective.

With C_1 shorted dc plate voltage from the previous stage will drive the grid of V_1 positive into saturation and cause a reduced output. An open R_1 will resuh in grid blocking and may cause audio oscillations at a slow rate. A shorted C_2 will result in reduced screen and output voltage and may also result in the burning out of resistor R_3 because of excessive screen currents. A reduced plate or screen grid voltage caused by an increase in the resistance of R_2 or R_3 will also cause reduced output voltage.

To determine the component at fault, first check the supply voltage and then plate and screen voltages with a high resistance voltmeter. If the supply voltage is low the trouble is in the power supply. If the supply voltage is normal but the plate voltage is low, plate load resistor R_2 may have increased in value. Likewise, if the screen voltage is low screen resistor R_3 may have increased in value. Check R_2 and R_3 for value with an ohmmeter. If zero screen voltage exists screen capacitor, C_2 may be shorted. Check C_2 for shorted condition by measuring the resistance to ground from the screen terminal. If the signal appears on the grid of the tube but the output is not limited to the proper value and the electrode potentials have been checked, check R_1 for proper value with an ohmmeter. If R_1 is not within tolerance this condition will exist. If C_1 is shorted the DC plate voltage from the preceding stage will drive V_1 into plate saturation. This condition is indicated by identical voltage readings to ground from either side of C_1, or by checking for a short with an in-circuit capacitance checker. If all tests are normal and the trouble persists, the tube is most likely at fault.

R-F PENTODE LIMITER (ELECTRON TUBE)

Application.

The r-f pentode limiter is used in FM receivers to remove amplitude variations from the i-f signal prior to being applied to an FM detector circuit.

Characteristics.

Constant output is obtained once limiting level is reached. Linear amplification occurs up to limiting level.

Screen grid and plate voltage determine limiting level for specific bias.

Grid limiting and plate current saturation limiting are used in conjunction with cutoff limiting.

Best performance is obtained with sharp cutoff pentode-has rapid rise time-has little droop.

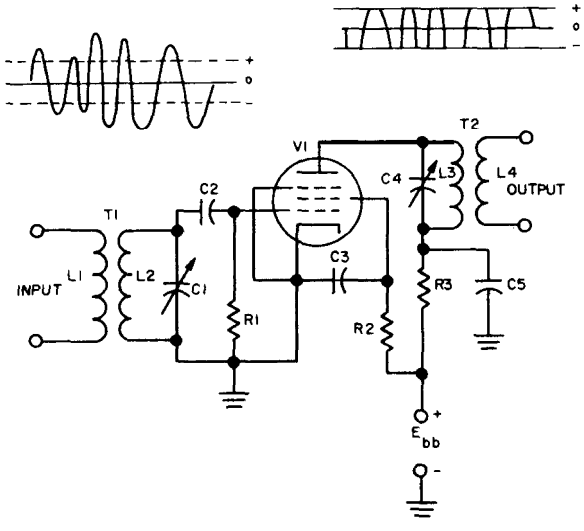
Circuit Analysis.

General. The pentode r-f limiter is located between the last i-f amplifier stage and FM detector stage. Grid current or the plate current saturation type of limiter operation is usually used for r-f limiters. Cutoff limiting is also used with one of the aforementioned methods, but it is not used by itself, since this method can only limit the negative halves of the alternating input waveform.

The pentode, besides offering sharp cutoff characteristics, makes available a greater range of screen grid and plate voltage. Operating the plate at a low voltage produces plate current saturation, as well as plate current cutoff, more readily. In order to do this the plate load resistor must be large enough to produce a load line below the knee of the pentode tube characteristic. Since the magnitude of the plate load resistor can not be made too large in wideband limiter design, grid current limiting must be used where a wideband limiter is required. The effective signal voltage values

that may produce current change, are those between the cutoff of the tube and the point at which grid current flow occurs or plate saturation occurs. These points, then are the limiting levels of the circuit.

Circuit Operation. A schematic of a typical r-f limiter circuit using a pentode type of electron tube is shown in the accompanying illustration.



Pentode R-F Limiter

The input signal is inductively coupled from the preceding i-f stages through primary L1 (of Tl) to secondary L2, with Cl and L2 providing the proper tuning and selectivity for i-f output transformer T1. The i-f signal is then capacitively coupled to the grid of V1 through coupling capacitor C2. The combination of capacitor C2 and grid leak resistor RI establishes the bias potential by grid current flow when a signal is applied. Plate load resistor R3 is used to drop the plate supply to the desired value of plate voltage. Screen grid dropping resistor R2 drops the supply voltage to the proper screen voltage value and bypass capacitor C3 places the screen grid at ground potential for i-f. C4 and L3 of (T2) form another tuned i-f circuit which enables the proper band of output frequencies to be inductively coupled by L-4 to the f-m detector. C5 in conjunction with plate load resistor R3 forms a decoupling circuit.

When a positive-going input signal is applied to the grid of limiter V1 grid current flows charging capacitor C2. The plate of C2 closest to the grid of V1 becomes negative and the opposite plate positive. When the signal swings negative, capacitor C2 discharges through resistor RI. The capacitor discharge current develops a voltage across RI which makes the grid negative with respect to the cathode. When the input signal again goes positive, C2 has not had sufficient time to discharge completely. No further grid current is drawn until the input signal becomes sufficiently positive to overcome the residual negative charge remaining on capacitor C2. Each additional cycle adds a little to the charge that remains from the last cycle. After several cycles of operation an average bias is established, and the voltage across R1 remains relatively constant. This constant voltage across RI establishes the average bias value around which the input voltage fluctuates. This bias point is dependent on several factors, which include the vacuum tube electrode potentials, the time constant of C2 and RI (TC=R1XC2) and the amplitude of the input signal. The last factor determines the amount of limiting performed by the grid leak bias method.

Limiting is accomplished by the instantaneous bias on the vacuum tube varying at the same rate that the peak amplitude of the input signal varies. If, on the positive portion of the signal the peak signal amplitude increases to the point of zero bias level, or about where grid current flows the charge on the plate of capacitor C2 closest to the grid becomes more negative with respect to the other plate. The grid bias is then increased instantaneously by the same amount to a new level and grid current no longer flows because the input level is not large enough to drive the bias to zero or above. This point is the point where limiting occurs, because in effect it is the highest positive voltage that the grid may attain. It is, thereby the value at which constant peak plate current flow occurs and the value for which minimum plate voltage is obtained.

This stable or constant (limited) plate output voltage can also be obtained by lowering the screen grid and plate voltage values to where plate current saturation, rather than grid current flow occurs, when the positive portion of the input signal reaches or exceeds the desired positive peak voltage. At this point plate current is maximum and will no longer increase to signal amplitude. Since plate current is maximum, then the plate output voltage is minimum, and remains at this limited minimum for any increase in input signal amplitude.

Although this method facilitates reaching cutoff with a less negative-going signal because of the lower electrode potentials, it is somewhat restricted by the magnitude of the plate load resistor. In order for plate saturation to occur before grid current flow, the plate load resistor value must be increased to decrease effective dc potential at the plate. By increasing the size of the plate load resistor, however, the usable bandwidth of the limiter is lowered. Grid current limiting is therefore preferred for wide-band applications even though in order for cutoff to occur a greater negative half cycle of voltage must be present.

When the input signal is operating over the negative half-cycle, the bias is also established by the grid RC time constant, the electrode potentials and the amplitude of the negative half cycle. If the magnitude of the negative half cycle is sufficient cutoff bias occurs. Plate current no longer flows at this cutoff point and plate voltage is at its maximum value. Thus, when the negative half cycle reaches or exceeds the cutoff bias level, plate output voltage remains at a constant limited value.

Limiting will ordy occur when the signal amplitude exceeds the voltage extremes necessary for grid current to flow on the positive half cycle, or (on the negative half cycle) for cutoff to occur. Any signal strength less than these amplitude extremes will result in plate current changes and plate voltage variations in accordance with this signal strength and no limiting. In order to have a constant limited output, then, the input (drive) signal strength must exceed the points where grid current flow and cutoff occurs.

Failure Analysis.

No Output. In a pentode r-f limiter a no-output condition may be caused by any of the following (provided the signal from the previous stage is the proper value): a shorted input tank circuit capacitor Cl or output tank circuit capacitor C4, a shorted screen bypass capacitor C3, an open or shorted transformer T1 or T2, an open coupling capacitor C2, an open bias resistor R1, or by lack of plate voltage caused by an open plate resistor, R3, or a shorted plate bypass capacitor, C5, or by a defective tube VI.

To determine the components at fault, first check the supply voltage, then the plate and screen voltages with a high resistance voltmeter. If the supply voltage is normal but the plate voltage is low or zero, plate load resistor R3 may have increased in value or opened. Check R3 for value with an ohmmeter. To check if capacitors C 1, C3, C4, or C5 are shorted, use an in-circuit capacitance checker. If the capacitor C2 is open or if T1 is defective, no signal would be present at the grid of V1. This maybe checked by an oscilloscope. If the plate circuit is satisfactory and a signal appears at the grid of V1, but there still is no output, check resistor R1 for proper value and continuity, since an open grid resistance will cause grid blocking. The blocked grid will be indicated by no output and a large negative grid bias which reduces as the voltmeter is connected from grid to ground substituting for the grid resistor. As the meter is left across the circuit the blocking action will subside. When the meter is removed the grid will again become blocked. This indicates that RI is either open or so large in value that it is useless.

If T1 is open or shorted no input signal will be applied to the grid of V1. Likewise, if T2 is open or shorted no output will be obtained. Check the resistance value of the corresponding transformer primaries and secondaries with an ohmmeter (be certain to turn off the plate power before measuring). If the resistance value obtained is zero, the winding is shorted. If the value obtained is infinite, the winding is open. If all tests are normal and the trouble persists, the tube is most likely at fault.

Low or Distorted Output, This condition may exist because of capacitor C2 being shorted, capacitor Cl being open, resistor R1 being open, L1 being defective because of a partial short or tube V1 being defective.

If C2 is shorted, d-c plate voltage from the previous stage will drive the grid of VI positive, and into saturation, causing a reduced output. If Cl were open, i-f transformer T1 will not resonate at the proper i-f and loss of gain will result Thus, there will be little or no output. An open resistor RI will result in grid blocking and may cause audio oscillations at a slow rate. If screen bypass capacitor C3 is shorted, the screen and output voltages will both be reduced and eventually will result in resistor R2 burning out because of excessive screen current. If screen bypass capacitor R3 is open, resistor R2 will have dropped across it the r-f voltage occurring at the screen grid, which will produce degeneration and result in altered screen and plate currents, and plate voltage. Reduced screen or plate voltage, caused by increased resistance of R2 or R3, will also cause a reduced output voltage.

If capacitor C4 is open, the tuned circuit of L2 and C4 will not be resonant to the proper i-f frequency band. If C5 is open, the r-f voltage appearing at the plate will be fed back into the power supply through R3 and cause feedback with possible oscillation.

To determine the component at fault, first check the supply voltage and then the plate and screen voltages with a high resistance voltmeter, If the supply voltage is low the trouble is in the power supply. If the supply voltage is normal but the plate is low, plate load resistor R3 may have increased in value. Likewise, if the screen voltage is low, screen resistor R2 may have increased in value. Check R2 and R3 for proper value with an ohmmeter.

A reduced plate or screen voltage may also be caused by open capacitors C3 or C5. Check C3 and C5 with an in-circuit capacitor checker if prior checks have failed to find the fault. This same check (in-circuit capacitor checker) may be used if symptoms seem to indicate open capacitors Cl or C4. If V1 is at a constant saturation level, check Cl for a short by measuring the voltage from each plate of Cl to ground with a high resistance voltmeter, or by checking for a short with an in-circuit capacitor checker. If symptoms indicate trouble in either input or output tank circuits and capacitors C 1 and C4 are not defective, remove one lead of the suspected winding and check the dc resistance value of the winding. If all tests are normal and the trouble persists the tube is most likely at fault.

PART 13-3. CLAMPERS

DIODE CLAMPER (ELECTRON TUBE)

Application.

The diode clamper (sometimes called a dc restorer) is used where it is desired to hold, or "clamp", the positive or negative extreme of a waveform to a zero reference level (the reference level for this circuit must be ground potential). This circuit is commonly used in radar, television, telemetering and pulse code communications, and computers.

Characteristics.

Input signal waveform contains both positive and negative amplitude extremes.

Output signal waveform varies between the reference level (ground) and some negative or positive value, which is determined by the peak-to-peak amplitude of the input waveform.

Input and output signals are in phase with one another.

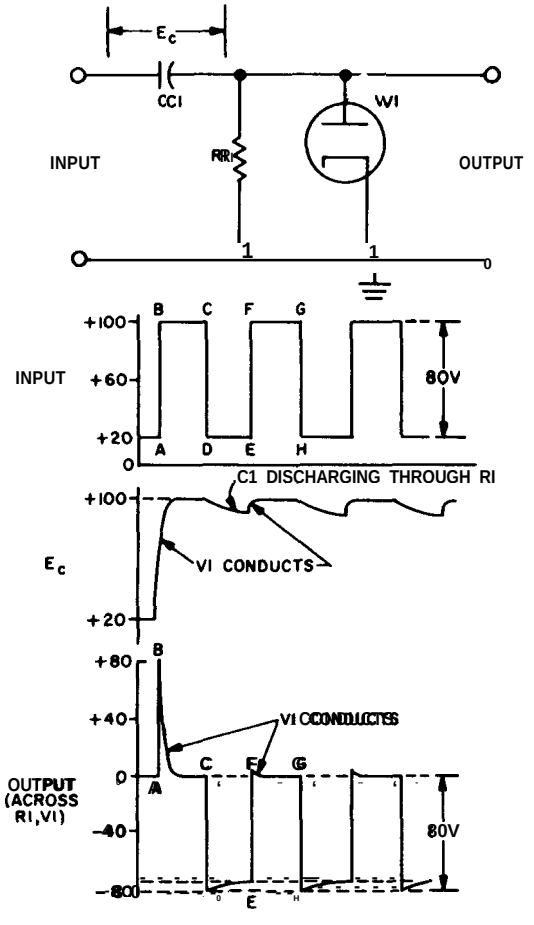
Uses diode in conjunction with an R-C coupling network; cathode of diode is at ground (chassis) potential.

Circuit Analysis.

General. The diode clamper circuit consists essentially of a diode connected in parallel with the resistor or a conventional R-C coupling network. The diode can be connected to clamp the waveform either negatively or positively. Since the two circuits are so similar, only the negative diode clamper will be discussed in detail. The positive diode clamper will be explained only briefly at the end of the discussion.

In the negative diode clamper, the diode is connected so that whenever the waveform swings in a positive direction the diode conducts to produce a short R-C time constant; whenever the waveform swings in a negative direction the diode does not conduct, and this results in a long R-C time constant. Thus, two different time constants are produced – a short time constant during the positive half cycle of the input waveform, and a long time constant during the negative half cycle. It is this difference in time constants that produces the clamping action for the output waveform.

Circuit Operation A negative diode clamper is shown in the following illustration, together with typical input and output waveforms. Capacitor Cl and resistor R1 form an R-C coupling network and determine the long time constant of the circuit. Electron tube V1 is an indirectly heated cathode-type diode; it is the clamper diode and, together with capacitor Cl, determines the short time constant of the circuit. The filament (heater) circuit for the diode is not shown in the schematic.



Negative Diode Clamper Circuit and Waveforms

The input waveform shown in the preceding illustration is typical of a square wave generated at the plate of a multivibrator stage. The waveform can be considered as the plate-voltage variation which is applied to the input of the clamping circuit. initially the plate voltage of the multivibrator stage is low (+20 volts) while the tube is conducting heavily the plate voltage rises to a high value (+100 volts) when the tube is non-conducting, or cut off. Thus when the stage is in operation a square wave is produced which has an 80 volt peak-to-peak amplitude. Coupling capacitor Cl of the R-C network is initially charged to a potential of +20 volts, which is the plate voltage of the multivibrator stage when the tube is conducting heavily.

The circuit conditions at this time are indicated by point A on the input and output waveforms of the accompanying illustration. Immediately following point A on the input waveform, the input to the clamper circuit suddenly rises 80 volts (from +20 volts to +100 volts) to point B. Since the charge on capacitor Cl cannot change immediately, the 80-volt change appears across resistor RI and also across diode V1. This makes the plate of diode V1 80 volts positive with respect to its cathode, and the diode conducts to charge capacitor Cl through a short time constant path. When conduction begins, the output voltage drops from point B on the output waveform to zero (reference level).

At point C on the input waveform, the input signal drops 80 volts (from +100 volts to +20 volts), but capacitor C 1 is charged to +100 volts and cannot change instantaneously; therefore, an 80-volt drop in signal voltage appears across resistor R1, causing the output to drop from zero (reference level) to –80 volts. Thus, between C and D on the waveforms, the input voltage drops from +100 to +20 volts, and the output voltage drops from zero (reference level) to –80 volts During the time interval between points D and E on the waveforms, capacitor Cl will discharge slightly through the long time+ onstant path offered by resistor RI until point E is reached.

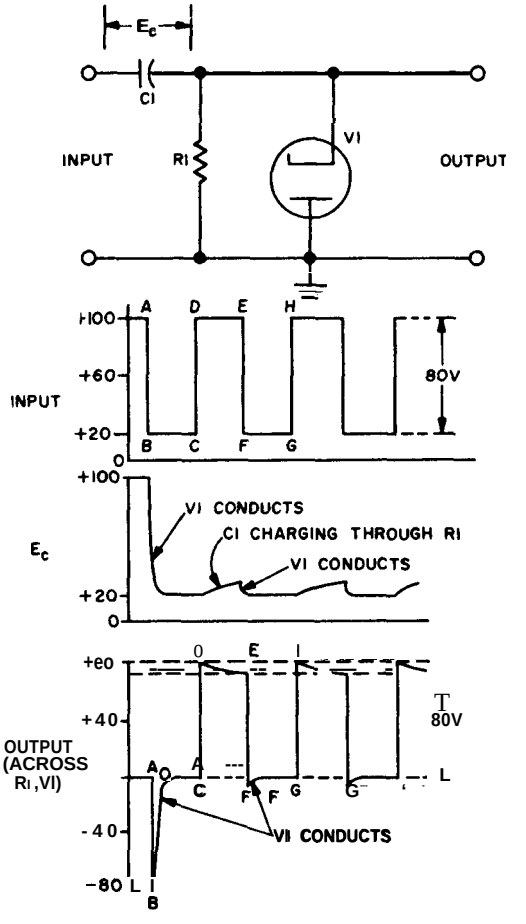
At point E on the input waveform, the input signal again rises 80 volts (from +20 volts to +100 volts) to point F on the input waveform. Once again the charge existing on capacitor Cl cannot change immediately, and the 80-volt change appears across resistor RI. However, an 80-volt change causes the output voltage to overshoot the zero reference level slightly because of a slight discharge of capacitor Cl which has occurred during the time interval between points D and E. Therefore, because of the voltage overshoot, a small positive voltage exists across resistor R1 and diode VI. The plate of the diode is positive with respect to its cathode, and the diode conducts momentarily to replace the slight loss of charge on capacitor Cl. The output quickly drops and remains at zero (reference level) until point G is reached. The input signal again drops (from +100 volts to +20 volts), and an 80-volt drop in signal voltage appears across resistor R1, again causing the output to drop from zero to –80 volts. Thus, between points G and H on the waveforms, the input voltage drops from +100 to +20 volts, and the output voltage drops from zero to –80 volts. Once again, capacitor

Cl begins to discharge through resistor R1 to complete another cycle.

The output waveform has purposely been drawn to show a substantial decrease in voltage caused by the discharge of capacitor Cl during the period of time the input waveform is at its negative extreme (point D to point E). In practice, however, the value of resistor RI is relatively large, and very little distortion results from the discharging of capacitor Cl through Rl, or from its charging through diode V1 (at point F).

From the explanation of the negative clamper operation given above, it is seen that the positive extreme of the input waveform has been held, or clamped, to the desired zero reference level and the entire waveform has been shifted negatively with respect to the reference level.

A positive diode clamper is shown in the accompanying illustration, together with typical input and output waveforms. The circuit operates in the same manner as the previously described negative diode clamper, except the diode is reversed, resulting in opposite polarities at the output, and the waveform is thus clamped positively instead of negatively.



Positive Diode Clampar Circuit and Waveforms

Failure Analysis.

General. Because of the relative simplicity of the negative diode clamper circuit, the failure analysis is also relatively simple and is limited to several possible failures.

Initially, the input signal should be checked to determine whether it is present and of the correct waveshape and amplitude. The diode, VI, should be checked to determine whether it is in satisfactory condition and whether the correct filament (heater) voltage is applied to the tube. In many cases a dc potential exists at the input of the clamper circuit; therefore, it is possible for coupling capacitor Cl to become ieaky (or shorted) and cuase a voltagedivider action to occur. Since capacitor Cl is in series with resistor R1, a continuous current flow can result if the capacitor is leaky (or shorted), and this will produce a change in the reference level at the output of the clamper circuit. Furthermore, in this case it is likely that diode V1 will conduct at all times A quick check to determine whether coupling capacitor Cl is leaky (or shorted) is to remove diode VI from the circuit and check for the presence of voltage developed across resistor R1.

If the value of resistor R1 increases considerably above its original value, distortion of the output waveform is likely to occur, especially when the input waveform is subject to changes in signal amplitude. As a result, distortion will occur during the time required for capacitor C 1 to reach a new reference level, which results from a change in signal amplitude. If the value of resistor R1 decreases considerably, distortion of the output waveform will occur because of the decrease R-C time constant, and, as a result, undesirable spikes will be present in the output waveform.

Since only three components are involved in the circuit (resistor Rl, capacitor Cl and diode Vi), these components are easily checked to determine

whether they are defective. Resistor RI can be measured with an ohmmeter to determine its resistance, capacitor Cl can be checked with a suitable capacitance analyzer, and diode VI can be checked in a tube tester.

DIODE CLAMPER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

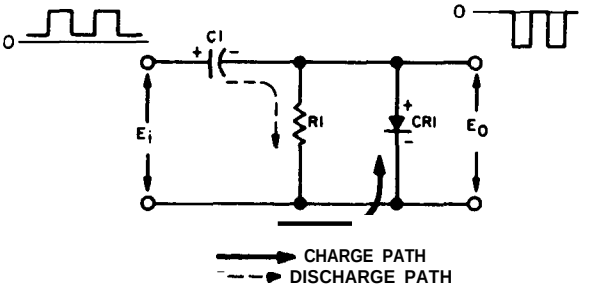
Some basic characteristics as electron tube version, but uses semiconductor diode instead of electron tube.

Circuit Analysis.

General. The unbiased diode clamp is usually employed as a shunt across the resistor of an R-C coupling circuit. By providing a low-resistance path during conduction periods and a high-resistance path during nonconducting periods, the diode provides different charge and discharge times for the coupling capacitor. The diode can be connected to clamp the waveform either negatively or positively. Since the two circuits are so similar, oniy the negative diode clamper will be discussed in detail. The positive diode clamper will be explained only briefly at the end of the discussion.

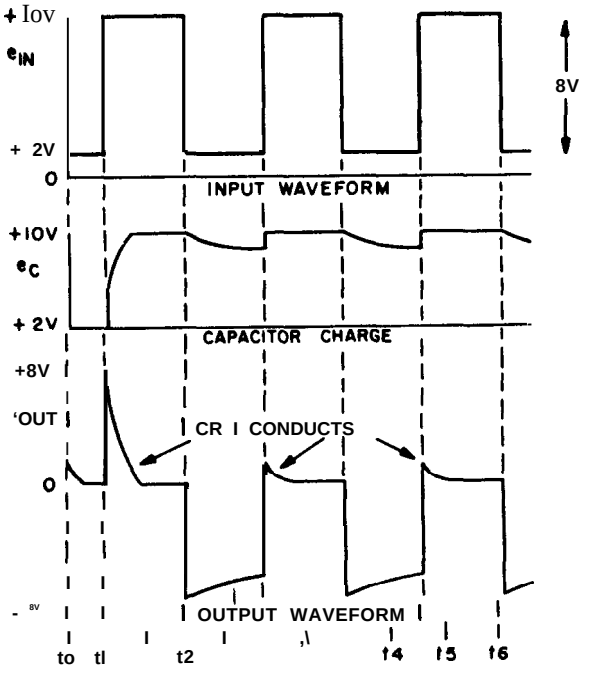
In the negative diode clamper, when the positive portion of the input waveform causes the diode to conduct, negative clamping is produced, as described in the following paragraph.

Circuit Oparation. The schematic of a basic unbiased diode clamp is shown in the following illustration. As shown, Cl is the coupling capacitor of an RC coupling network. Resistor R1 is the input resistor of the network and determines the long time constant (discharge period) of the circuit. Clamping diode CR1 connected in shunt with R1 determines the short time constant (charging time) of the circuit. When a positive input signal is applied it causes CRI to conduct, and Cl is quickly charged to the input potential. Since the output is taken from across R1 which is effectively short circuited by the conducting diode (forward resistance is only a few ohms), little or no output appears for the positive portion of any applied signal. During the negative portion of the input signal CRI does not conduct (except for reverse leakage current) consequently the negative portion of the input signal appears as the output across R1. This circuit acts to effectively shift the entire waveform in a negative direction by holding the positive peak of the input signal to the zero level. Therefore the input waveform can only appear as a negative output. Thus the positive portion is effectively eliminated by the clamping diode.



Negative Clamp

In the following illustration, the input waveform is shown as a square wave for ease of explanation. Likewise, the input waveform level is considered to vary from +2 to +10 volts. Such an input signal is typical of the waveform generated at the collector of an NPN transistor multivibrator (or an electron tube). Although a square wave is used in the following explanation of detailed circuit operation, any wave shape applied to the clamper input will be negatively clamped without appreciably changing the shape of the wave (provided the R1 Cl time constant is long with respect to the pulse duration).



ClamPar Input and Output Waveforms

Capacitor Cl is charged as indicated in the preceding illustration to a potential of +2 volts at the negative peak of the input waveform (to). At time t_1 the input to the clamper circuit rises 8 volts to a +1 O volts. Since capacitor Cl cannot change its charge immediately, the 8 volt change appears across RI and CR1, producing a positive spike on the output waveform. Since the anode of CR] is now 8 volts positive with respect to its cathode, CR1 conducts and charges Cl to +10 volts. The charging of Cl occurs rapidly because of the low forward resistance of the diode, and the low forward resistance of the diode shunting RI causes any output voltage appearing across R1 to drop to zero during time t_1 to t_2. Simultaneously) the diode stops conducting, and capacitor Cl remains in its charged condition for the duration of the pulse.

At t_2 the input signal drops 8 volts (from +10 volts to +2 volts). Since C 1 is charged to +10 volts and cannot discharge immediately through the long time constant circuit created by R1, this negative-going voltage appears across R1 as a negative 8 volt output. (CR1 cannot conduct because its anode is now negative with respect to its cathode). Thus a point t_2 on the waveform, the input voltage drops from +10 volts to +2 volts, and the output drops from zero to –8 volts. During the time interval between t_2 and t_3, capacitor C1 discharges slightly (from 8 volts to 7 volts, for example) through the long time constant path of R1.

At point t_3 of the input waveform, the inPut signal again rises 8 volts (from +2 to +1 O). Once again the charge on Cl cannot change immediately and the 8 volt positive change appears across RI. Because of the assumed 1 volt discharge through R1 between times t_2 and t_3, the 8 volt change now exceeds the capacitor charge voltage. Therefore, the output voltage overshoots the zero reference level and a positive (approximately 1 volt) signal appears across R1 and CR1. With the anode CR1 positive with relation to its cathode, the diode conducts momentarily to replace the slight loss of charge on Cl. As a result, the output voltage quickly drops to zero and remains at zero level until the end of the pulse at time t_4.

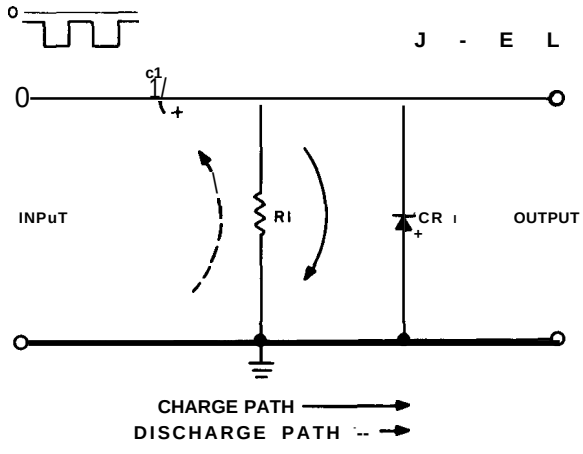
At time t_4 the input signal again drops from +10 to +2 volts. The 8 volt drop appears as a negative output across R1 causing the output voltage to drop from zero to –8 volts. Once again, Cl begins to discharge through the long time constant circuit as explained previously.

The output waveform has been purposely drawn to show a substantial decrease in voltage caused by the discharge of Cl during the duration of the negative peak of the input waveform (times t_2 to t_4 and t_4 to t_5). In practice, however, the value of R1 is relatively large so that little distortion results from the discharging of Cl or from its charging through CR1. The semiconductor diode, however, does have a much lower reverse resistance that of the electron tube. Since this back resistance is effectively connected in parallel with RI, it lowers the overall output resistance and reduces the value of the long time constant. Therefore, more distortion is produced by the semiconductor diode clamper than the tube diode.

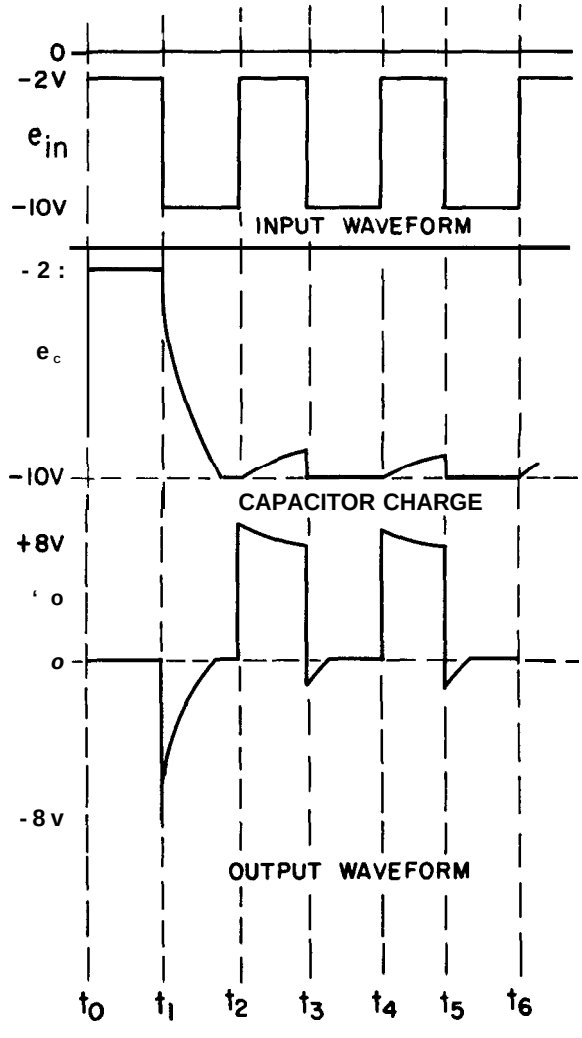
From the explanation of circuit operation given above, it is seen that the positive extreme of the input waveform has been held or clamped to zero reference level, and that the entire waveform has been shifted negatively with respect to this reference level.

'The schematic of a basic unbiased diode clamp and its associated waveforms are shown in the following illustrations. The circuit operates in the same

manner as the previously described negative diode clamper, except the diode is reversed, resulting in opposite polarities at the output, and the waveform is thus clamped positively instead of negatively.



Positive Clamper



Clamper Input and Output Waveforms

Failure Analysii.

General. Because of the relative simplicity of the diode clamper circuit, there are only a few possibilities of trouble. The capacitor, resistor, and diode can be checked for shorted or open-circuited conditions with an ohmmeter. Circuit functioning, however, must be checked with an oscilloscope to determine whether the waveform is correct and the operation is normal.

No Output. An open-circuited capacitor, a lack of input signal, or a shorted or defective diode can cause a no-output indication. Use an oscilloscope to determine whether the proper input signal is present and whether it appears across RI.

Low Output. A leaky or partially shorted capacitor can cause other than normal output. Usually such a condition will be indicated by a change in the dc voltage measured across RI, assuming a normal input signal. A defective diode can also cause this condition, and is usually indicated by a much-lower-than-normal reverse resistance.

Distortion. Normally there should be no distortion of the output signal. Any distortion visible on an oscilloscope (with a frequency response high enough for the pulse used) indicates a change in circuit time constants due to defective components. Use an "in-circuit" type of capacitor checker to determine whether the capacitor is leaky. The reamining elements can be checked with an ohmmeter. (Be certain to observe the proper polarity when checking the diode; otherwise, an erroneous indication will be obtained.)

Clamping Level Changes. A change in the clamping level could be caused by a defective diode, a leaky coupling capacitor, Cl, or a change of input pulse amplitude. As long as the input pulse amplitude is constant clamping will occur as described above. If, however, the pulse amplitude varies from pulse to pulse, the low amplitude pulses will not be properly restored. This action occurs because the low amplitude pulse is unable to reach the zero level or rise above it. Thus the diode can not operate to restore the charge lost in the discharging of capacitor Cl through the long time constant circuit between pulses. Hence the following pulse will start at some point below the zero level. If excessive, it may be possible to read a negative voltage across R1.

In the case of a leaky capacitor, the diode will conduct constantly for a positive voltage (NPN collector polarity) applied to the anode, or with a constant negative voltage (PNP collector polarity) applied it will act as a biased type clamp. This condition may be determined by making a voltage check with a VTVM connected across the output of the clamp.

BIASED DIODE CLAMPER (ELECTRON TUBE)

Application.

The negative-biased diode clamper is used when it is desired to shift and hold the reference level (negative extreme for positive diode clamper, or positive extreme for negative diode clamper) of the applied signal to some negative value.

The positive-biased diode clamper is used when it is desired to shift the reference level of the applied signal in a positive direction. This type of circuit is commonly used in radar, television, and computers.

Characteristics.

Establishes a dc reference level of a signal, but does not affect its amplitude.

" The reference level is always a negative or positive value equal to the negative or positive bias voltage.

Input and output voltages are in phase.

Uses a diode, an r-c network, and a bias voltage supply.

A negative-biased diode clamper may be used as either a positive or negative clamper.

Circuit Analysis.

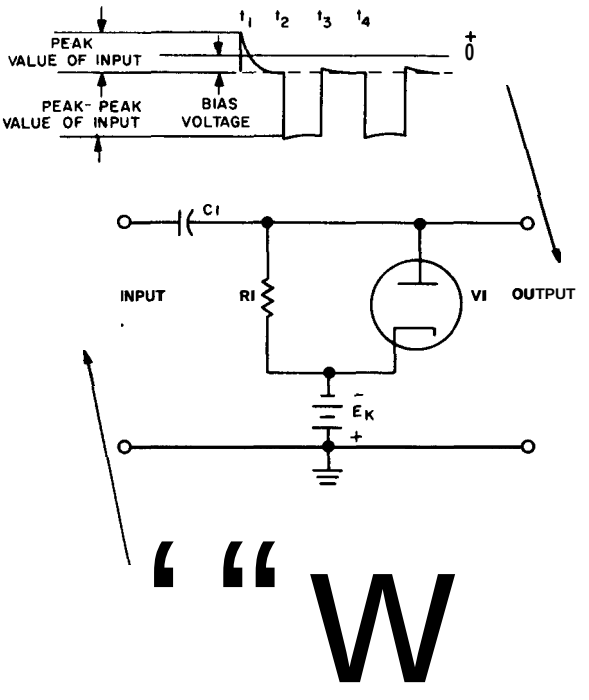
General. A diode clamper (positive or negative) is connected so that whenever the signal swings in one direction (positive direction for negative clamping-negative direction for positive clamping) diode VI conducts to produce a short r-c time constant; whenever the signal swings in the opposite direction diode V1 does not conduct, and this results in a time constant dependent on a resistor in parallel with the diode and coupling capacitor Cl, which is long with respect to the time constant of the resistance of the diode and the coupling capacitor. Thus, two different time constants are produced; a short time constant when V1 is conducting and a long time constant when V1 is not conducting.

The output voltage is obtained across the parallel combination of the diode and the resistor. During the short time constant all of the input signal voltage is developed across the coupling capacitor and none is developed across the diode and resistor, and thus no

output is developed. During the long time constant, practically none of the signal voltage is developed across the coupling capacitor and practically all of the signal voltage is developed across the resistor and diode, and thus practically all of the signal appears at the output.

The clamping level is dependent on the input voltage value; normally the clamping occurs at a zero voltage reference level and extends in a positive or negative voltage direction to a voltage value equal to the peak to peak input voltage. With the insertion of a negative bias voltage the reference level is shifted in a negative direction. A negative or positive diode clamper having a negative bias will have the minimum negative voltage of the output at a reference level equal to the value of the bias voltage. A negative diode clamper (biased positive) will have its highest positive value as the reference level. The reference level will be, in any case, a value equal to the value of the bias voltage.

Because of the similarity between the negatively biased and the positively biased diode clampers, only the negatively biased diode clarnper will be discussed in detail. The positively biased diode clamper will be explained briefly at the end of the discussion.



Negatively-Biased Negative Diode Clamper (Tuba Type)

Circuit Operation. A negatively biased negative diode clamper is shown in the following illustration. Capacitor Cl and resistor R1 form an r-c coupling network and determine the long time constant associated with the circuit. Electron tube V1 is an indirectly heated cathode type of diode. This diode during the time of its conduction, shunts R1 and together with capacitor Cl determines the short time constant of the circuit. Voltage source E_K provides a negative bias voltage which alters the reference level from zero to a negative reference level equal to the bias potential.

The input waveform shown in the accompanying illustration is a typical square wave. Prior to t_1 on the signal voltage waveform there is no input voltage.

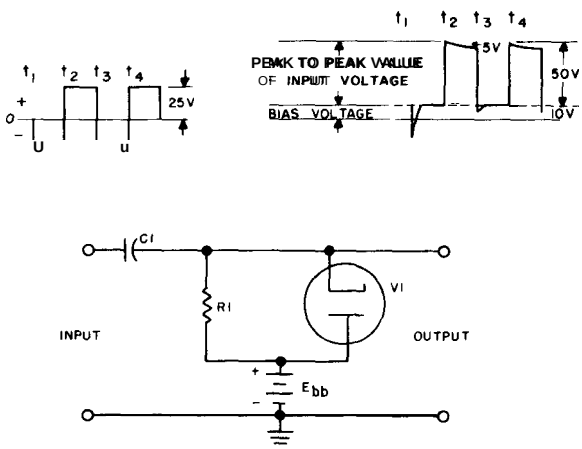
Prior to t_1 on the output voltage waveform, the output voltage is maintained at the bias voltage value. At t_1, first leading edge of the input square wave occurs. Since Cl cannot instantaneously charge to this value, the full signal voltage appears on the plate of V1. The output voltage at t_1 is the algebraic addition of the voltage across V1 and the negative bias voltage. Capacitor Cl charges rapiclly, however, because of the very small time constant (with respect to the frequency of the input signal) of Cl and the small resistance of V1 during its conduction. The output voltage diminishes to the bias voltage at the same rate that Cl charges. This voltage diminishes well before t_2 is reached. Then the input signal reaches t_2, capacitor Cl again cannot change its charge instantaneously, and a high negative voltage appears on the plate of V]. Therefore, diode V1 does not conduct and all the voltage appears across R1. The output voltage at t_2 is the algebraic sum of the negative voltage across R1 and the negative bias voltage.

During the pulse period between t_2 and t_3 capacitor C 1 discharges slightly through R1 for the duration of the negative pulse. Since the time constant of R1 and Cl is large, however, only a slight amount of this voltage leaks off. The amount of the voltage that discharges through RI subtracts from the voltage originally applied across R1 at t_2. Hence, at t_3, the initial negative charge is less than at t_2, accounting for the dip in the waveform.

When t_3 is reached and the input signal rises in a positive direction V1 conducts, and capacitor Cl again cahnot respond instantaneously to the rapid change. Hence the full voltage appears across the diode. The output voltage this time, however, is not only the voltage across V1 plus the bias voltage but it is this algebraic addition minus the voltage that is present across RI. Since the voltage across RI has been reduced by the discharge of Cl, the voltage across R1 is less than the voltage across V1 by the amount of voltage that has leaked off Cl at t_3. The output voltage at t_3 is then slightly more postive than the bias. This produces the slight positive peak on the waveform at t_3, since the anode of V1 is more positive than the cathode, V1 conducts and quickly charges, removing the small pip caused by the initird surge across V1. The output voltage then drops to that of the bias voltage for the remainder of the pulse width, period t_3 to t_4 on the waveform. When t_4 is reached the action is the same as that occurring at t_2 and the cycle repeats.

By reversing the diode (see the preceding illustrated circuit), the circuit becomes a negatively-biased positive diode clamper. The positive diode clamper has a positive output and may have either a positive or negative reference level. By retaining the negative bias, the reference level remains negative; by reversing the bias, the reference level is then shifted to a positive voltage. A positively-biased positive diode clamper is shown in the following illustration.

The positively-biased positive diode clamper operates in the same reamer as the previously described negatively-biased negative diode clamper, except the diode and the battery voltage is reversed, resulting in a circuit operation that is opposite the previous discussion.



positively-Biased Positive Diode Clampar (Tube Type)

Failure Analysis.

General. Because of the relative simplicity of the positively or negatively biased positive or negative diode clamper circuit, the failure analysis is also simple and is limited to only a few possible failures.

Initially, the input signal should be checked to determine whether it is present and of correct waveshape and amplitude. If the bias battery or supply voltage should become open no output would be obtained. If the bias supply voltage should become shorted, an output would exist but the reference level would be shifted to zero instead of some positive or negative value. In many cases, a dc potential exists at

the input of the clamper circuit; therefore, it is possible for coupling capacitor Cl to become leaky (or shorted) and cause a voltage divider action to occur. Since capacitor Cl is in series with resistor RI a continuous current flow can result if the capacitor is leaky (or shorted), and this will produce a change in the reference level at the output of the clamper circuit.

If the value of resistor R1 increases considerably above its original value, distortion of the output waveform is likely to occur, especially when the input waveform is subject to changes in signal amplitude. If the value of RI decreases considerably, distortion of the output waveform will occur because of the decreased r-c time constant, and as a result, undesirable spikes will be present in the output waveform.

There should be little difficulty in determining the component at fault, since there are only four components in the circuit. Resistor RI may be measured with an ohmmeter to determine if the value is within tolerance. Capacitor Cl maybe checked with a capacitor analyzer or by measuring the voltage from each plate of Cl to ground (if the voltages measured are equal, the capacitor is shorted). If every other component has been checked and the trouble still exists, diode V1 must be at fault.

BIASED DIODE CLAMPER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

Essentially the same characteristics as electron tube version, but uses semiconductor diode instead of electron tube diode.

Because the reverse resistance of a semiconductor diode is lower than that of an electron tube, the type of diode used is selected to have a very high reverse resistance. This is necessary to keep the shunting effect of the reverse resistance to a minimum.

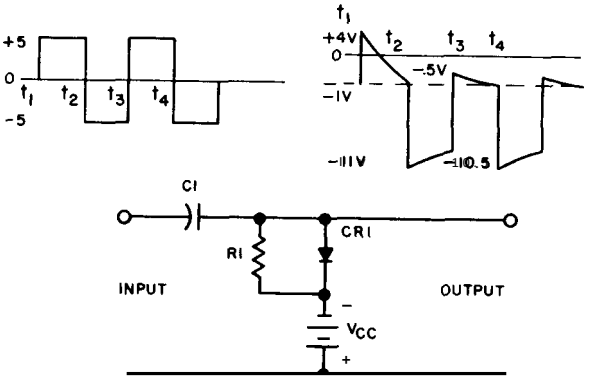
Circuit Analysis.

General. The biased diode clamper may be of either the positive or negative type, depending upon the relative connection of the diode with respect to the bias. Under all circumstances, the reference level of the negatively-biased diode clamper will be at some negative value, and the reference level of the positively-biased diode clamper will be at some positive value. Since these two types of biased clampers are so similar, only the negatively biased diode clamper will be discussed in detail. The positively biased diode clamper will be explained only briefly at the end of the discussion.

In a negatively-biased positive diode clamper, the output waveform will start at this negative value and extend in a positive direction. If it is a negatively-biased negative diode clamper, the output waveform will start at this negative reference level, and extend in a negative direction. The circuit is comprised basically of a diode and an RC network. The diode acts as a switch, closing on one hrdf cycle to provide a very short RC time for the capacitor, and opening on the alternate half cycle, to provide a long time constant which depends upon the size of a resistor in conjunction with the capacitor. The overall result at the output is a reproduction of the input, but shifted to a new reference level.

Circuit Operation. A typical negatively-biased negative diode clamper is shown in the following illustration.

Capacitor Cl and resistor R1 form an RC coupling network and determine the long time constant associated with the circuit. Diode CR1, during the time of its conduction, together with Cl, determine the short time constant associated with the circuit. The bias supply, V_{cc} alters the reference level from zero to a level equal to the bias.



NeWtively-Biased **Negative Diode Clamper**

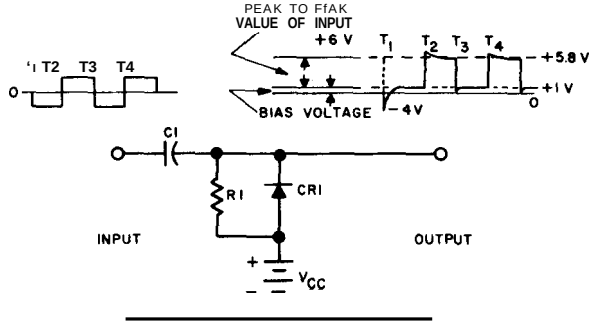
When the circuit is initially energized and with no signal applied to the input, the diode begins conducting because of the negative potential (V_{CC}) applied to the cathode. As CR1 conducts, capacitor Cl begins charging, and when its charge is equal to V_{CC}, the diode cuts off, since its anode and cathode potentials are now equal. The voltage at the output is at this timeequal to the bias voltage V_{cc}, or –1 volt.

When a signal is applied, as illustrated, the following action occurs. At time t_1, the voltage increases almost instantly from O volts to a +5 volts. (The voltages used here are only for ease of explanation), Capacitor Cl cannot change its charge immediately (because of the property of capacitors), and the anode of CR1 suddenly becomes more positive than its cathode and begins conducting. Because Cl cannot immediately change its charge, the entire input voltage is developed across the diode, and the output, taken from across the diode, increases 5 volts in a positive direction. Because it does not start at O volts, but at O –1 volt, as shown on the illustration, the output rises to +4 volts. The conducting state of CR1 provides a very short time constant for the capacitor, however, aod Cl rapidly charges to the new voltage. As Cl charges, the voltage drop across CR1 decreases, and once again reaches –1 volt when Cl is fully charged.

The output remains at this voltage until the negative swing of the input signal at time t_2. At this time the input swings from a +5 volts to a –5 volts. Again, Cl camot immediately change its charge, but this time the diode camot conduct, because its anode is negative with respect to its cathode. The entire input voltage is therefore developed across RI, and the output voltage changes 10 volts in a negative direction from the -l-volt reference level, or to–11 volts. Because the diode is not conducting, R1 provides a long time constant for Cl and the capacitor begins charging very slowly to the –5 volts of the input signal. The capacitor charges very slowly because of the long RC time constant, and when the input signal reaches t_3, the total output has only decreased to, for example, from -11 to -10.5 volts (the capacitor has charged to .5 volt). At time t_3, the input again rises to +5 volts, bringing CR1 into conduction. This sudden +10 volt rise also produces a +10 volt increase in the output. Since the total output is 10.5 volts at this time, a +10 volt increase brings it up to –.5 volts, which accounts for the small positive-going peak at t_3 in the output waveform. Because of the short RC time provided by CR1, the capacitor quickly charges again to –1 volt eliminating the peak, and the output remains a –1 volt until time t_4 when the cycle again repeats.

By reversing the diode, the circuit can be converted into a negatively-biased, positive diode clamper. The difference at the output then will be that the entire output waveform will be clamped above the negative bias voltage, instead of below it as in the negative clamper.

By reversing the battery, the circuit can be converted into a positively-biased diode clamper. The following illustration shows a typical positively-biased positive diode clamper. The operation is essentially the same as the negatively-biased diode clamper, except that with this circuit arrangement, the output voltage is always clamped at some value of positive voltage, as determined by the bias voltage. The circuit can be converted to a positively-biased negative diode clamper by reversal of the diode.



Positively -Biasad Positive Diode Clamper

Failure Analysis.

No Output. The absence of an input signal, or an open Cl are the only probable causes of a no-output condition. Check for the presence of the input signal with an oscilloscope. If the signal is not present, the fault lies in a preceding stage, and the cfamper is probably not defective. If a signal is present, check Cl with an in-circuit capacitor checker. There is also the possibility that two components such as CR1 and V_{CC}, or R1 and V_{cc}, are both shorted at the same time, thus producing a short circuit across the output. Check the bias supply with a high resistance voltmeter for proper voltage, and RI and CR1 with an

ohmmeter. Care should be used in checking the diode, as erroneous indications may be obtained by not observing proper polarities. For the special case where the diode is not completely shorted, but reads a very low resistance, of say 2000 ohms or less, it can be considered defective.

Low or Distorted Output. A partially shorted CR1, a leaky Cl, or RI decreasing in vrdue can cause a low output condition to exist, Actually, the output will not be low without being distorted nor will it be distorted without being low. Check Cl with an in-circuit capacitor checker, and R1 and CR1 with an ohmmeter. Care should be used in checking the diode, as erroneous indications may be obtained by not observing proper polarities. For the case where the diode is not completely shorted, but reads a very low resistance of, say 2000 ohms or less, it can be considered defective,

Change in Clamping Level. A change in the bias supply voltage, V_{cc}, will cause the output clamping level to change. Check for the proper value of voltage with a high resistance voltmeter.

TRIODE CLAMPER (ELECTRON TUBE)

Application.

A triode clamper is used where it is desired to obtain amplification of the input signal as well as clamp one extreme of the signal.

Characteristics.

Clamping is accomplished between the grid and the cathode, the grid acting as a diode plate.

Clamping between the grid and the cathode can only be in a negative direction, since the coupling capacitor must be connected to the grid of the triode.

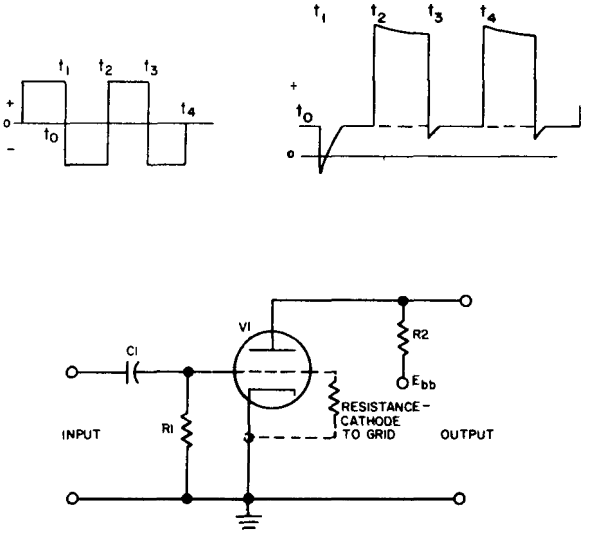
Output taken from the plate of the triode will be clamped in a positive direction.

Circuit Analysis.

General. The circuit operation of the basic single-tube triode clamper is largely similar to that of the diode clamper. In the triode clarnper, the control grid serves the same function as the diode plate in the diode clamper circuit. The grid-leak bias resistor and coupling capacitor in conjunction with the grid to cathode resistance of the triode provides a means by which two time constants may be produced. These time constants enable a certain bias level to be established, which fixes the reference level to which the output level is clamped.

The grid is maintained as a negative voltage, and since the plate voltage varies inversely and is of opposite polarity, the output voltage is clamped at a positive reference level. The action of the triode also provides amplification of the input signal.

Circuit Operation. A basic single-tube tnode clamper is shown in the accompanying illustration. Cl and RI are the input coupling capacitor and the grid leak bias resistor, respectively. They form the long time constant circuit associated with the clamper. The cathode to grid resistance of triode VI during the time of maximum conduction along with Cl form the short time constant circuit associated with the clamper. R2 is the plate load resistor, which also provides the proper dc plate voltage to the plate of V1.

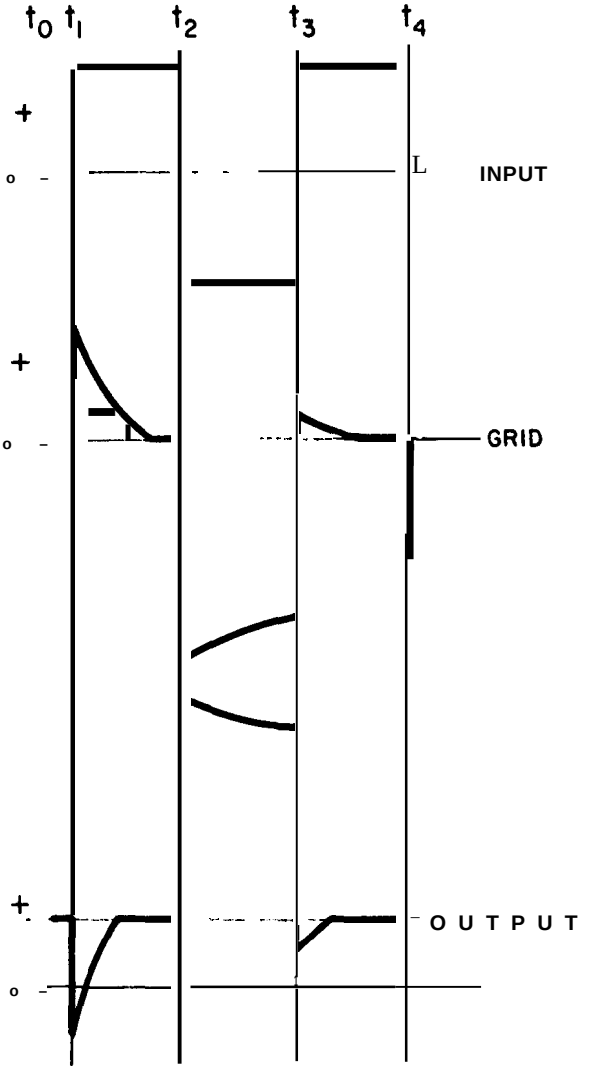


Basic Single-Tube Triode Clamper

The input signal is a typical square wave, having equal positive and negative amplitudes as shown in the following illustration. Prior to the application of the square wave at time T_o, the output voltage is held at a certain level due to the plate voltage being developed across the plate load resistor R2. This

voltage value **constitutes** the reference or clamping level of the output voltage. Times t_1 and t_3 represent the leading edges, and times t_2 and t_4 represent the trailing edges of the input square wave.

At time t_1, the first positive-going leading edge occurs and appears at the grid of VI. Since capacitor Cl cannot immediately change its charge the entire voltage appears across R1. Grid current immediately flows from cathode to grid and begins charging capacitor Cl. The time required to charge Cl is very short because of the low cathode to grid resistance of V1. As Cl becomes fully charged, the grid side of Cl becomes negative, and the grid is at the same negative potential. This charging action continually reduces the amount of tube conduction from the time of the initial application of the leading edge of the square wave to the time where Cl becomes fully charged. This varies the plate output voltage from some negative value to some positive value (the reference level) where it remains constant for the duration of the pulse, until the trailing edge of the input waveform is reached at time t_2. At t_2, the negative-going trailing edge of the input signal causes a negative voltage to appear across R1 and on the grid of V1. The negative grid swing causes the plate current to reduce, and the plate output voltage, therefore, rises to nearly the full value of the supply (goes **positive).** At this time, the input signal reaches its maximum negative swing and the output voltage reaches its maximum positive swing. For the duration of the pulse to time t_3 a long time constant path is offered through R1 to discharge Cl, since V1 is no longer conducting from grid to cathode (no grid current is flowing). Because of the long time constant and the relatively short pulse width time, Cl discharges only slightly before the next positive leading edge of the input signal **appears** at t_3. Thus the output signal drops a few volts. At time t_3 the positive-going input signal drives the grid of V1 positive so that grid current flows. Meanwhile the increased plate current causes the plate voltage to drop below the clamping level because of the slight loss of voltage during the discharge period. Actually, during this period, the grid voltage is driven above zero bias into the positive region and conduction through the short time constant path through the grid to cathode current quickly charges Cl to the clamping level, and removes the overshoot pip on the grid waveform. Thus, the dip in current below the clamping level in the plate circuit is minimized by grid current drawn by V1, and the plate current then remains constant until the trailing edge of the input pulse at t_4. At t_4 the cycle again repeats, and action is the same as described for the period between t_2 and t_4. Actually, the distortion shown in the illustration of the output waveform is exaggerated to facilitate understanding circuit action. In practice the time constant of **C1** and RI is sufficiently large that very little distortion of the waveform occurs.



Clamper Waveforms

Failure Analysis.

No Output. If a square wave signal within the design limitations of the triode clamping circuit is applied to the input of the circuit a "no output" condition may be the result of no plate voltage existing at the plate of VI. This may be due to a faulty plate supply voltage source or due to an open plate load resistor, R2. The only other faulty component that would result in a "no output" condition is a faulty triode V1.

In order to determine which component is the cause of the "no output" condition, first check to see, with an oscilloscope, if the correct input signal is applied. If a correct signal is applied, check for the presence of plate voltage. If no plate voltage is present, check resistor R2 with an ohmmeter. If R2 is an acceptable value of resistance, check the plate supply voltage source with a high resistance voltmeter to determine if any plate supply voltage exists. If there is no plate supply voltage, try to adjust the source for the correct voltage value. If all these components have been checked and the "no output" condition stiU exists the triode must be faulty.

Low or Distorted Output. If a "low or distorted output" condition exists it may be due to the square wave input signal not being within the design limitations of the triode clamping circuit. This condition may also be due to any of the following component failures: open or shorted input capacitor Cl, open or shorted grid leak resistor R1, shorted plate load resistor R2, incorrect value of plate Ebb, Or a defective triode V1.

To determine why the output is low or distorted, first check the square wave input signal with an oscilloscope. Check the capacitor Cl with an in-circuit capacitor checker to determine if it is open, or measure the voltage from both sides of Cl to ground to determine if Cl is shorted. (If the measured voltages are equal the capacitor is shorted.) Check resistor R1 with an ohmmeter. If resistor RI has an acceptable resistance value, check resistor R2 with en ohmmeter. If resistor R2 has an acceptable resistance value, measure, the value of the plate Voltage supply, E_{bb}, with a high resistance voltmeter. If the plate supply voltage is incorrect, try to adjust the plate voltage supply source for the correct voltage value. If all these components have been checked and the "low or distorted" condition still exists, the triode must be defective.

TRIO DE, BASIC COMMON-BASE CLAMPER

Application.

The basic common-base triode clamper maintains between specific voltage levels the maximum positive and negative voltages developed at the collector of the transistor used in the clamping circuit. This circuit is usually used as a switching amplifier to maintain a constant output pulse amplitude.

Characteristics.

Common base transistor configuration provides an output with no current amplification and no phase inversion.

Collector voltage is clamped, not the output voltage.

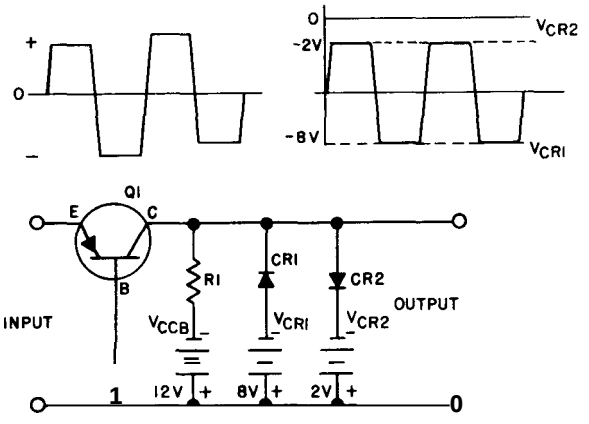
Two diodes provides clamping action.

Diode bias potentials establish minimum and maximum clamping levels.

Cirouit Analysis.

General. The clamping action to be discussed occurs in the collector circuit of the common base connected transistor. Normally, the signal voltage in conjunction with the series combination of the collector load resistor and the collector supply voltage develops a certain collector voltage. If the input signal varies above some level, however, one of two diodes begins conducting. These diodes are connected in parallel with each other and with the collector supply and load. The conduction of the diode maintains or clamps the collector voltage at the bias value. If the signal varies below some level in the opposite direction the other diode conducts, causing the collector voltage to be maintained or clamped at another lower voltage level. During the time that the signal is between clamping levels, the collector voltage varies in accordance with the input signal voltage variation.

Circuit Operation. The circuit of the triode, basic common-base clamper used in this application is shown in the accompanying illustration.



Triode, Basic Common 6ese Clamper

The input signal voltage, as illustrated, is a square-wave pulse type signal which may vary from maximum to minimum amplitudes. It is applied to the emitter of transistor Q1, connected in a common base configuration. The collector voltage variation corresponds to the input voltage variation and is developed across the collector load resistor, R1, by the collector supply voltage V_{CCB}. Diode CR1 and its base voltage V_{CR1} establish a negative clamping level, below which the collector voltage cannot go. Diode CR2 and the bias voltage V_{CR2} establish a Positive clamping level above which the collector voltage cannot go.

The input signal applied to the emitter of Q1 is amplified and in-phase when it appears as the output voltage at the collector of Q1. If the output voltage developed at the collector of Q1 is between the voltage limits of VCR 1 and V_{CR2} the diode cannot conduct. The collector voltage varies in accordance with V_{CCB} minus the output voltage developed across RI (V_{R1}), which depends upon the collector current. Once the input signal varies enough to cause the positive collector voltage swing to exceed the value of V_{CR2} (resumed to be –2 volts), diode CR2 conducts because the anode is driven positive and forward-biases the diode. The collector voltage is then maintained at the value of V_{CR2} until the signal voltage drops to a point at which the the positive collector voltage swing becomes less than the voltage V_{CR2}, at which time CR2 becomes reverse biased, stops conducting, and the collector voltage is again dependent on V_{CCB} minus V_{R1}.

If the input signal varies enough in the opposite (negative) direction to cause the collector voltage to become the same as, or more negative than the value V_{CRI} (assumed to be –8 volts) diode CR1 is forward-biased and conducts. The collector voltage is then maintained at the value of V_{CR1} until the signal voltage increases to a value where the collector voltage becomes more positive than the voltage V_{CR1}, at which time diode CR1 is reverse biased, stops conducting, and the collector voltage is again dependent on V_{CCB} minus V_{R1}.

By clamping both the positive and negative levels, the transistor is prevented from saturating and causing hole storage effects which would increase the pulse length, or from being driven to cutoff when the input is in the other direction. It also has the advantage of not requiring special selection of transistors at the time of replacement, since the operating limits are made such that any transistor of the same type will operate satisfactorily in this circuit. This circuit is not used with sine-wave inputs except where clipping effects are desired.

Failure Analysis.

No-Output. A no-output condition may prevail due to any of the following defects: no input signal present at the emitter of Q1, an open or shorted collector supply voltage V_{CCB}, an open collector load resistor, R 1, or a defective transistor, Q1.

The location of the cause of the no-output condition may be found by first determining if an input signal is present with an oscilloscope. If the input signal is present, check collector supply voltage, V_{CCB}, with a voltmeter. If the collector supply voltage is present check resistor R1 with an ohmmeter. If all other possibilities have been checked and a no-output condition still exists, transistor Q1 can be considered defective.

Low or Distorted Output. This condition may be due to a faulty input signal. If the input signal is found to be correct by an oscilloscope the low or distorted output condition may be due to any of the following conditions: improper voltage values for, collector supply voltage V_{CCB}, bias voltage V_{CR1}, or bias voltage V_{CR2}; shorted or open diodes CR1 or CR2; or a load resistance (Rl) which is not the proper resistance value; or a defective transistor, Q1.

To determine which of the possible causes of the low or distorted output condition is responsible; first,

check the voltage values V_{CCB}, V_{CR1}, and V_{CR2} with a high resistance voltmeter. If any of these values is incorrect adjust the particular voltage source for the proper value. If these voltages are correct, check diodes CR1 and CR2 with an ohmmeter. If the diodes are good, the ohmmeter will read zero resistance when placed across the diode in a forward direction, and will read infinite resistance or a very high resistance when placed across the diode in the reverse direction. If the diodes are good, check resistor R1 with an ohmmeter. If all of the preceding items have been checked and found satisfactory, transistor Q1 must be the faulty component.

SYNCHRONIZED TRIODE CLAMPER (ELECTRON TUBE)

Application.

A synchronized triode clamper is used in television and radar circuitry where it is desired to hold a signal voltage to a zero reference level and allow the signal to vary both positively and negatively from the zero reference level.

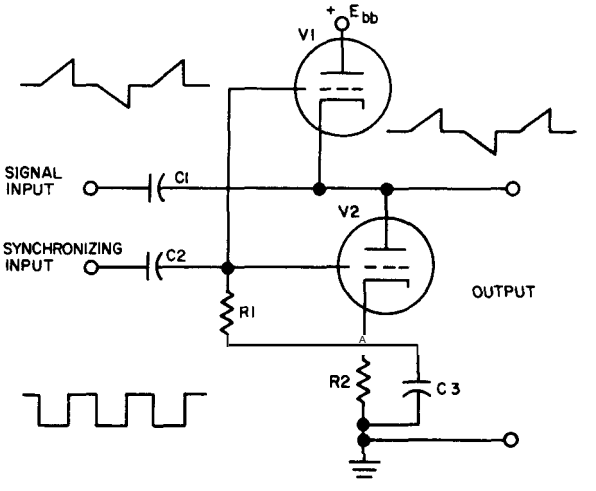
Characteristics.

Uses two triodes connected in series.
Clamping occurs between input signal variations.
Synchronizing pulses are required.

Circuit Analysis.

General. A synchronized triode clamper utilizes the conduction of two triodes to maintain a specific reference level during the time that no signal is present. At the time that the input signal occurs, a negative synchronizing pulse drives the triodes into a nonconducting state for the duration of the synchronizing pulse. The duration of the synchronizing pulse and the duration of the input signal are the same. Any variation in the voltage between input signals (when the triodes are conducting) changes the amount of conduction of the triodes and changes the amount of plate voltage and plate resistance of the triodes. The change in plate voltage and plate resistance is such that the output voltage is maintained at the reference level.

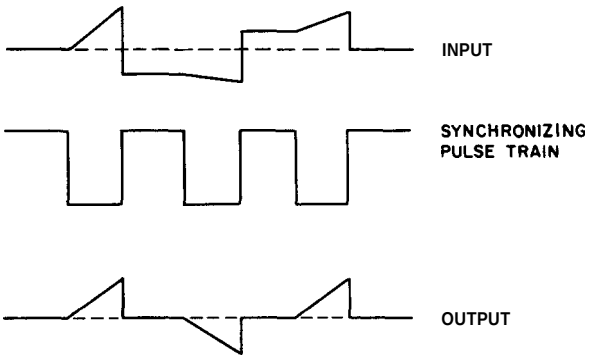
Circuit **Operation. A typical** triode clamping circuit is shown in the following illustration. The input is coupled through capacitor Cl directly to the output. The series combination of triode V1, triode V2, and cathode bias resistor R2 intersects this input line (between capacitor Cl and the output) at the point where the cathode of V1 and the plate of V2 are connected. Capacitor C2 couples a series of negative synchronizing pulses to the grids of triodes V1 and V2. Resistor R1 develops a potential difference (bias) between the cathode and the grid of V2 during the time of the synchronizing pulse. Capacitor C3 is an ac bypass capacitor for cathode bias resistor R2.



Synchronized Triode Clamper

The input signal, in this case, is a series of positive and negative going sawtooth waveforms extending from the zero voltage reference line. There is a steady-state period with no signal variation between the sawtooth waveforms.

A synchronizing pulse signal is applied to capacitor C2. This synchronizing pulse signal consists of negative pulses equal in duration to and occurring at the same time as the sawtooth waveforms. The period between each sawtooth, therefore, is equal to the period between each synchronizing pulse. A diagram of the corresponding time and amplitude relationships of the input, synchronizing, and output waveforms is shown in the following illustration.



Clamper Waveforms

At the time either a positive or negative sawtooth waveform is applied to the input of capacitor C 1, a negative synchronizing pulse is applied to the synchronizing input through capacitor C2 and applied to the grids of triodes V1 and V2. This synchronizing pulse cuts off the triodes V1 and V2 for the duration of the pulse, which is equal to the period of the sawtooth waveform. When the duration of the sawtooth waveform ends, the duration of the synchronizing pulse is likewise completed, and triodes V1 and V2 return to conduction, forming a voltage divider network. This voltage divider consists of the two triodes and a cathode bias resistor R2 in a series connection, extending between plate voltage supply Ebb and ground.

If there should be any voltage at the input that varies from the zero reference line, at this time, the conduction of the triodes will vary in such a way as to compensate for the voltage variation and to maintain the output at the zero reference. If this voltage variation is positive, the voltage at the cathode of V1 and the voltage at the plate of V2 is made more positive. The increased plate voltage of V2, in most cases, is relatively ineffective in changing the amount of conduction of V2. The increased voltage at the cathode of VI, however, causes the grid voltage to appear more negative, thereby increasing the bias. (This positive increase in voltage is then much more effective in changing the conduction of V1 than in changing the conduction of V2). The conduction of VI is then reduced causing the plate resistance of VI to increase, thereby causing a greater voltage drop across VI. With the increased voltage drop across V1, there will be less voltage available at the plate of V2, and thus at the output. This voltage decrease at the plate of V2 and at the output is equal to the positive voltage variation occurring at the input. The output voltage is, therefore, maintained at the zero reference level.

If the voltage variation, at the time that triodes VI and V2 are in the state of conduction, is negative, the voltage at the plate of V2 and at the cathode of V1 is negative. The voltage decrease at the cathode of V1 causes the grid voltage to appear more positive, thereby decreasing the bias. (This decrease in voltage is then much more effective in changing the conduction of V1 than in changing the conduction of V2.) The conduction of V1 is increased causing the plate resistance of V1 to decrease and causing the voltage drop across V1 to decrease. A more positive voltage is then present at the cathode of VI, at the plate of V2 and at the output. This voltage increase is equal to the negative voltage variation at the input. Thus output voltage is maintained at the zero reference level for a negative voltage variation as well as a positive voltage variation.

Failure Analysis.

No Output. A "no output" condition may be due to any of the following failures: an open coupling capacitor C 1, an open synchronizing pulse capacitor C2, no input signal, or no synchronizing pulse train. These failures may be located by measuring capacitors Cl and C2 with an in-circuit capacitor checker, and by observing the input signal with an oscilloscope. If either the input signal or the synchronizing pulse train is not present at the respective inputs, check the input signal source or the synchronizing pulse source with an oscilloscope. If the "no-output" condition still exists after these checks have been made, a bad connection somewhere in the circuit must be the cause.

Low or Distorted Output. A low or distorted output may be due to any of the following defects (provided the proper input signal is applied): low or no plate supply voltage, improper synchronizing pulse, open or shorted resistor R2, open or shorted resistor R1, open or shorted capacitor C3, shorted capacitor C 1, shorted capacitor C2, or, if the condition still exists after checking these components, triode V1, or triode V2, or both triodes must be defective.

To determine which of these components is at fault, first check the input signal with an oscilloscope. If the input signal is correct, proceed to the synchronizing pulse input and check the synchronizing pulse train with an oscilloscope. If either the input signal or the synchronizing signal is incorrect the trouble is not in the clamping circuit, but is in same stage prior to the clamper. If the synchronizing pulse train is correct, check the plate supply voltage with a high resist-resistance voltmeter. If the plate supply voltage is corcheck resistors RI and R2 with an ohmmeter. Check capacitor C3 with an in-circuit capacitor checker, or by measuring the voltage from both plates of C3 to ground. If both voltages are equal the capacitor is shorted. If all components are found to be satisfactory the fault must be in either triode V1 or triode V2, or in both triodes.

PART 13-4. WAVESHAPING CIRCUITS

R-C DIFFERENTIATOR

Application.

The R-C differentiator is used to produce a pip or peaked waveform, for timing or synchronizing purposes, from a square or rectangular-shaped input signal. It is also used to perform the electrical analog of differentiation for computer applications. It may also be used to produce specifically distorted waveshapes for special applications, such as trigger and marker pulses.

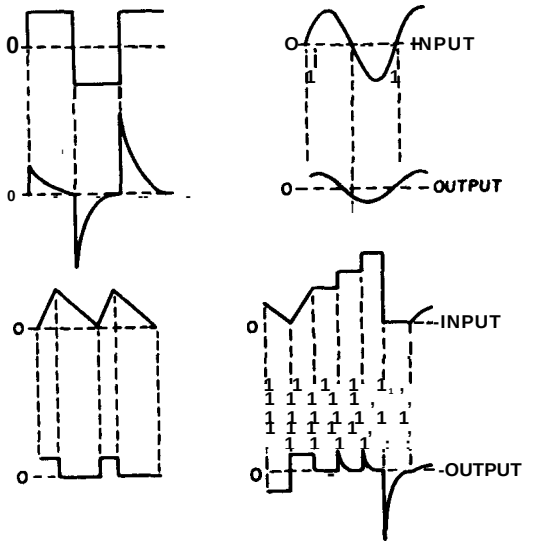
Characteristics.

Input waveshape distorted (nonsinusoidal).
Short time constant R-C network used.
Functions essentially as a high-pass filter.
Output taken from across the resistor.
No amplification produced.

Circuit Analysis.

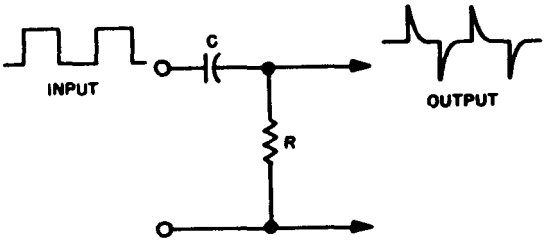
General. The output of a differentiator is proportional to the rate of change of the input signal. For a rising (positive-going) input the differentiator produces a positive puke, for a falling (negative-going) input it produces a negative pulse, and, for a constant input it produces no output. The differentiator electronically simulates the mathematical operation of taking the first derivative. Second, third, and fourth derivatives may be obtained by cascading an equivalent number of differentiators. Theoretically the differentiator is accurate only when the output voltage is very small in comparison with the input voltage. In practice, this is achieved by using the shortest possible time constant for the highest frequency component involved in the waveform being differentiated. For computer, fire control, and similar operations, differentiation of the basic signal voltage produces an output voltage that represents the speed of the object, double differentiation yields the acceleration of theobject, and triple differentiation yields the rate of change of acceleration. For timing and synchronizing use, a sharp pulse is produced for each leading edge and trailing edge of the input waveform. Although the circuit provides no amplification, for a square-wave input the peak output of the differentiator is twice that of the input signal, a positive pulse being produced for the positive leading edge and a negative pulse for the negative trailing edge. For other nonsymmetncal waveforms, since no d-c component is passed through the coupling capacitor, a peak output less than the maximum is obtained, and the output waveform is arranged about the average vrdue as a zero axis. When differentiated, a triangular pulse will produce a rectangular output; a sinusoidal wave will not be changed in shape, but the signal will be shifted in phase and reduced in amplitude. The accompanying figure illustrates the various outputs for different input waveforms.

Circuit Operation. The basic R-C differentiator is shown in the following schematic. The input is applied between the capacitor and ground, and the output is taken across the resistor. Usually this R-C combination constitutes the input or interstage coupling network; especially where R-C coupling is used.



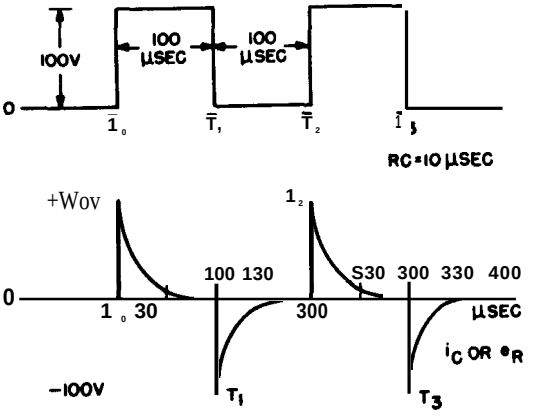
Differentiated Waveforms

When the reactance of capacitor C at the highest frequency to be passed is negligible, the entire input voltage is applied across the resistor. The capacitor quickly charges on the leading edge of the input



Differentiating Network

pulse, and this high-frequency signal is passed, essentially without attenuation, to the input of the following amplifier or control stage. When the time between the leading and trailing edges of the input signal is relatively long (greater than 10 time constants), the capacitor charges, producing a peaked waveform, and remains in the charged condition until the trailing edge occurs. The trailing edge then allows the capacitor charge to be impressed across the resistor, and the capacitor discharges, producing another peaked waveform; however, this time it is of reversed polarity, after which it remains at rest until the next input puke. The passage of the charging current through resistor R develops the voltage which is the output of the differentiator. An exaggerated version of the differentiator current and voltage waveforms is shown in the following illustration.



Differentiator Current and Voltages

The exact functioning of the differentiator is easy to understand by considering the charge on coupling capacitor C, shown in the schematic drawing. Referring to the current and voltage waveforms of the preceding figure, assume a 100-microsecond square-wave input, with a 100-volt amplitude. At time to, capacitor C is assumed to have no charge, and the leading edge of the square wave is applied. Since the charge, or voltage on the capacitor cannot change instantaneously, but takes a finite time, a high current flows through resistor R and creates a large pulse of voltage, which is in effect the leading edge of the square wave passed through the capacitor. During the interval between time t. and t,, the capacitive charging current through C decreases in an exponential manner. The time required to charge or discharge the capacitor is determined by the circuit time constant. In this instance, assume that C is 100 picofarads and R is 100 kilohms; then the RC time constant is 10 microseconds. From the universal time constant chart in Section 2, it is seen that in 50 microseconds (5 time constants) the capacitor will have charged to 99.3% of the maximum possible charge, and that in

100 microseconds (10 time constants) a complete charge (or discharge) is assured. The current and voltage illustration shows the capacitor charging current for the 100-microsecond period (the figure is also a representation of the output voltage of the differentiator). Between t. and t_1 the square wave amplitude is constant and, since there is no change, the differentiator does not produce an output. The capacitor voltage changes from zero toward a maximum value of 100 volts (assuming no losses); the charging voltage is bucked by the capacitor voltage, thus producing the exponential charging rate. By the end of period t_1 the capacitor is fully charged and the negative-going trailing edge of the input signal occurs, causing an instantaneous high flow of discharge current through R. Between t_1 and t_2 capacitor C discharges in a manner similar to that of the charge, and the negative differentiated spike is produced across R. To be a true mathematical derivative of the input voltage, the capacitor voltage must equal the input voltage, and the current will be proportional to the derivative of the input voltage. This condition can be approached by reducing the vrdue of R until practically all of the voltage developed appears across the capacitor instead of the resistor. At this time R is practically a short circuit and no output exists. Therefore, in practical differentiators, the time constant is reduced to as small a value as possible. Usually a time constant of l/10th the period of the input pulse produces satisfactory output spikes. The effect of reducing the time constant can be understood by referring again to the preceding illustration of current and voltage waveforms.

Assume a time constant of only 1 microsecond; then in 10 microseconds the capacitor is fully charged, and the circuit rests for 90 microseconds until another change occurs. Actually, since usually only the top portion of the differentiated signal is selected for use, the approach to a true thin spike is practically achieved and the effective charging period occurs for only a few microseconds. For timing, marker and synchronizing uses, the width of this spike in some cases is not very critical, since the leading edge rather than the trailing edge is used. Where the trailing edge is used, the width of the spike is important. In computer use, where the mathematicrd analog is important, both R and the time constant are reduced to the lowest possible value. Practical limitations imposed on these values are the input and output resistances of the stages between which the differentiator is connected, and stray capacitance across the differentiator output produces a capacitive voltage divider effect, which limits the output voltage to a lower value than the applied input voltage. Also, when the percentage change in capacitance is on the order of 20% of the value of C, the RC time constant is affected. With the example given in the figure, a stray capacitance of 20 picofarads (because of wiring, parts placement, etc) is one-fifth (or 20%) of the vahre of C, and this would effectively change the charge time. Or, considering the stray capacitance as producing a frequency-selective effect, it is clear that the high frequencies in the input signal (which cause the effect that the differentiator utilizes) would tend to be bypassed to ground, leaving only the low frequencies, which have a slow rate of change and produce little effect on the differentiator.

Failure Analysis.

No Output. Since only two components are involved, it is evident that only an open circuit at the input, or a short circuit at the output, could produce a no-output condition (open capacitor or shorted resistor).

Distorted Output. Only a change in component values or associated stray capacitance and resistance values could change the time constant and waveshapes. Distorted output is usually caused by improper input signrds. When checking the waveform at the differentiator, the effect of the shunt resistance or capacitance produced by the test instrument input should be considered. When distortion is discovered in the following tube circuits, it is probably caused by improper action in these circuits. A direct check of the output as compared with the input to the differentiator using a high-impedance oscilloscope, will indicate whether the circuit is performing properly. A shorted capacitor or an open resistor would cause the output to be a duplicate of the input (no differentiation taking place).

R-L DIFFERENTIATOR

Application.

The R-L differentiator is used to distort an applied waveform (such as a square wave) into a peaked wave for the purpose of providing trigger and marker pulses. It is also used to electronically perform the mathematical function of differentiation in computers, and for separating the horizontal sync in television receivers.

Characteristics

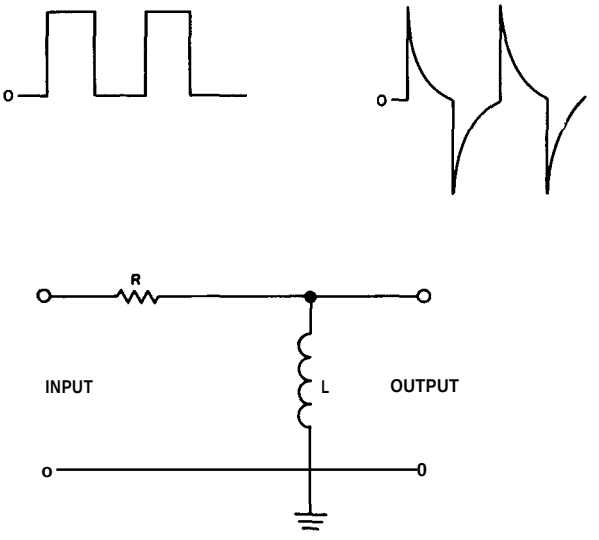
Produces distortion of the input waveform.
Has a short time constant.
Output is taken from across inductor.
Functions essentirdly as a high-pass falter.
Output is similar to the output of an R-C differentiator.

Circuit Analysis.

General. The output of a differentiator is proportional to the rate of change of the input signal. For a rising (positive going) input the differentiator produces a positive pulse, for a falling (negative going) input it produces a negative pulse, and for a constant input it produces no output. The differentiator electronically simulates the mathematical operation of taking the first derivative. Second, third, and fourth derivatives may be obtained by cascading an equivalent number of differentiators. Theoretically the differentiator is accurate only when the output voltage is very small in comparison with the input voltage. In practice, this is achieved by using the shortest possible time constant for the highest frequency component involved in the waveform being differentiated. For computer, fire control, and similar operations, differentiation of the basic signal voltage produces an output voltage that represents the speed of the object, double differentiation yields the rate of change of acceleration. For timing and synchronizing use, a sharp pulse is produced for each leading edge and trailing edge of the input waveform.

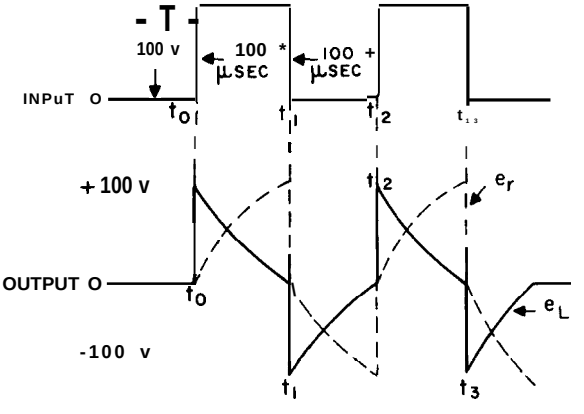
Circuit Operation. A schematic of a basic R-L differentiator is shown in the following illustration.

The input is applied between the resistor and ground, and the output is taken across the inductor. The time constant (in seconds) of an R-L circuit is found by dividing the inductance (in Henrys) by the resistance (in ohms) TC=L/R. Thus to shorten the time constant of an LR circuit it is necessary to increase resistance R rather than decrease R as in the R-C circuit. The counter emf produced in an inductor causes it to have the property of opposing any change in current flow. By referring to the universal time-constant chart in Section 2 of this Handbook, it is noted that the inductor voltage decreases from the applied voltage at an exponential rate to approximately zero at the end of 5L/R time intervals. Likewise, when the source is removed, a counter emf of opposite polarity is induced in the inductor, and this tends to keep current flowing. This voltage also decreases at an exponential rate. Thus, if a square pulse having a time duration of 5L/R time intervals is applied, a peaked waveform appears as the output voltage. This output waveform has a shape that is similar to the output obtained from an R/C differentiator.



Basic R-L Differentiator Circuit

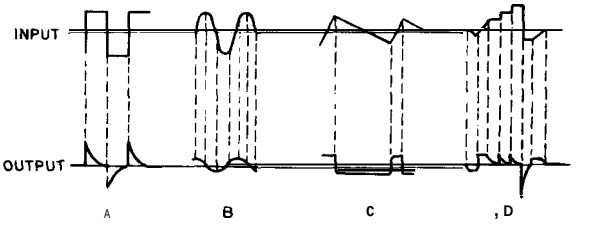
The exact functioning of the differentiator maybe easier understood by referring to the following illustration.



Differentiator Waveforms

With a square wave pulse of 100 volts amplitude applied as an input signal at time to, the output is a positive 100 volts spike. At this time there is no voltage drop across resistor R, since the inductive effect of L is to build up instantly a back emf that equals the applied signal and prevents instant current flow through the inductor. Between time t. and t_1 current begins to flow through inductor L and a small voltage drop is developed across resistor R. As the current flow through R increases, the voltage drop (shown in dotted lines in the waveform figures) increases. Meanwhile, the voltage developed across the inductor, e_L, is decreasing, and, since the output is taken across L, it is also decreasing (the decrease of voltage across coil L representa the voltage used in building up a magnetic field around L). The sum of the voltage drops across R and L equal the applied voltage. The current through inductor L increases exponentially and the voltage across resistor R increases, likewise. Since the time constant assumed in the illustration is 10 microseconds and the pulse width is 100 microseconds the steady-state condition is reached before the pulse ends. Since there now is no change in current, there is no voltage developed across the inductor and the output voltage is zero. At time t_1 the trailing edge of the input pulse occurs and drives the signal in a negative direction. Instantly a negative 100 volt spike appears across L and at the output. At the same time, the field around the coil collapses and produces a current through L in the opposite direction. During time t_1 to t2 the negative voltage across the inductor decreases exponentially while the current increases exponentially. As the current flow through R increases, the voltage drop across it, likewise increases, and the sum of the voltage drops across R and L equals the applied voltage. With the 10 microsecond time constant and 100 microsecond pulse width, the steady state condition is again reached before the pulse ends. Since there now is no change in current, there is no voltage developed across the inductor and the output voltage is zero. At time t_2, the positive-going leading edge of the pulse appears and the cycle repeats.

The following illustration shows the differentiated output waveforms for several different input waveforms.



Differentiating Effects upon Different Waveforms

Although the circuit provides no amplification, for a square wave input, the peak output of the differentiator is twice that of the input signal. A positive pulse is produced for the positive leading edge and a negative pulse for the negative trailing edge.

With a sine-wave input the output remains a sine-wave as shown in part B of the illustration, the only differences being that the output sine-wave is of a smaller amplitude and is advanced in phase. The advance for a perfect differentiator is 90 degrees, but 89 degrees is not uncommon.

The sawtooth, shown in part C of the illustration is converted into a low amplitude square wave. Part D illustrates effect of a differentiator upon the application of a complex waveform.

Since the inductor has distributed (turns) capacitance across it, undesired resonant responses may occur in L-R circuits containing large values of inductance; therefore, the use of these networks is usually limited to high frequence applications.

Failure Analysis.

No Output. Since only two components are involved, it is evident that only an open circuit at the input, or a short circuit at the output, could produce a no-output condition.

Low or Distorted Output. Only a change in component values or associated stray capacitance, inductance, and resistance values could change the time constant and waveshapes. Distorted output is usually caused by improper input signals. When checking the waveform at the differentiator, the effect of the shunt resistance or capacitance produced by the test instrument input should be considered. When distortion is discovered in the following tube circuits, it is

491-044 0 73 78

probably caused by improper action in these circuits. A direct check of the output as compared with the input of the differentiator using a high-impedance oscilloscope, will indicate whether the circuit is performing properly. A shorted resistor or an open coil would cause the output to be a duplicate of the input (no differentiation taking place).

R-C INTEGRATOR

Application

The R-C integrator is used as a waveshaping network in radio, television, radar, and **computers,** as well as many other special electronic applications.

Characteristics.

Input waveshape distorted (non-sinusoidal).

Produces a distortion of the input waveform.

Provides a wider range of time constants than an R-L integrator.

Has a long time constant.

Output is taken from across the capacitor.

Has the configuration of a low-pass falter.

No amplification is produced.

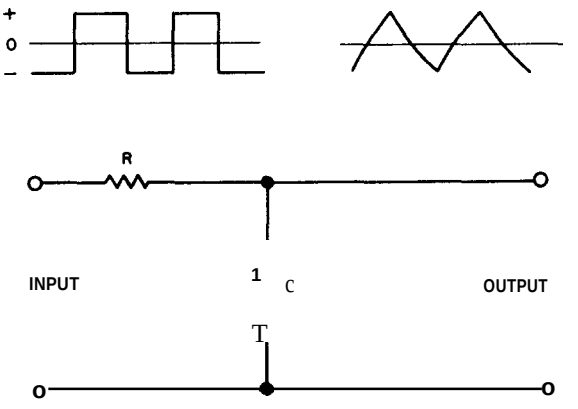
Circuit Analysis.

General. The R-C integrator circuit works in almost exact opposition to the R-C differentiator. It has a long time constant, and the output is taken from across the capacitor. The time constant of the integrator circuit should be 5 times (or more) the period of one alternation of the input waveform, for the circuit to electronically perform the mathematical operation of integration. As in the case of the differentiator, this action in practice is approximate, but the approximation can be made very close.

The higher the resistance in the R-C integrator, the more closely the output voltage follows the ideal integrator waveform. However, the higher this resistance, the smaller the output voltage. Conversely, decreasing the resistance in the R-C integrator circuit, results in a shorter time constant and a higher output voltage. However, as the resistance is reduced in value, the output voltage departs from the ideal integrator waveform. In fact if the resistance, (and time constant) of the R-C circuit is sufficiently reduced, a point will be reached where the circuit no longer acts as an integrator.

The output of an integrator is in the form of a voltage that represents the average energy content of the input signrd. For example, if the input is a steady d-c voltage, the same voltage will appear at the output, but, if the input is in the form of a series of narrow, widely separated pulses, the output voltage will be only a fraction of the input pulse vrdue.

Circuit Operation. A schematic of a basic R-C integrator is shown in the following illustration.

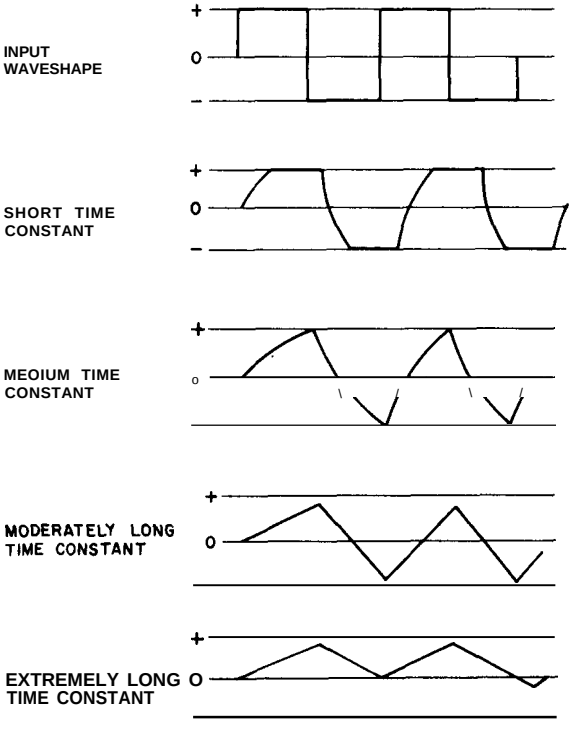


Basic R-C Integrator Circuit

As the square wave voltage applied to the input of the circuit goes positive, the capacitor charges exponentially at a rate determined by the time constant of the circuit. This time constant is calculated by multiplying the value of the resistor by the value of the capacitor (T=RC). For instance, a circuit containing a lOOK resistor and a 50 picofarad capacitor would have a time constant of 5 microseconds, and if the value of the capacitor was increased ten times to 500 picofarads, the time constant would be ten times longer or 50 microseconds. The rise in voltage across the capacitor occurs as the voltage acorss R decreases from its maximum value. The voltage drop across the capacitor is always the difference between the input voltage and the voltage drop across the resistor. The rise in voltage across the capacitor occurs only for the duration of the applied square wave puke. When the applied voltage drops from its maximum value, the capacitor discharges exponentially at the same rate

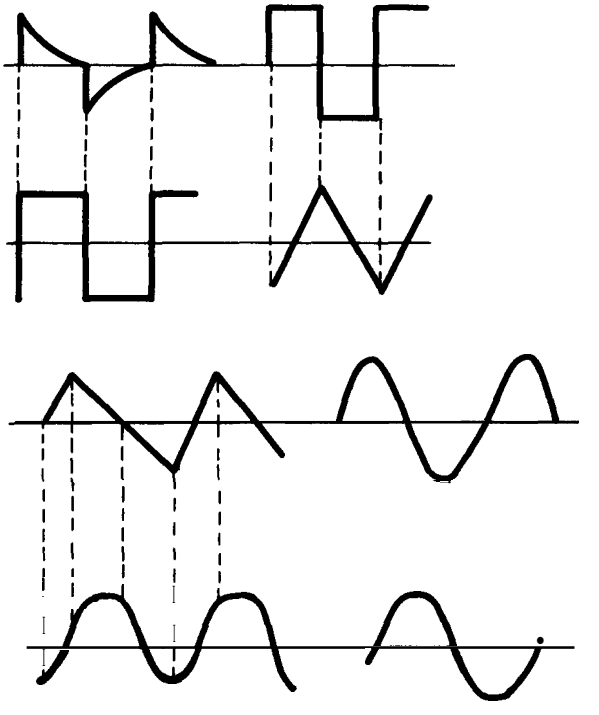
that it charged, due to the time constant of the circuit. This gradual decrease in voltage across C effectively causes a negative pulse across R. If a square wave is applied to an R-C integrator circuit, a nonsymmetricrd saw-tooth waveform is produced. The principle of integration is used in saw-tooth generators to produce the linear rise in voltage by using a long time constant circuit, and to use only the straight portion of the exponential change waveform for linearity.

The following waveform illustration shows the integrating effect of various time constants on a square wave.



Effects of Changing Time Constant

As can be seen from the waveforms in the illustration, a short time constant integrator does not change the input waveform very much except to distort the high frequency portions of the waveform (leading and trailing edges), and the low frequency (flat) portion is practically unchanged. As the time constant is changed to a medium value time constant, the waveshape changes to that of a rounded-off triangle (sweep waveform). With a moderately long time constant, the triangular waveform is equally distributed about the central zero axis and the sides are practically straight. When the time constant is made extremely long, is consists of somewhat elongated (stretched) sawtoothed waveforms of reduced amplitude which gradually approach the zero axis, and eventually, after a number of time constants, becomes symmetrically aligned around the center (zero) axis. A short time constant would be considered one which amounted to only one tenth of the pulse duration time. A medium time constant would be of the order of half the pulse duration, while a moderately long time constant would be approximately equivalent to the full pulse width. A long or extremely long time constant would be considered to amount to two or three pulse widths or longer.



Integrating Effect of Different Waveforms

The preceding illustration shows different types of inputs and their respective output for an R-C integrator circuit. The amplitudes of the waveshapes are different and bear no relation to each other as shown in the illustration. When a peaked waveform is

applied to an R-C integrator circuit, the resultant output will be a square waveform. Applying a square wave to the input of an integrator circuit produces an output waveform of triangular shape. The integration of a triangular wave results in a parabolic output wave. Integrating a sine wave with a different amplitude and phase, but with the same sinusoidal wave. shape (usually considered to be a cosine waveform).

Failura Analysis.

No Output. Since only two components are involved, it is evident that only an open circuit at the input, or a short circuit at the output, could produce a no-output condition (open resistor or shorted capacitor). Both of these items could be checked for with an ohmmeter. If the resistor is open the meter will indicate infinity, and if the capacitor is shorted the meter will read zero ohms.

Distorted Output. Only a change in component values, or associated component values, could change the time constant and waveshapes. Distorted output is usually caused by improper input signrds. When distortion is discovered in the following tube or transistor circuits, it is probably caused by improper action in these circuits. A direct check of the output as compared with the input to the integrator using a high-impedance oscilloscope, will indicate whether the circuit is performing properly. A shorter resistor or an open capacitor would cause the output to be a duplicate of the input (no integration taking place). The value of the resistor can be checked with an ohmmeter. While the capacitor can also be checked for a short with the ohmmeter, it is better practice to use an in-circuit capacitance checker, and also to check the capacitor for both proper value and leakage.

R-L INTEGRATOR

Application.

The R-L integrator is used as a waveshaping network in various types of electronic equipments such as radio, radar, television and in other special electronic application. It is also used as an analog in performing the mathematical function of integration in computers.

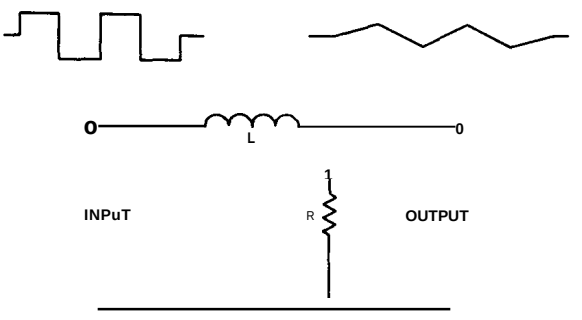
Characteristics.

Produces distortion of the input waveshape.
Has a long time constant.
Output is taken across the resistor.
Has the configuration of a low pass falter.
Output is in the form of a voltage that represents the average energy content of the input waveform.

Circuit Analysis.

Ganaral. An integrating circuit is a circuit whose output is substantially the time integral of its input waveform. The R-L integrator circuit works in almost exact opposition to the R-L differentiator. It has a long time constant and the output is taken from across the resistor. If the time constant of the integrator circuit is 5 times (or more) the period of one alternation of the input waveform the circuit will electronically perform the mathematical operation of integration. This action is approximate in practice, but the approximation can be made very accurate. Since inductor action is the heart of the operation of the R-L integrator a brief review of inductor action follows. The property of inductance is such as to oppose a change in current. This opposition (impedance) exerted by an inductor exists because a counter emf is produced across the inductor by the change in the magnetic field of the inductor, current flow does not rise to a maximum vrdue immediately. Rather, it is initially zero and increases at an exponential rate, as the inductor becomes charged and the counter e.m.f. decreases. Likewise, when the applied voltage is removed, circuit current does not fall to zero immediately, but decreases at an exponential rate as the energy stored in the magnetic field of the inductor is discharged. In the R-L integrator circuit the longer the time constant, the more closely the output waveform follows the ideal integrator waveform. However, the longer the time constant, the smaller is the output voltage.

Circuit Operation. The accompanying schematic diagram illustrates a typical R-L integrator.

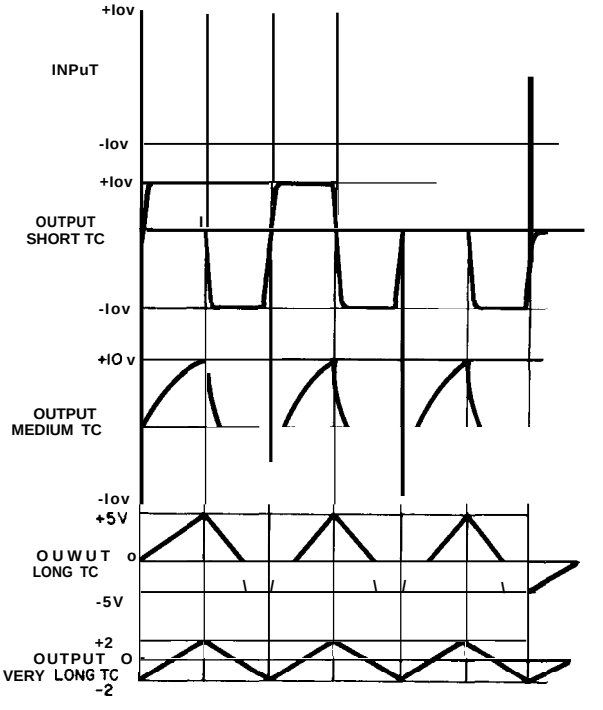


Typical R-L Integrator

This R-L integrator consists of a series R-L circuit with the output taken across the resistor. The charge and discharge time of the inductor (the time constant) is determined by the values of inductance and resistance in the circuit using the formula TC=L/R. Thus an integrator circuit consisting of a .1 henry inductor and a 10,000-ohm resistor has a time constant of 10 microseconds.

When a square wave is applied to the input of the integrator circuit the inductor begins to charge. The impedance, caused by counter e.m.f. generated by the expanding magnetic field is initially maximum, but decreases exponentially at a rate determined by the values of L and R as the magnetic field of the inductor approaches its limit. Circuit current, therefore, begins at zero and increases exponentially as the circuit impedance decreases. It is evident that the IR drop (voltage) across the output resistor begins at zero and increases as the inductor becomes charged. If the time constant is very long the increase in output voltage is nearly linear, but the peak of the output waveform attains only a fraction of the amplitude of the input signal, since the inductor attains only a slight charge during the period when voltage is applied to the input. When the input signal falls back to its reference level, the inductor discharges exponentially at the same rate as it charged. The decreasing current induced in the circuit by the collapsing field of the inductor results in a steadily decreasing voltage developed across output resistor R. The output of an integrator circuit with a long time constant (2 or more pulse widths), therefore, is a triangular waveform, which slopes up (positive) during the period when a positive pulse is applied, and slopes down (negative) during the period when the input is at its reference level. Conversely, when a negative going pulse is applied to the R-L integrator the output voltage goes negative and when the input voltage returns to its reference level. the output voltage goes positive.

The following waveforms represent the integrating effects of various time constant integrator circuits on a square wave input.



Effects of Various Time constants On A Square Wave

As can be seen from the waveforms in the illustration, a short time constant integrator has little effect on the output waveform, only the high frequency components (leading and trailing edges) are attenuated. As the time constant is increased the output begins to resemble a sweep waveform. A further increase in time constant results in a more linear rise and fall of the output waveform. Notice that the output waveform of the long and very long time constant integrator does not reach the peak amplitude of the input waveform, but is rdways a much lower value.

Failure Analysis.

No Output. Since there are only two components in the R-L integrator, a no-output condition could only be caused by an open inductor, a shorted resistor, or by no signal input. Both the inductor and the resistor can easily be checked for the above mentioned conditions with an ohmmeter. Presence of the input signal can be determined by observing the waveform present at the input to the integrator with an oscilloscope.

Distorted Output. Generally speaking, an integrator circuit will either function as designed or not at all. However, it is possible for either the inductor ***or the*** resistor ***to*** change value. This would change the integrator time constant, and the output waveshape would be altered. The resistor may be checked for proper value with an ohmmeter, and the inductor can be checked for proper value with an impedance bridge. It is also possible for the inductor to become shorted or the resistor to become open. This would result in the output being a duplicate of the input (no integration taking place). The components can be checked as explained previously. The most common cause of distorted output is probably distorted input. The quality of the input signal can be easily determined by viewing the waveform present at the integrator input with an oscilloscope.

SATURABLE-CORE REACTOR PEAKING CIRCUIT

Application.

The saturable-core reactor peaking circuit is used to produce a peaked pulse of voltage from a sine wave input.

Characteristics.

Utilizes a saturable reactor.

Output voltage pulses are in phase with the input signal.

Usually operated near resonance.

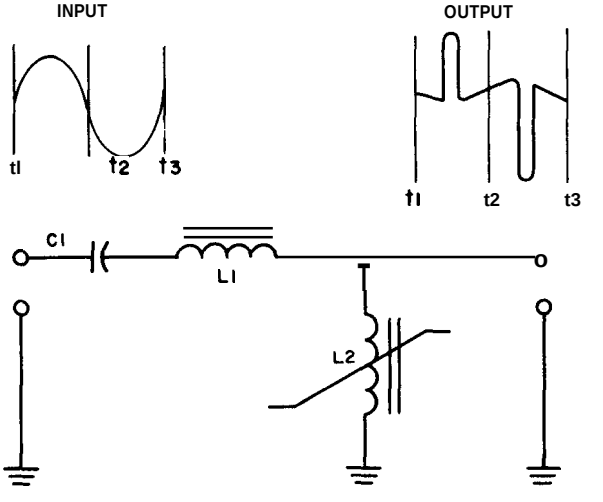
Output puke width is determined by the circuit Q.

Circuit Analysis.

General. The saturable-core reactor peaking circuit produces sharp voltage pulses from a sine wave input signal by utilizing the properties of a saturable reactor. A saturable-core reactor is a type of inductor in which a relatively low value of current produces magnetic saturation of the core.

Magnetic saturation of an inductor core can be defined as the point where a further increase in current flow through the inductor windings does not result in any further increase in magnetic field. The property of inductance is such as to oppose a change in current. This opposition (impedance) exerted by an inductor exists because a counter e.m.f. is produced across the inductor, which opposes the applied voltage. If the core of a inductor were to become saturated, the counter e.rn.f. would drop to a low value, and its opposition to current flow (impedance) would also drop to a low value. It is this ability to change impedance that enables the saturable+ ore reactor peaking circuit to produce a pulse output from a sinewave input.

Circuit Oparation. The accompanying schematic diagram illustrates a typical saturable-core reactor peaking circuit.



Saturable-Core Reactor Peaking Circuit

The circuit illustrated above consists simple of conventional capacitor Cl, conventional inductor L1, and saturable core reactor L2. Component values are chosen so that the circuit appears slightly capacitive when L2 is saturated and slightly inductive when L2 is unsaturated (the inductance of L2 decreases when

L2 becomes saturated). To illustrate the capacitive-inductive relationships when L2 is saturated or unsaturated, assume for the sake of illustration that Cl has a capacitive reactance of 100 ohms at the operating frequency and that LI has an inductive reactance of 75 ohms at the operating frequency. Assume further that L2 also has an inductive reactance of 40 ohms when unsaturated and 10 ohms when saturated. The reactance of both Cl and L1 remain constant. It can be seen that during the period when L2 is unsaturated there is a total of 115 ohms of inductive reactance and 100 ohms of capacitive reactance in the circuit. The circuit, therefore, appears inductive since the effect of L1 predominates. Likewise, when L2 is saturated there is 100 ohms of capacitive reactance but ordy 85 ohms of inductive reactance, and the circuit now appears capacitive.

When a sine wave is applied to the saturable+ ore reactor peaking circuit, L2 becomes saturated by the relatively high current flowing through it, and the voltage across L2 is very low, since the inductance of L2 is also very low at this time. Since the circuit is slightly capacitive during the saturation of L2, the current in the circuit leads the applied voltage by almost 90°, and the output voltage is approximately 180 degrees out of phase with the applied voltage, since the voltage across L2 also leads the current by nearly 90°. This output voltage is very low in amplitude, since L2 offers little impedance while in the saturated state. Inductor L2 becomes unsaturated when the input voltage is at a peak, since at this time circuit current is at a minimum due to the 90° phase shift. At this time (when L2 is unsaturated) the inductance of L2 becomes high. This makes the circuit highly inductive and causes the circuit current to lag the applied voltage by almost 90°. However, the voltage across L1 (the output) leads the circuit current by ahnost 90°, since voltage leads current across an inductor and is, therefore, in phase with the input. This condition persists for only a short period of time until the circuit current increases and becomes sufficient to saturate L2. During this short period of time a large amplitude pulse which is inphase with the input is produced. The duration of this pulse coincides with the duration of the unsaturated condition of L2 and is determined mainly by the circuit Q. Thus, a large amplitude positive pulse is produced when the applied sine wave passes through its positive peak, and a large amplitude negative pulse is produced when the applied sine wave passes through its negative peak. Since L2 is saturated during most of the input cycle, the output is extremely low except for the short time during the peaks of voltage when L2 is in an unsaturated condition.

Failure Analysis.

No Output. A no-output condition could result if any component in the saturable reactor peaking circuit became shorted or open. Inductors L1 and L2 can easily be checked by measuring the resistance of the windings and checking for a short or leakage to ground with an ohmmeter. Capacitor Cl can be checked with an in-circuit capacitor checker. Do not overlook the possibility that a no-output condition is the result of no-input. This can easily be checked by observing if the waveform is present at the circuit input with an oscilloscope.

Low Output. Generally speaking, since there are few components involved, the saturable-core reactor peaking circuit will either function as designed or not at all. However, a low-output condition could result from a partially shorted component or from excessive leakage to ground of the windings of L1 or L2, or from a low amplitude input. Resistance checks of the inductor windings and resistance checks to ground, with the bottom of L2 disconnected, should reveal whether or not a partially shorted component or leak age to ground is the cause of low output. The amplitude of the input signal can easily be checked by observing the waveform present at the input with an oscilloscope.

Distorted Output. Since the duration of the output pulse is determined mainly by the Q of the circuit, a change in circuit value could alter the Q of the circuit and thus alter the output waveshape. Checks for excessive leakage to ground should be made using an ohmmeter, since leakage to ground would affect the circuit Q. Cl, L1 and L2 can be checked for proper value with an impedance bridge.

SEMICONDUCTOR PULSE SHAPER

Application.

The semiconductor pulse shaper is used in computer, control, and communication equipment to reshape a pulse which has suffered deterioration of its waveshape after passing through a chain of gates. It is also used in conjunction with a multivibrator to form a 1 μ sec. pulse with sharp leading and trailing edges.

Characteristics.

Reshapes pulses into pulses with sharp leading and trailing edges.

Utilizes two transistors connected in the common-emitter configuration.

Requires three power supply voltages.

Output pulse width is constant and is determined by circuit components.

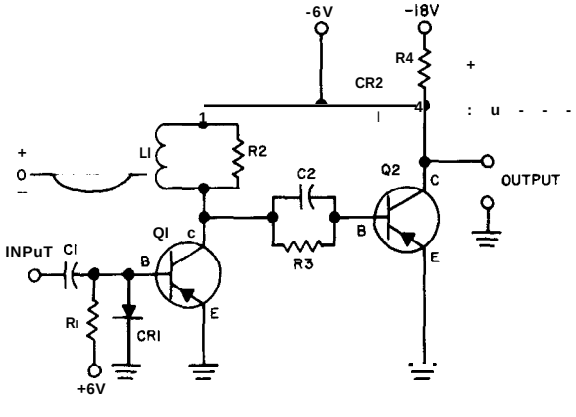
Capable of driving several loads.

Circuit Analysis.

General. The semiconductor pulse shaping circuit consists of two common-emitter amplifiers. The first stage, which employs on R-L collector load, performs the primary shaping function and controls the output pulse width. The second stage, an overdrive amplifier, serves as a buffer power amplifier, and in addition squares off the trailing edge of the output pulse.

The output pulse width is primarily determined by the ***values*** of the inductive load of the first stage and the input capacitor, but is also affected by transistor characteristics, as well as changes in the power supply voltage. In most instances circuit values are chosen which produce an output pulse width of 1 microsecond.

Circuit Operation. The accompanying schematic diagram illustrates a typical semiconductor pulse shaper using the commonanitter configuration.



Semiconductor Pulse Shaper

Capacitor Cl couples the input pulse to the base of transistor Q1. Resistor RI and diode CR1 form a voltage divider between ground and the +6 volt bias supply to apply reverse bias to the base of transistor Q1. Inductor Ll and resistor R2 form the collector load for transistor Q1, and capacitor C2 together with resistor R3 forms an interstage coupling network from the collector of Q1 to the base of Q2. Transistor **Q2, which is** operated as an overdriven amplifier, serves as the output stage, with resistor R4 as its collector load, and diode CR2 limiting the output to the level of the -6 volt power supply.

In the quiescent state (no signal input) transistor Q1 is reverse biased by the positive voltage at the junction of voltage divider R1-CR1. The collector of Q1 is at approximately –6 volts since Q1 forward collector current is cut off, and transistor Q2 is heavily forward biased by the negative collector voltage of Q1 direct-coupled through R3. With Q2 conducting heavily, the output voltage is very close to ground potential. When a negative pulse is applied to the pulse shaper, voltage divider diode CR1 is reverse biased and transistor Q1 is driven into conduction by the charging current flowing through the emitter-base junction of Q1 and into capacitor Cl. The rapid rise in charging current through the emitter-base junction of Q1 rapidly drives Q1 into saturation, and the voltage on the collector of Q1 rises sharply to ground potential. This rapid positive swing in collector voltage on Q1 is coupled through R3 and C2 to the base of output transistor Q2, and Q2 is rapidly cutoff. The collector voltage of Q2 (the output voltage) which was previously held at ground potential due to the heavy conduction of Q2 now rapidly falls to the -6 volt supply level. This is the beginning of the output pulse. The amplitude of the output pulse is maintained at a constant -6 volts by the action of limiting diode CR2. Transistor Q1 is maintained in a saturated state by the charging current of Cl flowing through the emitter-base junction of Q1. This current decreases as Cl becomes charged, but remains sufficient to keep Q1 saturated for the duration of the output pulse. During the period when Q1 is saturated, collector current is limited by the impedance of the load (Ll and R2). Initially, the impedance of L1 is high, but it decreases as L1 becomes charged and collector current increases. Consequently, during the period when Q1 is in saturation, collector voltage on Q1 remains constant and output transistor Q2 remains cut off. Hence, the output voltage remains at -6 volts. When the desired output pulse width is completed, the impedance of LI is so low that the base

drive **caused** by the charging current of Cl is insufficient to maintain collector current at the previous level. (Base drive decreases as Cl charges). Collector current then decreases rapidly and Q1 collector voltage quickly falls to –6 volts, which drives output transistor Q2 into saturation. The output voltage rises sharply to ground potential as the conduction of Q2 increases. The rapid transition of Q2 from cutoff to saturation is aided by the discharge through the emitter-base junction of Q1, of the energy stored in L1. The term "cutoff" has been used loosely in the preceding paragraphs. Actually the transistors are not cut off in the sense that a vacuum tube can be cut off, since there is always some reverse leakage current flowing, but the magnitude of this current is insignificant. The values of Cl and L1 are the determining factors affecting output pulse width, since the output pulse is completed when Cl and L1 become fully charged and cause the collector current of Q1 to begin decreasing,

Failura Analysis.

General. When making voltage checks, use a vacuum tube voltmeter to avoid the low values of multiplier resistance employed on the low voltage ranges of the standard 20,000 ohms-per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No **Output. A no-output** condition could result from failure of either transistor or failure of one of the power supplies. Semiconductor circuits are generally miniaturized printed circuits. Circuits of this type are subject to shorts caused by a small drop of solder, or any conductive object that may fall across printed circuit leads, or these leads may become open by a hairline crack in the printed board. Plug-in type contacts, often employed in printed circuit boards, sometimes fail to make contact due to dirty or bent contacts. It is often wise to visually check the printed circuit board for evidence of any of the above conditions before attempting to troubleshoot the circuit. Power supply voltages should be checked with a vacuum-tube-voltmeter, and adjusted or repaired if necessary. It should be noted that deterioration with age causing lack of gain may result under high temperature conditions. Unlike vacuum tubes, however, transistors have operated for years without noticeable deterioration under proper operating conditions. If the transistor is not at fault, a defective circuit component is likely the cause of no output. Voltage checks of transistors elements with a vacuum tube voltmeter, or resistance checks with the circuit deenergized, should indicate the component at fault. Resistors R3 or R4 could cause a no-output condition if they failed, as could diode CRI if it became shorted. Failure of other circuit components could possibly cause a no-output condition to exist, but are much more likely to cause distortion of the output waveshape. This condition will be discussed in detail in the following paragraph. Do not overlook the possibility that a no-output condition is the result of no input signal reaching the pulse shaper. The existance of this condition can readily be determined by observing the waveform present at the input to capacitor Cl with an oscilloscope.

Distorted Output. The term distorted output is used in the following paragraph to describe any output condition other than the proper output with respect to the pulse width, pulse amplitude, and pulse rise and fall time since a circuit defect usually causes more than one of these symptoms of improper output to appear. Defective transistors and improper power supply voltages are often the cause of a distorted output. The power supply voltages should be checked and adjusted if necessary, they should be within 1070 of their nominal values. If the power supply voltages are correct and the transistors are good a defective circuit component is the next most likely cause of improper output. A significant change in the vahre of any component could alter the output waveshape. Since the value of L1 and Cl determine the pulse width a change in the value of these components would, naturally, affect the output pulse width. L1 and Cl can be checked for proper value on an inductance-capacitance bridge. Resistors RI and R2 also affect pulse width but to a lesser degree than Cl and L1. Diode CR2 limits the amplitude of the output pulse to -6 volts. If CR2 opened, the amplitude of the output pulse would increase. The input pulse must be of the correct polarity, and have sufficient amplitude and duration to properly trigger the pulse shaper, if a good output pulse is to be generated. The condition of the input pulse may be checked by observing the waveform present at the input to capacitor Cl with an oscilloscope.

PART 13-5. TIME DELAY CIRCUITS

BASIC PHANTASTRON CIRCUITS

Application.

The phantastron circuit is used to generate a rectangular waveform, or linear sweep, whose duration is almost directly proportional to a control voltage. Because of its extreme linearity and accuracy, this waveform is used as a delayed timing pulse, usually in radar or display equipment. It is also used to produce time-delayed trigger pulses for synchronizing purposes and movable marker signals for display. For example, it is used as a time-modulated pulse, to indicate antenna position at any instant of rotation, or as a range strobe or delay marker.

Characteristics.

Operation is similar to the operation of a multivibrator.

Pulse width or delay varies linearly with the applied control voltage.

Requires an electron tube of the pentode or penta. grid type.

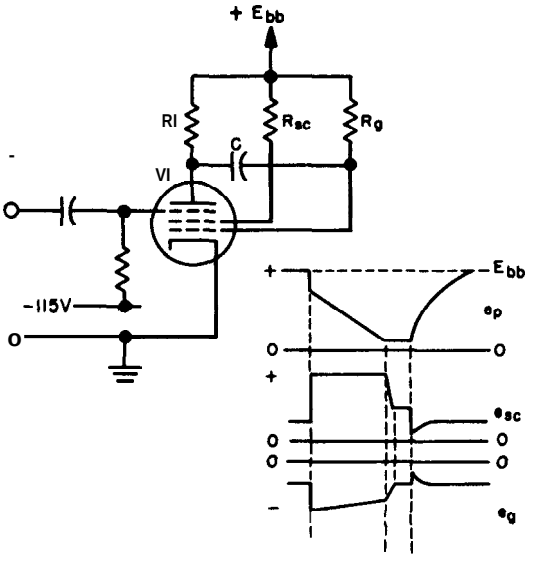
Output can be taken from the cathode, screen, or plate, and may be either positive or negative, as selected.

Provides either a low-impedance or high-impedance output, determined by output connections.

May be self-controlled or externally controlled.

Circuit Analysis.

General. The operation of the phantastron circuit is breed on the use of a Miller-type linear sweep generator which uses a suppressor-gated pentode, as shown in the following illustration.



Miller Linear Sweep Generator

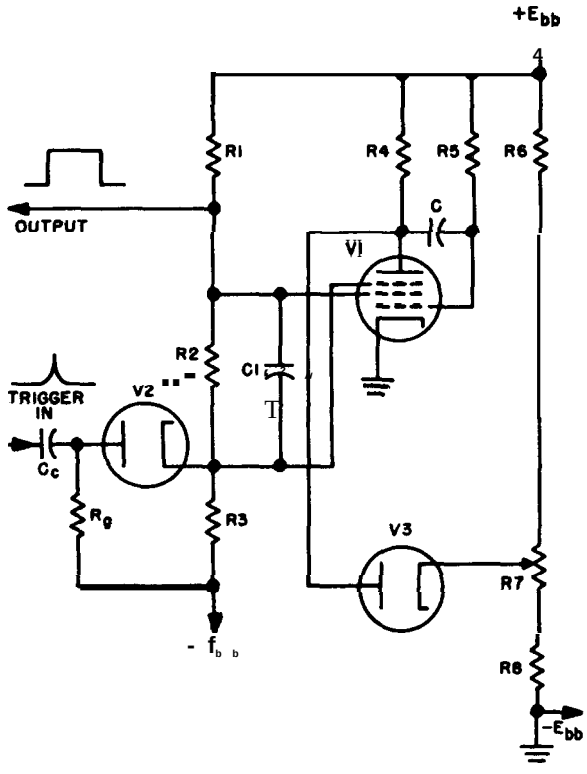
In the Miller linear sweep generator, the suppressor grid is normally biased (negative) to prevent plate current flow, while the screen conducts heavily. The grid is returned to B+ through a resistor so that it is effectively at zero potential, and the cathode is grounded. When a positive gate is applied to the suppressor, plate current flows and produces a voltage drop across the plate load resistor. This negative-swinging plate voltage is fed back through a small capacitor to the grid, and quickly drives the grid negative; thus, it maintains the plate current at a small value, and also greatly reduces the screen current. Reduction of the

heavy screen current produces a large positive swing on the screen, and the tube essentially remains in this condition, producing a positive screen gate. Meanwhile the plate current flows under control of the feedback voltage applied to the grid until no further feedback is produced, During this time the plate-current increase is linear, and the plate voltage continues to drop. (The normal discharge of C through R_g would cause the current through the tube to increase in an exponential manner, thereby causing the plate voltage to drop exponentially. However, any exponential change is fed back to the grid 180 degrees out of phase with the normal discharge of C, thereby causing a linear increase in plate current.) At a point about 2 volts above ground, however, no further plate swing is possible, and the screen again conducts heavily, returning almost to the initial operating point. When the suppressor gate ends, the plate current is cut off, the screen returns to its initial operating point, and the cycle is ready to be resumed under control of the next gate. The following schematic shows the basic Miller circuit. Observe that the screen is not coupled, that a separate bias source is used for the suppressor, and that an external sweep gate is necessary. These are the main ways in which it differs from the phantastron.

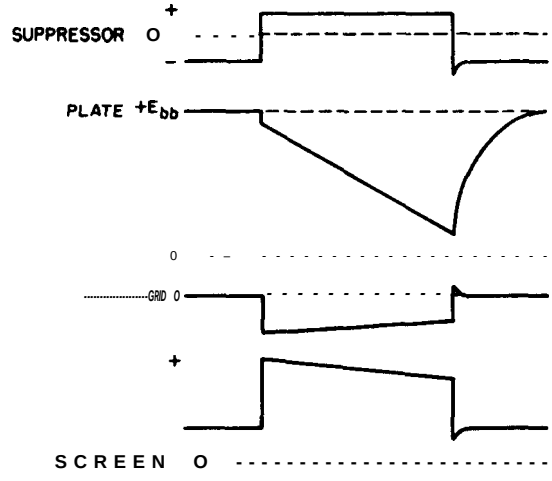
From the circuit action described previously, it is clear that changing the applied plate voltage will determine the point, and the time, at which the plate voltage "bottoms" (with respect to the leading edge of the input waveform) and the screen resumes control. Changing the values of feedback capacitor C and grid resistor R will also determine the time of operation (by controlling the speed of the grid-plate feedback action). Both methods of controlling the time are used in phantastron circuits.

Circuit Operation. As mentioned previously, there are two basic types of phantastron circuits in use–the screen-coupled and the cathode-coupled. The name is derived from the manner in which the gate for the suppressor is obtained. Recall that in the Miller circuit a positive gate is developed on the screen during operation; by coupling the screen to the suppressor, either directly or through a capacitor, this gate is used in the screen-coupled phantastron to control operation. A trigger pulse is needed only to start operation, because turn-off is automatic. By inserting a cathode resistor between the cathode and ground, a negative gate is developed and used to control the cathode-coupled phantastron. Each of these circuits will be discussed more thoroughly in the following paragraphs.

Screen-Coupled Circuit, A typical monostable screen+ oupled pentode circuit is shown in the following figure. This circuit is started by a positive trigger applied to the suppressor grid, and at the end of operation it returns to the initial starting condition, ready to repeat the cycle of operation when the next trigger arrives. The output taken from the screen is a rectangular positive gate whose duration, or length, is controlled by R7. In the illustration, tube VI is the basic phantastron, and diode V2 acts as a trigger injector and also as a disconnecting diode to effectively isolate the trigger circuit after the action is started. Diode V3 sets the maximum level of plate voltage as controlled by the position of R7, and, since the turn-off level is fixed, it effectively controls the time during which the circuit produces the linear gate or sweep. Operation occurs at the rate fixed by the discharge of C through R5. In some circuits R5 is made variable to set the maximum time delay, and R7 is provided as an external control to permit selection of the exact time duration required. Feedback capacitor C provides regenerative feedback from plate to grid, to allow quick response to any changes in the plate circuit. Capacitor Cl couples the positive gate from the screen to the suppressor, thereby holding the tube in a condition where the plate current can flow.



Basic Screen-Coupled Phantastron



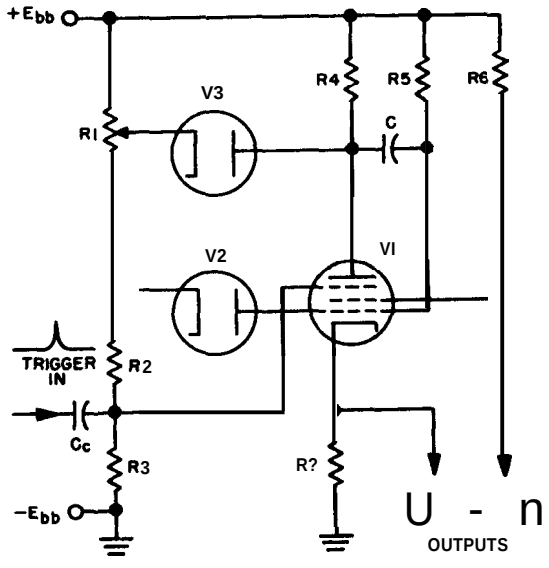
Waveforms of Scraan-Coupled Phantastron

Circuit operation can best be understood by referring to the waveforms developed in the tube elements shown in the following illustration, while reading the description of the circuit action. Three steps are involved in the circuit action–turn-on, linear sweep development, and turn-off. Before initiation of action, the circuit is resting with the plate current cut off, because a negative voltage is applied to the suppressor element through R3. Resistors R1, R2, and R3 form a combined suppressor and screen grid voltage divider connected between B plus and C minus. The values are such that the screen is positive and the suppressor is sufficiently negative to cut off plate current. Since they are directly connected, both elements are dc coupled; also, through capacitor Cl they are ac coupled. Therefore, both dc and ac voltages appearing on one element also affect the other element. Since the cathode is grounded and the grid is connected through R5 to B+, the grid remains near zero bias. Thus, although the plate current is cut off, the screen current is heavy. When a positive trigger is applied to the plate of disconnecting diode V2 through coupling capacitor Cc, the diode conducts, and the positive trigger appears across R3 and is applied to the suppressor of VI. The trigger is large enough to overcome the fixed negative bias and drive the suppressor positive. Therefore, the plate current flows through R4. Since R4 is a relatively large-value resistor, the plate current quickly goes from zero to a low value, and simultaneously the negative swing produced across R4 is applied through C to the grid, driving it from zero to a negative value

of only a few volts, but sufficiently negative to reduce the total cathode current. The grid is now in full control, and the reduction of screen current produces a large positive increase in screen voltage. Through Cl the positive-going screen voltage is fed back to the suppressor so that the action is regenerative; as a result, the tube is quickly triggered from the static condition to the operating condition, which produces a screen waveform with a sharp leading edge. The linear sweep development or timing cycle now begins, with the plate current of V1 increasing steadily. Since the grid is returned to B+, the grid voltage attempts to reach the zero bias level; however, it can change only slowly because the plate side of feedback capacitor C is steadily decreasing, so that any positive grid swing is immediately counteracted by a negative plate swing fed back to the grid. Therefore, capacitor C starts to discharge and electrons flow from the plate of V1, discharging C through R5. Thus C discharges at a rate determined by the time constant of C and R5 (in some circuits R5 is made variable to permit changing the rate of operation). In discharging, the grid side of capacitor C gradually becomes most positive, causing an increased current flow through R4 and producing a constant decrease in plate voltage. The positive increment on the grid is always slightly greater than the negative plate swing it produces; therefore, the grid potential gradually rises, and the plate potential gradually drops. When the plate reaches the point where a voltage change on the grid will produce no further plate-voltage change, the turn-off point is reached. Up to this time a positive gate has been produced in the screen circuit and coupled to the suppressor. A negative gate has been developed on the grid which is smaller in amplitude from the leading edge to the trailing edge by about a volt. (The amount is dependent upon the gain of the tube.)

Since the tube plate voltage is only a volt or so above zero and the plate current can no longer increase, but the grid voltage is still rising toward zero, causing an increase in current flow, the screen current increases. The moment the screen current increases, the screen voltage drops and feeds back a negative swing through Cl to the suppressor. The suppressor grid then resumes its original negative condition, stops any flow of plate current, and assumes control again. Since this action is regenerative, a sharp trailing edge is produced. Simultaneous with plate current cutoff, the plate voltage swings positive and feeds back to the grid a positive voltage, which helps the grid to return to normal zero bias condition. Since the charge on C cannot change instantly, the plate swing tapers off exponentially and the tube is not ready for another trigger cycle until it has completely recovered. Diode V3, a "plate-catching" diode (because of the way it "catches", or arrests, the positive excursion of the plate voltage), operates to catch the plate at a specific voltage, so that with a fixed bottoming point the length of the output pulse and its time duration depend on the plate voltage fixed by V3. The cathode of V3 is biased positive by the voltage divider consisting of R6, R7, and R8, as controlled by potentiometer R7. When the plate voltage of VI is greater than the positive voltage applied to the cathode of V3, the diode conducts and quickly brings the plate voltage of V1 down to the level of the cathode voltage. Thus, the linear sweep action always starts at the voltage set by R7, and the duration of the phantastron gate (or the length of the sweep) is thereby determined. Because the amplitude of the plate sweep depends on the level at which it starts, R7 directly controls the amplitude. The amplitude of the screen gate is determined by the voltage applied and the screen current, and is only slightly affected by R7.

Cathode-Coupled Circuits. A typical cathode-coupled pentode is shown in the following schematic. This circuit is also started by a positive trigger applied to the suppressor grid and turns itself off automatically like the screen-coupled circuit. The output can be taken from either the screen or cathode, or both. The screen output is a positive gate, and the cathode output is a negative gate.



Basic Cethode-Couplad Phantastron

In this **circuit,** tube VI is the basic phantastron, with diode V3 operating to control the plate voltage level and determine the duration of the output gate. To minimize overshoot on the control grid, cathode, and screen grid (positive on the control grid and cathode, negative on the screen grid), diode V2 is connected between R1 and R2 on a voltage divider network consisting of RI, R2, and R3. (The voltage on the cathode of V2 is normally 1 or 2 volts less than the cathode voltage of V].) Note that no negative supply is needed to bias the suppressor. Cathode bias is used, end the suppressor is held at a lower positive potential than the cathode; thus, it is effectively biased negative with respect to the cathode, cutting off plate current. The screen is drawing current, which produces a positive voltage on the cathode. When a positive input trigger appears across R3, it is applied to the suppressor. This trigger is prevented from affecting the control grid by automatically reverse-biasing diode V2. The grid is normally biased near zero, being held by diode V2 at a potential determined by the voltage divider (Rl, R2, and R3) connected between B+ and ground, and the cathode is positive with respect to the grid by approximately 1 or 2 volts. When the trigger is applied, it overcomes the bias between the suppressor and cathode, and plate current flows. The decrease in plate voltage, due to the flow of plate current, is fed back to the grid through capacitor C, causing the tube current to decrease and the cathode voltage to drop. This drop in cathode voltage further decreases the bias between the suppressor and cathode, and plate current increases further. Since the total tube current is decreasing and the plate current is increasing, the screen current must decrease. This action is regenerative, and plate current will jump from zero to a value determined by the tube characteristics. (Note that the bias between the cathode and suppressor is decreasing, which is regenerative, causing the plate current to increase. The bias between the cathode and grid is increasing. This action is degenerative, which decreases the total tube current. Therefore, there must be a point where these two effects are equal and the current will stabilize for an instant.) At this instant there is no further change in plate voltage, and the grid voltage increases in the positive direction at a rate determined by C and R5, since it is returned to E_{bb} through resistor R5. This causes the plate current to increase. As the plate current increases, the plate voltage decreases, and this negative change is coupled through C to the grid. It can be seen that his signal is degenerative, and prevents the plate current from increasing rapidly. This action continues, providing a linear sweep until the plate voltage drops to a level at which it can no longer cause an increase in plate current. At this time, degenerative feedback to the grid stops, and the grid will go in a positive direction more quickly. This causes an increase in the total tube current, and thus an increase in cathode voltage, an increase in cathode-to-suppressor bias, and a decrease in plate current. With the total tube current increasing and the plate current decreasing, the screen current must be increasing. It can be seen that the action taking place is regenerative, as the plate will go positive, causing the grid to go positive, and the plate current will go rapidly to cutoff, leaving the tube in its **pretriggered** condition. The positive swing in the grid is limited by the "catching" diode, V2. Before the circuit is ready for the next cycle of operation, capacitor C must recharge through R3, R2, V2, and R4. As in the **screen-coupled** phamtastron, this circuit is also of the slow-recovery type.

As stated previously, when the phantastron is triggered there is a large drop in the screen current. This produces a positive waveform on the screen with a steep leading edge. As the tube current gradually increases, producing the linear sweep in the plate

circuit, the screen current increases in the same manner, but by a smaller amount, in proportion to the plate current. The screen waveform will therefore decrease linearly by a small amount until plate current cutoff (described previously) is reached. At plate current cutoff, the screen current increases abruptly, causing a steep trailing edge. Negative overshoots at the trailing edge of the waveform will be limited by the action of diode V2.

The resultant waveform across the cathode resistor can be visualized from the previous description of tube operation, by taking into account the changes in the total tube current. This waveform will be a negative gate with steep leading and trailing edges and with the flat portion falling off in amplitude at a linear rate. Any positive overshoot at the trailing edge will be limited by diode V2.

As in the screen-coupled phantastron, resistor R5 can be made variable to set the maximum width or delay. R1 is variable, and is connected to the plate of VI through diode V3, thereby setting the level of plate voltage at which the phantastron begins its action (when triggered). It can be seen that this will determine the amplitude and thus the duration of the plate waveform. R1 is usually an external control to vary the width or delay, and R5 can be an internal adjustment to set the maximum width or delay.

tn contrast to the screen-coupled phantastron, the cathode-coupled phantastron, has a smaller range of operation. The maximum plate amplitude swing of V1 is limited by the value of the cathode resistor, in that "bottoming" of the plate voltage occurs at a more positive potential than in the case of the screen-coupled phrmtastron.

Failure Analysis.

No Output. Lack of plate or screen voltage because of an open bleeder resistor network (consisting of R1, R2, and R3) or open load resistors will prevent operation, as will a faulty electron tube. Loss of input trigger will also render the circuit inoperative. It is also possible for excessive bias to make the circuit inoperative because the trigger amplitude is not sufficient to overcome the bias and initiate operation. Such a condition is indicated when an input trigger can be seen on the suppressor with an oscilloscope and voltage appears on all tube elements, but either the grid or cathode voltage is higher than normal. This is most likely to occur in the screen-coupled circuit, where a negative fix supply is employed with a common bleeder to obtain bias. Since the cathode-coupled circuit develops its own bias, an excessive current drain or short-circuit condition would be needed to increase bias to the non-operating point.

Distorted Output. Distortion is indicated by a non-linear waveform or an inaccurate time delay. Linearity of sweep development is the basic property of this circuit, with the controlling elements being the applied dc control voltage and the RC time constant in the feedback circuit. Control voltage trouble may occur when the circuit uses a separate external control from a separate power supply, as power supply fluctuations can easily change the operating level and hence the pulse duration. Failure of the plate-catching diode is usually indicated by lack of control over the entire range of operation, whereas partial control is more likely to result from changing power supply voltage or a defective control. Change of time constant due to changes in circuit values or to failure or partial shorting of the capacitor will change the rate of operation and hence the time delay. It should be most noticeable for the longer delay times. False triggering due to the pickup of noise or stray pulses in the control cabling (on remote units) may affect both the starting and stopping of the gate. If the disconnecting or triggering diode is used, however, such pickup will affect only the start unless it is coupled to the suppressor through stray capacitance, and this is rather unlikely to occur. Generally it is rather difficult to pinpoint trouble in this type of circuit unless an oscilloscope is used to observe the waveforms at each electrode, because there are four basic types of trouble, namely, starting trouble, stopping trouble, linearity, and recovery-time failure.

Low or Unstable Output. Low screen-gate output indicates improper screen voltage or current, which may be caused by a defective electron tube or a change in resistance value in the screen circuit. Low cathode-gate output indicates low cathode current, which is the sum of all element currents, and therefore may be due to any one of numerous causes. Usually a voltage check will indicate the defective component. Instability in the form of jitter may be caused by power supply voltage fluctuations, noise, or false triggers picked up by unshielded wiring. An oscilloscope waveform check will reveal the cause of the instability, which can then be traced to its source.

FAST-RECOVERY PHANTASTRON CIRCUIT

Application%

The fast-recovery phantastron circuit is used to generate a linear sweep, or rectangular-wave output, whose duration is directly proportional to a control voltage. Because of its extreme linearity and accuracy, the phantastron output waveform is used as a delayed timing pulse, to produce timedelayed trigger pulses for synchronizing purposes, and movable marker signals for display.

Characteristics.

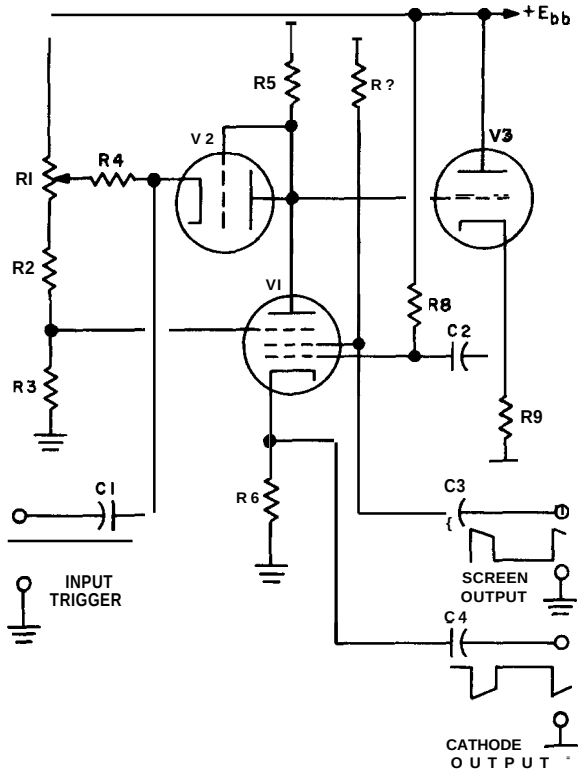
Same characteristics as basic Phantastron Circuit (previous discussion), except that it requires a negative trigger or gate to the plate, or a positive trigger or gate to the suppressor grid to be turned on; turn-off is automatic.

Circuit Analysis.

General. The fast-recovery phantastron circuit is considered to be a relaxation oscillator similar to the multivibrator in operation. Whereas the multivibrator derives its timing from an exponential waveform developed by an R-C network, the phantastron uses a basic Miller-type sweep generator to produce a linear timing waveform. (The operation of the basic Miller linear sweep generator is described in the discussion of Basic Phantastron Circuits presented earlier in this Section of this Handbook.) The phantastron is usually turned on by the application of a gating or trigger pulse, and is turned off automatically by an internally generated waveform.

The rapid return to the stable operating condition at turn-off is the basic property of the fast-recovery phantastron circuit. The rapid recovery is accomplished by charging the feedback capacitor through the low cathode-to-plate conduction resistance of a cathode follower, rather than through the high-resistance plate-load resistor of the phantastron. The effect of the rapid charge path is to return the plate voltage of the phantastron circuit to its stable-condition level immediately in order to prepare the circuit, in as short a time as possible, for the next input trigger pulse. Although the cathode follower decreases the usable range of the control voltage and the linearity, it is necessary in order to reduce the recovery time when long-duration delays are desired. Whether the slow-recovery or fast-recovery phantastron circuit is used in a given application is determined by the recovery time requirements; otherwise, the circuit function in the same manner and serve the same purpose. Both a positive and a negative rectangular-wave output with well-defined leading edges may be obtained from the phantastron, depending on whether the output connection is made to the screen or cathode, respectively.

Circuit Operation. The following schematic illustrates atypical pentode cathode-coupled fast-recovery phantastron circuit. The circuit is turned on by application of a negative trigger pulse to the plate; turn-off is automatic by an internally generated gate. Pentode tube VI is the phantastron proper. This tube must have the capability of providing two control elements; that is, the suppressor grid must be capable of performing the function of another control grid. A suitable tube for use as a phantastron is the miniature-type 5725 pentode because of the sharp cutoff characteristic of its suppressor grid. Another suitable tube is the pentode type 6AS6. A pentagrid tube such as the 6SA7 can also be used in the phantastron circuit if certain modifications are incorporated in the circuit design. (A basic pentagrid tube phantastron multivibrator circuit is discussed in Section 7 of this Handbook.)



Fast-Recovery Cathode-Coupled Phantastron

The diode-comected triode, V2, functions as a trigger injector as well as a clamping diode for controlling the plate-voltage level and determining the duration of the output gate. The maximum value of operating plate voltage is clamped to a level determined by the setting of potentiometer R1 in the cathode of V2, and, since the turn-off level is fixed, the setting of this potentiometer effectively controls the time during which the circuit produces the linear gate or sweep. Triode V3 is the cathode follower circuit through which feedback capacitor C2 is rapidly charged in order to permit the phantastron plate voltage to rapidly return to the maximum operating level determined by trigger injector and clamping diode V2. Although the illustration shows two separate triodes for V2 and V3, in practical circuit applications a single twin-triode is frequently used for economy of tubes.

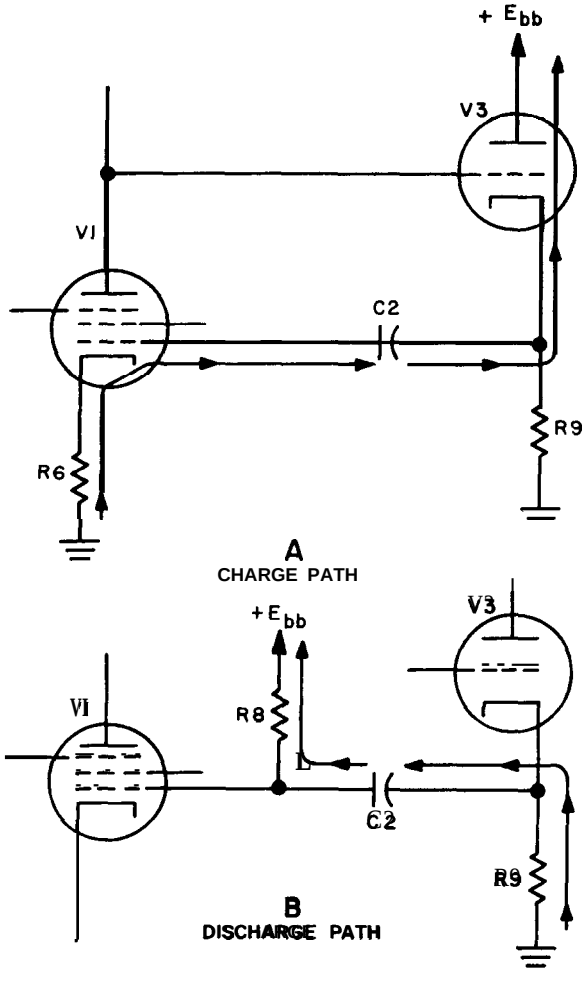
Potentiometer R1 and resistors R2 and R3 form a voltage divider from the positive voltage supply (tEbb) to ground. The resistance values are such that the positive voltage developed across resistor R3 is less than the positive voltage developed across cathode-bias and load resistor R6; thus, the suppressor grid is effectively biased negative with respect to the cathode, and plate current is cut off. As mentioned previously, the setting of the wiper arm of potentiometer RI establishes the voltage level at the phantastron plate, thereby determining the gate length. Resistor R4 is a decoupling resistor in the cathode of the trigger injector and clamping diode, V2. Resistor R5 is the phantastron plate-load resistor; R7 is the screen grid load resistor, and R9 is the cathode-load and coupling resistor for the cathode follower circuit.

Resistor R8 returns the phantastron control grid to the positive voltage supply, setting the bias level that initially permits the screen grid to conduct heavily. Operation of the circuit occurs at the rate determined by the discharge of feedback capacitor C2 through resistor R8; in some circuits this grid-return resistor, which usually has a value exceeding 1 megohm, is made variable to set the maximum delay or pulse width of the output gate. The action of cathode follower V3 and capacitor C2 provides feedback from the phantastron plate to its grid, to allow rapid response to any change in the plate voltage. Capacitor Cl couples the input trigger to the cathode of trigger injector and clamping diode V2; this trigger initiates (or turns on) the phantastron action. Capacitors C3 and C4 are the output coupling capacitors for the screen grid and cathode, respectively; a positive gate is obtained from the screen grid, and a negative gate from the cathode. If desired, a linear sawtooth waveform can be obtained from the plate of the phantastron circuit.

The following simplified schematic diagram shows the charge and discharge paths for capacitor C2. The charge path (part A of the illustration) is from ground through the phantastron cathode resistor, R6, and the low cathode-to-grid conduction resistance of V1 to the left side of the capacitor, and then from the right side of the capacitor through the low cathode-to-plate conduction resistance of the cathode follower and the positive voltage supply back to ground. This is the fast-recovery charge path for capacitor C2. That is, when the plate voltage of the phantastron rises, as it

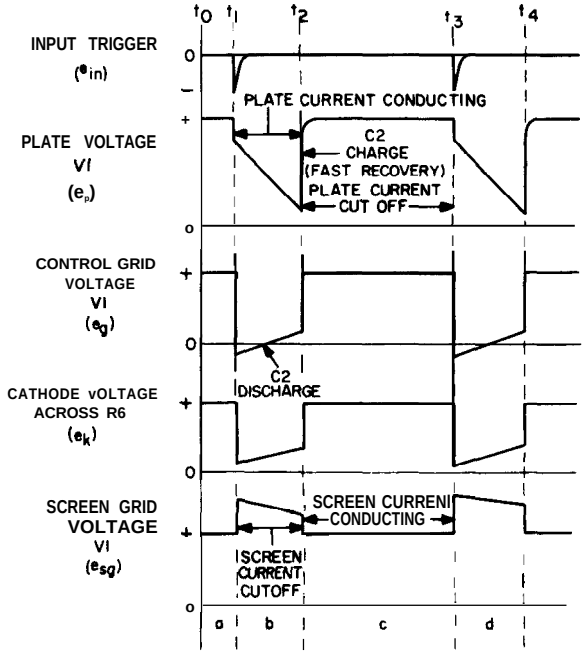
491-044 O 7379

does at the end of the gate, it is free to do so without the interference of any lumped capacitance; tube interelectrode capacitance and stray wire capacitance are the only hindrances. The resistance in the charging path is also low at this time, since it consists mainly of the low conduction resistance of the cathode follower. The discharge path (part B of the illustration) for capacitor C2 is from its left side through grid-bias resistor R8 and the positive voltage supply to ground, and then from ground through the cathode40ad resistor, R9, of the cathode follower to the right side of the capacitor. The long R-C time constant of this path causes capacitor C2 to discharge at a linear rate during the time that screen current is low (near cutoff) and the phantastron tube is drawing heavy plate current.



Charge and discharge Paths for Capacitor C2

The operation of the fast-recovery phantastron circuit can best be understood by referring to the preceding circuit illustrations and the following waveform illustration during the following discussion. When voltage is first applied, the plate section is in cutoff end there is heavy screen grid current. The conduction of screen current is a result of the fact that the operating voltage on this electrode is sufficiently positive to attract electrons emitted by the cathode as a result of the positive bias on the control grid (positive voltage return to B+ through resistor R8); this permits the flow of cathode current at this time. The current through cathode-bias resistor R6 produces a voltage drop across this resistor. The positive potential at the top of resistor R6 is now greater than the positive potential at the suppressor grid, which is obtained across voltage divider resistor R3. A bias voltage is therefore established between the suppressor grid and the cathode; this bias is sufficient to cut off the plate current while having no effect on the screen current.



Theoretical Waveforms for Fast-Recovery Cethode-Coupled Phantastron

Because there is no plate current, the plate voltage rises to the level determined by the setting of potentiometer R1 in the cathode of the trigger injector and clamping diode, V2. This same positive plate voltage is also impressed on the cathode follower control grid, since this grid and the phantastron plate are electrically identical. The cathode follower now conducts, and the flow of current through its cathode-load resistor, R9, develops a positive potential at the top of this resistor. This positive potential is coupled through capacitor C2 to the control grid of the phantastron, where it further increases phantastron conduction. The positive potential on the phantastron control grid also causes this grid to draw current and charge capacitor C2 through the path described previously. The foregoing action is instantaneous and causes the phantastron to assume its stable state, as depicted during time interval a on the waveform illustration. The circuit remains in this condition (heavy screen current and plate current cut off) until a negative trigger is applied to the phantastron plate through trigger injector and clamping diode V2 at instant t_1.

When the negative trigger (e_{in}) is applied through capacitor Cl to the cathode of V2, it forward-biases the diode and permits plate current to flow. This current, in turn, causes an immediate drop in the plate voltage developed across plate-load resistor R5. The negative-going signal is also on the grid of the cathode follower, V3, where it acts as a bias to reduce the conduction through V3, thereby reducing the voltage drop across its cathode-load resistor, R9. The negative-going signal at the top of resistor R9 is coupled through capacitor C2 to the control grid of the phantastron tube, V1, where it drives this grid sufficiently negative to reduce the conduction of the phantastron. Since the phantastron cathode current is reduced, the screen current is also reduced; thus a positive-going voltage is produced at the screen grid. Through cathode-follower action of the phantastron circuit, the negative-going signal on its control grid is coupled to the cathode, where it now reduces the bias between the cathode and suppressor grid. With a decrease in this bias voltage there is an increase in plate current, resulting in a further drop in plate voltage. The action just described is cumulative and instantaneous. Thus, when the negative trigger is applied to the cathode of V2 at t_1, there is an immediate fall in phantastron plate voltage and a sharp rise in plate current (the fall in plate voltage is fed to the grid through cathode follower V3 and capacitor C2 driving the control grid negative), there is a sharp rise in screen voltage and a decrease in screen current, and there is a decrease in total cathode current and a sharp decrease in cathode voltage. AU of the voltage relationships are depicted at t_1 on the waveform illustration.

The fact that the phantastron plate current increases while the cathode current decreases is possible because the screen current is now decreasing. Therefore, the rise in plate current results from the fact that the plate draws current which had previously gone to the screen grid. That is, the bias between the cathode and the suppressor grid is decreasing, which is a regenerative action, causing the plate current to increase. Simultaneously, the bias between the cathode and the control grid is increasing, which is a degenerative action, causing the total tube current (and screen grid current) to decrease. The screen grid current is only reduced – not cut off completely; if it were cut off completely, plate current would also be cut off and the circuit would not function. Hence, there must be a point where the regenerative and degenerative effects are equal and the current stabilizes for an instant. This is the instant (at t_1 when the sharp drop in plate voltage ceases) at which capacitor C2 begins its discharge action.

As capacitor C2 discharges during the interval b, it loses electrons from its left side, in effect making this side of the capacitor (and the control grid of the phantastron) more positive to reduce the bias between the control grid and the cathode. The reduction in control grid bias permits a heavier flow of plate current through the phantastron, which gradually raises the voltage drop across cathode-bias resistor R6 (e_k waveform), as illustrated during time interval b. The rate of change of tube current is governed by the discharge rate of capacitor C2 through resistor R8. Thus, in discharging, the control grid side of capacitor C2 gradually becomes more positive, causing an increase in plate current; this produces a constant decrease in plate voltage, which is fed back to the grid through cathode follower V3 and capacitor C2. The positive voltage increment on the control grid is always slightly greater than the negative-going plate signal it produces; therefore, the grid potential gradually rises and the plate potential gradually drops, as depicted by the respective control grid (e_g) and plate (e_p) waveforms during time interval b.

The action described during time interval b continues until the plate voltage becomes so low (only a few volts) that phantastron tube V1 can no longer amplify the changes in plate voltage. At this instant, t_2, capacitor C2 stops discharging and the control grid is rapidly driven positive, causing the tube current to increase at a very fast rate. The rapid rise of current through cathode-bias resistor R6 produces a high positive potential on the cathode, which, in relation to the positive potential on the suppressor grid, is a bias sufficient to cut off plate current. Since the total tube current is increasing at this instant, the additional current must flow in the screen grid circuit. The action now occurring is regenerative. As the plate voltage, whose swing is limited by trigger injector and clamping diode V2, goes positive because of plate current cutoff, the positive-going signal is coupled through cathode follower V3 and capacitor C2 to the phantastron control grid; this signal causes a further increase in tube current, thereby producing a higher voltage drop across cathode resistor R6 to increase the bias on the suppressor grid and further cut off plate current. The positive-going grid of the phantastron draws current and now rapidly charges capacitor C2 through the low cathode-to plate conduction resistance of the cathode follower. Thus, at instant t_2, the phantastron is rapidly returned to its original state of plate current cutoff and maximum screen grid current, as illustrated during time interval C_1 until the next trigger pulse at t_3 again causes a cycle of phantastron action.

As mentioned previously, when the phantastron is triggered (turned on) there is a sudden drop in screen current. This produces a positive-going voltage on the screen with a steep leading edge (e_{sg} waveform). As the tube current gradually increases, producing the linear drop in plate voltage, the screen current increases in the same manner, but by a much smaller amount. The screen waveform will thus decrease linearly by a small amount until the point of plate-current (described previously) is reached. At the instant of plate-current cutoff, screen current increases sharply, causing a sharp drop in screen voltage, as depicted by the trailing edge of the e_{sg} voltage waveform; this is the positive-gate output waveform coupled through capacitor C3 to the screen output terminals. The resultant negative-gate output, e_k, taken across phantastron cathode-load resistor R6, is coupled through capacitor C4 to the cathode output terminals. This negative-gate waveform also has steep leading are trailing edges, with the flat portion falling off in amplitude at a linear rate.

From the circuit action just described, it is evident that changing the value of the voltage applied to the plate will determine the point, and the time, at which the plate voltage "bottoms", with respect to the time of application of the input trigger. Potentiometer R1 is comected to the phantastron plate through diode V2, thereby setting the level of plate voltage at which the phantastron begins its action when triggered. Changing the value of either feedback capacitor C2 or grid resistor R8 will also affect the pulse width by controlling the rate of discharge of capacitor C2. For example, increasing the value of capacitor C2 or resistor R8 will increase their R-C time constant, thereby causing capacitor C2 to discharge more slowly and increase the width of the delay gate. A decrease in the value of either capacitor C2 or resistor R8 will have the opposite effect on the width of the delay gate. In some phantastron circuits the grid resistor, R8 in this case, is made variable so as to control the maximum width of the delay gate. When made variable the grid resistor is usually an internal adjustment, whereas potentiometer R1 is usually an external control.

If it is desired to obtain several ranges of delay with the phantastron, the most satisfactory method is to leave the value of the grid return resistor (R8) fixed and switch in different values of capacitance for the feedback capacitor (C2). A cathode follower will provide a low-impedance point for the switching and minimize the effects of stray wire capacitance, in addition to providing a fast-recovery path. A disadvantage of using the cathode follower in the phantastron is that it increases the maximum error of the circuit. Ordinarily, the phantastron linearity is obtained by the feedback between plate and control grid, which tends to maintain a constant discharge of the feedback capacitor (C2). Since the gain of the cathode follower is less than unity, the compensation is not as linear as when the feedback occurs through the capacitor alone. However, a slight error (approximately 0.4 percent at a control voltage of 150 volts, for example) can be tolerated when it is necessary to reduce the recovery time of the circuit for long-duration output gate signals.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being

applied to the circuit and whether it is of the proper polarity and amplitude. Lack of an input trigger at the cathode of trigger injector and clamping diode V2 can be due to an open input coupling capacitor, Cl, or to failure of the external input-trigger source. It is also possible for a defective trigger injector and clamping diode tube, V2, as well as excessive bias, to make the circuit inoperative; the excessive bias will prevent the fixed-amplitude input trigger from overcoming this level and initiating the phantastron action. The foregoing conditions are indicated when an input trigger can be seen with an oscilloscope on the cathode of V2 and voltage appears on all tube elements, but either the phantastron control grid or cathode voltage is higher than normal. This is most likely to occur when a negative voltage source is used with a common bleeder network to obtain the bias (as in a screen-coupled circuit). Since this cathode-coupled pentode circuit develops its own bias, an excessive current drain or short-circuit condition would be needed to increase the bias to the non-operating point.

Failure of the positive voltage supply, $+E_{bb}$, will disrupt the operation of the circuit, as will an open cathode circuit of either the phantastron or the cathode follower. With tubes installed in the circuit, the filament, plate, screen, and suppressor grid voltages should be measured, as well as the bias voltage developed across phantastron cathode resistor R6, to determine whether the applied voltages are within tolerance or whether an associated electrode resistor is open. If feedback capacitor C2 is open or cathode follower V3 is inoperative, there will be no feedback signal to promote the phantastron action. An open output coupling capacitor, C3 or C4, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective phantastron tube; however, a low screen gate output can also be caused by a decrease in applied voltage or a change in resistance value in the screen circuit. Low cathode gate output indicates low cathode current, which is the sum of all tube element currents, and thus may be caused by any one of numerous conditions (decreased tube conductance, reduced plate or screen voltage, etc). Usually, a voltage check will locate the defective circuit and component. A leaky or shorted output coupling capacitor, C3 or C4, will form a voltage divider with the input resistor of the following state. If the input resistor of this next stage is returned to ground or to a negative supply, the voltage at the screen grid or cathode will be reduced, and the operation of the state will be upset by the change in voltage applied to its grid,

Distorted **or Unstable Output.** Distortion is indicated by a nonlinear waveform or an inaccurate time delay. Linearity and accuracy of the output gate waveform development is the basic property of this circuit, with the controlling elements being the applied d-c control voltage and the R-C time constant in the feedback circuit. Control voltage trouble may occur when the circuit uses a separate external control from a separate power supply, since power supply fluctuations can easily change the operating level and, therefore, the gate duration. A change in time constant due to circuit values or to feedback capacitor failure or leakage will change the rate of operation and, hence, the gate length; this should be most noticeable for the longer gate lengths. False triggering due to pickup of noise or stray pulses in the control cabling (on remote units) may affect both the turn-on and turn-off of the gate. This instability, or jitter, can also be caused by power supply fluctuations. An oscilloscope waveform check at each electrode is usually the best method to checking for the cause of jitter, which can then be traced to its source.

Incorrect Frequency. The fast-recovery phantastron circuit has no components governing the frequency of its output gate signal; this frequency is governed by the input trigger applied to the circuit. Therefore, any change in the output gate frequency is a result of improper operation of the trigger generating circuits.

ELECTROMECHANICAL (ACOUSTIC) DELAY LINES

Application.

An electromechanical or sonic delay line provides a means of retarding the passage of a signal or wave for a predetermined length of time without distorting the original composition of the signal or wave. This type of delay line is used in computers and in radar equipments such as moving target indicators (MTI).

Characteristics.

Delay line acts as a medium between electrical and sound impulses.

Delay line is composed of quartz crystal slabs and a mercury column.

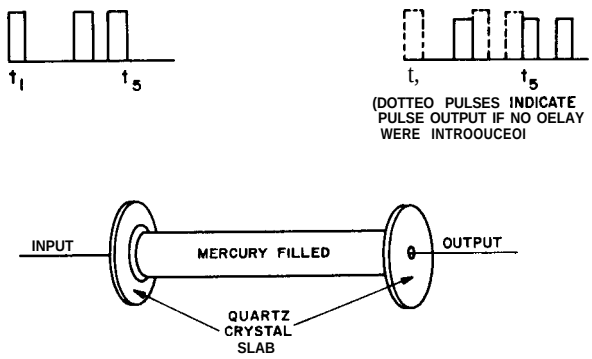
Amount of time delay depends on length of mercury column.

Time delay affected by temperature variations.

Circuit Analysis.

General. The electromechanical (acoustic) delay line utilizes the piezoelectric effect of a quartz crystrd slab to convert any electrical impulses within a circuit to sonic impulses. These sonic impulses traverse a column of mercury of specific length and are reconverted to electrical impulses by another quartz crystal slab at the opposite end of the mercury column. The overall effect is a resultant decrease in velocity relative to the velocity of electrical impulses traveling an equivalent distance. Therefore, by increasing the length of the mercury column, the longer the impulses will remain in the sonic state, and the greater will be the delay of the impulses.

Circuit Operation. A pictorial representation of an acoustic delay line is shown in the following illustration. The delay line consists of two quartz crystal slabs and a column of mercury in a cylindrical container between the two crystal slabs. As electrical impulses are applied to the first crystal slab of the delay line, the piezoelectric effect associated with crystalline substances causes these impulses to be converted into corresponding mechanical expansions and contractions. One of the expanding and contracting surfaces of the crystal contacts the mercury column in such a way that these mechanical or sonic vibrations are conducted through the column in the same way that electrons are conducted through a wire. Sonic impulses travel at a considerably lower speed than electrical impulses and by increasing the length of the mercury column the time is required for the impulses to travel from one end of the mercury column to the other becomes greater. The amount of time delay is proportional to the ratio of the velocity of sound in mercury to the velocity of electrical impulses through the conducting material used in the circuit, multiplied times the length of the mercury column.



Electromechanical (Amustic) Delay Line

Upon reaching the end of the mercury column, the sonic vibrations are converted to electrical vibrations by again applying the sonic vibrations to a crystal slab. This crystal, as the first crystal, contacts the mercury column along a plane of the crystal in which sonic or mechanical impulses can be applied or obtained (which happens to be perpendicular to the plane along which sonic impulses are applied or obtained. (See the following illustration.)

X ELECTRICAL AXIS

Y MECHANICAL STRESS AXIS

Crystal Axis

Failure Analysis.

Since the sonic delay line is a single component the failure analysis can be simplified. If no signal is obtained at the output of the delay line and the proper signal is applied at the input, the mercury might have leaked from the cylinder which is supposed to contain it. Another cause of a no-output condition may be an open crystal or a crystal shorted to the metallic case containing it. It will not be necessary to determine which part of the delay line is at fault, since any defect will make it necessary for the entire delay line to be replaced.

A distorted output may be due to the effect of temperature changes within the area where the delay line is used. If extreme temperatures occur, there is a possibility that the crystals may be damaged. In order to prevent or correct this condition constant temperature monitoring should be provided.

ELECTROMAGNETIC DELAY LINES

Application.

Artificial delay lines of the electromagnetic type are used to generate rectangular pulses of fixed duration (in radar receiver and transmitter applications); to produce a rectangular waveform from a step function of voltage (as used in starting and delay triggers for test equipment and video display units); to terminate a pulse produced by a regenerative device such as a blocking oscillator or multivibrator (as used in radar, timing circuits, and computers); and to duplicate on existing pulse at a later time (a simple case of time delay). These lines are commonly used for many types of waveshaping and pulse-forming applications.

Characteristics.

Provides a constant attenuation of signal, depending upon material and construction.

Consists of a number of equal sections (or half-sections) of lumped capacitance and inductance, providing a definite delay interval.

Provides a definite phase shift which can be repeated at specific intervals.

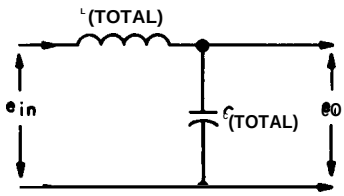
Possesses an inherent characteristic (surge) impedance which must be matched to input and output circuits for proper operation.

Similar in operation to a real transmission line, but greatly reduced in physical size.

Circuit Analysis.

General. Delay lines are simple to construct, reliable, permanent in their characteristics, and accurately reproducible in manufacture. The delay line operates by virtue of the finite velocity with which the signal travels along the delay line. For open-wire lines there is practically no difference in the velocity of propagation of the signal as compared with the velocity of propagation in free space, so that multiples of a physical quarter-wavelength of line must be used to produce the delay. This results in long and bulky lines. Even with the standard type of line, the delay is on the order of 0.003 microsecond per foot. A special coaxial delay line is produced with a spiral-wound center conductor (distributed-constant line)

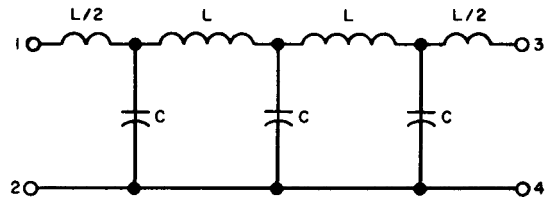
to provide better results; however, measured results at 5 MHz are only on the order of 0.042 microsecond per foot. Therefore, artificial lines consisting of lumped values of inductance and capacitance (which occupy a small space) are connected together in low-pass falter arrangements to provide the desired characteristics. Since a real transmission line has uniformly distributed inductance and capacitance, artificial lines can, in a small space, provide the electrical equivalent of a long line. The basic equivalent circuit of the distributed-constant artificial delay line is shown in the following illustration.



Distributed-constant Delay Line Equivalent

The functioning of this type of line is similar to that of the lumped-constant artificial delay line in all respects. It is used mainly for small delays of 1 microsecond or less where the total length of the line is conveniently held to a range of from 6 to 30 inches, depending upon the construction. Units have been manufactured with characteristic impedances of from 200 to 4000 ohms. The characteristic impedance (Z) is determined by the total distributed constants per inch, centimeter, or foot, by means of the standard formula $Z = \sqrt{L/C}$; the values are in ohms, henries, and microfarads. Time delay is given by the formula $T = \sqrt{LC}$; the values are in seconds, henries, and microfarads. For a given impedance and time delay, the inductance is determined by L = TZ, and the capacitance by C = T/Z. In actual practice, the manufacturer lists these values and the microseconds per unit length. Thus for a given delay only a specified length is required, avoiding any complicated calculations. Since the distributed+ onstant type of line is not as commonly used as the lumped+ onstant type of line, but functions similarly, for practical purposes the discussion of the lumped+ onstant type of line which follows applies to both types (neglecting end effects, temperature, and frequency response).

The schematic equivalent of a simple lumped-constant tvpe of artificial transmission line is shown in the following illustration. Basically, this circuit is that of a constant k low-pass falter with half T section terminations, utilizing one full T section of delay (plus the hrdves for a total delay of two sections). Actually, the number of sections varies with the design (usually from five to eight sections are sufficient).

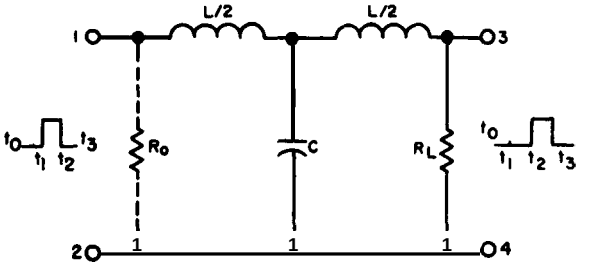


Lumped-Constant Equivalent Circuit

The manner in which the artificial delay line is employed in a circuit determines how it functions. Generally speaking, there are three forms of operation to be considered. One form is that of a simple delay line which delays the input pulse or signal by a period of time equal to the time it takes to traverse the line; in this case the termination of the signal initiates circuit action after a predetermined delay time. In the second form, the reflected input pulse or signal is permitted to traverse the line, be reflected, and return to the origin; circuit action is initiated after 2n delay periods. In the third form, the line is charged to a specific storage level and is then discharged to form a precise pulse with a duration equal - to the discharge-delay period. In each of these forms of operation, performance is generally based upon the theory of charge and discharge of an ideal lossless transmission line.

Circuit Operation. Consider now the case of the simple delay line. In this instance, the line is terminated in its characteristic impedance (the input need not be terminated unless power transfer is required, since there is no reflection). Assume the simple balanced T section equivalent circuit in the following figure. As far as the input circuit is concerned, the artificial transmission line appears as though it were a resistor equivalent to the characteristic (surge)

impedance of the line (R_0). Assume that a rectangular l-microsecond pulse is applied, and that a delay of 2 microseconds is desired. (The delay line is usually placed in series with the grid of a trigger circuit. Let us also assume that a negative trigger is required to initiate action.)



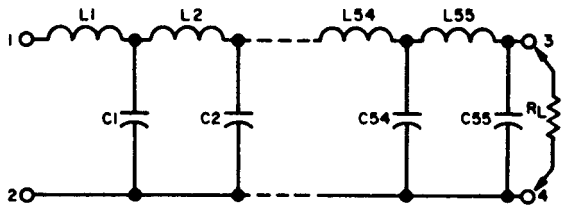
Properly Terminated Line Action

At the beginning of the cycle (time T_1), the positive pulse is applied to the line input at terminals 1-2). Immediately, the voltage across the line input rises to the pulse value (input is unterminated). At the load end of the line, however, no voltage as yet appears. Since the line constants are chosen for a l-microsecond delay, it takes this length of time for the initird pulse to travel to the end of the line (because of the low propagation of the line). During this interval, capacitor C is being charged through left-hand inductor L/2. At time T_2 (1 microsecond later), capacitor C is charged and pulse voltage now appears at output terminals 34, across R_L. Note that this is still the leading edge of the initial pulse. At time T_2 the initial pulse terminates and the input voltage across terminals 1-2 drops to zero. Capacitor C now discharges through right-hand inductor L/2 until time T_3. When time T_3 is reached, the capacitor is completely discharged and the voltage across R_L drops to zero. Thus, 2 microseconds after the start of the initial pulse, the negative trailing edge of the pulse appears at the grid of the trigger tube, and the trigger is initiated (by the trailing edge of the pulse) with a 2-microsecond delay. During the delay period, simple R-L-C charge and discharge action was postulated, as supported by simple transient theory.

In practice, a number of sections of L and C are required to provide pulse transfer and delay without distortion. All delay lines have resistance which distorts the pulse by causing a reduction of current as the line is charged, with a consequent slope in the top of the pulse. The inductance opposes the change in current and affects the circuit at the very beginning when the charging current quickly assumes a high value, and then acts to maintain the current flow after the maximum current value is reached and tends to decrease, With a large inductance the rise and fall of current is more gradual; with a smaller inductance the current rises and falls more rapidly. The addition of the capacitance to the circuit causes the current to reach a definite maximum value. The smaller the capacitance, the smaller the maximum value of current and the shorter the period of time required to reach maximum current. When both inductance and capacitance are combined, and the inductance is very small and the capacitance very large, the circuit action is controlled mainly by the resistance in the circuit. Under these conditions the charging current rises very quickly and remains constant for a relatively long period of time (because a relatively long time is necessary to charge the capacitor). Thus the response curve closely resembles the input step voltage. Ideally, as L approaches zero and C approaches infinity, so that only resistance is left in the circuit, the output waveform approaches the input waveform. This is theoretically true because a purely resistive circuit has no transient response and, therefore, does not change the shape of the input voltage waveform. With only resistance in the circuit, however, there would be no delay. Consequently, a practical compromise is reached by employing a number of L-C sections having a small inductance and a relatively large capacitance.

A detailed analysis of the operation of a typical distributed+ onstant type of delay line (chosen for ease of explanation) using actual values follows. As constructed, the line consists of very fine wire (No. 40 AWG, 0.0031 inch in diameter), wound on a plastic core. This continuously wound coil has a diameter of approximately 3/16 inch, and contains 109 turns per centimeter of length to provide a rated inductance of 20 microhenries per centimeter. An insulating sleeve is placed over the coil, and an external copper braid is used to provide a shielded outer conductor, which forms a capacitance of 16.5 picofarads per centimeter with the coil. The measured time delay is 0.018 microsecond per centimeter. To produce the l-microsecond time delay mentioned in the previous discussion, a 55-centimeter length of this

line is required. Therefore, we can consider the line to be made up of 55 sections (1 cm long), forming an equivalent ladder-type line as illustrated in the accompanying figure.



Ladder-type Delay Line Equivalent

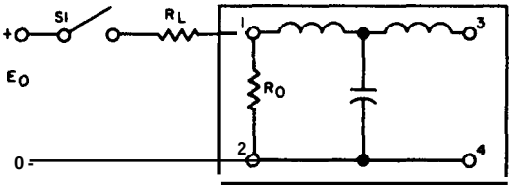
Although in the previous discussion on ideal pulse was assumed, with zero rise time, a practical square input pulse has a finite rise time. A value of 0.03 microsecond for a 1-microsecond pulse is representative of actual rise and fall time tolerances encountered in practice. When this pulse is applied to the input of the line at time T_1, terminals 1 and 2, coil L1 provides a counter emf which slows down or opposes the passage of current flow through it. The current through L1 is the charging current for capacitor Cl and the remainder of the line sections. Capacitor Cl charges in accordance with the time constant LIC1 (0.018 microsecond). Since the rise time of the pulse is 0.03 microsecond, capacitor Cl charges quickly. During this period the voltage across L1 decreases while the voltage across Cl increases. In effect, the input voltage is applied to L2 after being delayed 0.018 microsecond. Since it takes 10 time constants to reach approximately full charge, the amplitude is less than that of the original pulse, and approximates a final value of about 0.6 that of the original value (at the end of the line). These line sections are effectively comected in series with the line, and the pulse travels progressively down the line from L1 through L55. Capacitor C55 is charged to the same value as Ll was after one time constant, and at a time (T_2) exactly 1 microsecond later, In other words, the leading edge of the pulse reaches the end of the line at that instant.

Since the duration of the pulse is 1 microsecond, the entire line is still charging. In the next instant, however, the input pulse terminates, and the negative-going trailing edge is applied to L1. At this time, Cl is fully charged and begins to discharge. The discharge path is the reverse of the charge path. The discharge action is similar to the charge action; that is, at the end of one time constant Cl is discharged substantially, and the effect is as if a negative voltage were applied between L2 and ground. The discharge pulse travels progressively down the line. During this time (T_2 to T_3) the amplitude of the output pulse remains constant, since the flat top of the input pulse is being reproduced by the constant charge voltage to which C55 is held. This action is the result of the small (fast) time constant per section (full charge is reached in approximately 0.09 microsecond). A slight rounding off of the leading edge is produced in practice (by exponential charging action); however, in the ideal case discussed previously, no such action was assumed. Practically, this rounding off effect is negligible, and the shape of the input pulse is retained as long as the pulse rise time is longer than the time constant per section. (When the rise time is less than the time constant per section, a noticeable rounding off or distortion of the pulse shape occurs.)

• Once the discharge action is started by the trailing edge of the input waveform (time T_2), it continues until C55 is reached. The discharge of C55 through terminating resistor R_L (at time T_3), comected across terminals 3 and 4, represents the trailing edge delayed 1 microsecond. Since the leading edge was also delayed 1 microsecond, the total delay from the leading edge to the trailing edge (or trigger) for the time period T_1 to T_3 is exactly 2 microseconds (within practical limits). A fewer number of sections or a change in the values of the inductance and capacitance used will change the delay time. In the case of the **lumped-constant** delay line, the action is identical. Instead of special construction, however, the delay line merely consists of a number of small inductors and capacitors connected in the ladder-type arrangement illustrated previously.

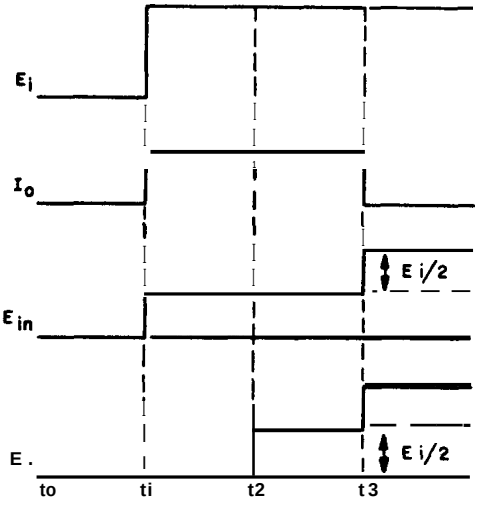
Open-Circuited Line. Consider now the case of the artificial delay line which is ***not*** terminated in its characteristic impedance. Let us assume that the line is open-circuited and is represented by the simple circuit shown in the following figure. The delay line is connected in series with load resistor R_L and switch S1 to ad+ source of voltage E_o. Assume that the line at time T. is completely discharged, with S1 open. At time T_1, switch S1 is closed, and voltage E_o is applied across load resistor R_L and R. in series (R. is the surge or characteristic impedance of the delay line).

Assuming that R_L and R. are equal, the applied voltage divides equally, and half the applied voltage appears at terminals 1-2 (line input). The line is designed to have a velocity of propagation much less that of an open-wire line; thus, at time T_2 the voltage has just reached terminals 3-4. Since the line is open-circuited, the applied voltage is reflected back in phase (with the same polarity) toward the line input. Since current will not flow through the open circuit, the current polarity is reversed, and the reflected wave cancels the current of the incident wave to give a total zero current. Thus, the voltage at terminals 34 is effectively doubled, and a reflected voltage equal to E. travels back to the source. When the source is reached at time T_3, the input voltage and reflected voltage are equal, current flow ceases, and the pulse is terminated. At this time the line is charged to the applied voltage. While the output end of the line is not terminated, the input is usually matched with a resistor (R_L) equal to R. so that the reflected pulse is absorbed on its return. During the interval between pulses or signals (when S1 is open), the line discharges; thus it is ready to start another cycle of operation when S1 is again closed.



Open Circuited Delay Line Equivalent

The current and voltage relationships for the openunded line are shown in the following figure.

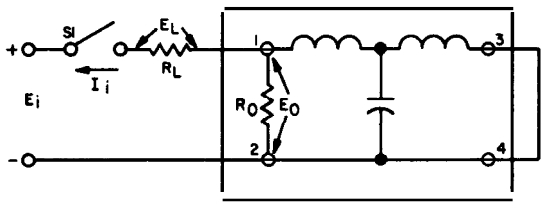


Current and Voltage Relationships of Open-Circuited Line

It can be seen that E_1 is the applied voltage or step function, which at the closing of S1 jumps to its maximum value. Simultaneously, charging current 1_0 does likewise. Since the flow of 1_0 through R. produces the voltage E_{in} applied to the line, and since equal resistors R_L and R. form a voltage divider across the input, the voltage E_{in} is reduced to half of E_i, remains at this value during the time of two delay periods, and then returns to the source value when the line is fully charged and no further charging current flows. At the output of the line the step function E. rises to one-half maximum value after one delay period, and then to full value at the end of the remaining delay period. With the line fully charged at the end of two delay periods, it remains at the original applied value of E_i until S1 is opened; the line

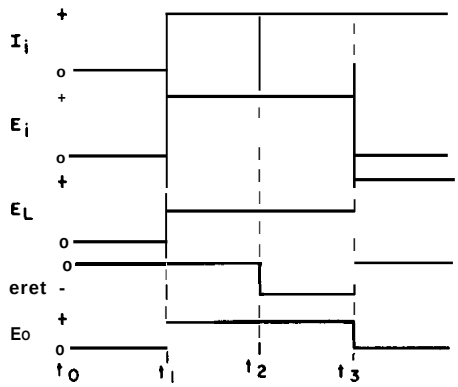
then discharges. In practice, this is usually accomplished through the grid resistor of the stage which it triggers (the delay line is connected in parallel across the grid resistor in place of the conventional grid capacitor). Thus we can say that an open-ended delay line operates on a step function of voltage to produce a pulse of current equal in duration to twice the length of the line. The pulse across the characteristic impedance in series with the line has one-half the amplitude of the step function.

Short-Circuited Line. Consider now the case of an artificial delay line which is terminated bv a short circuit at terminals 3-4, as shown in the following figure. The illustration is identical to the illustration of the open-circuited line shown previously, except that the output is short-circuited. At time T_1 when S1 is closed, the applied voltage divides equally between R_L and R_o. At time T_2 the voltage reaches terminals 3-4 and is inverted in polarity by the short circuit and sent back toward the source. Simultaneously, the current is reflected back in phase with the source wave. Therefore, the current doubles while the voltages of the reflected and incident wave cancel to produce zero voltage. The current wave then travels back to the source in coincidence with the oppositely polarized reflected voltage. When the source is reached at time T_3, the input voltage across R. is completely canceled and is therefore zero, while the current is double the starting value. In effect, the input to the line at this time is short-circuited also, and the line is completely discharged, ready for another cycle of operation.



Short-Circuited Delay Line Equivalent

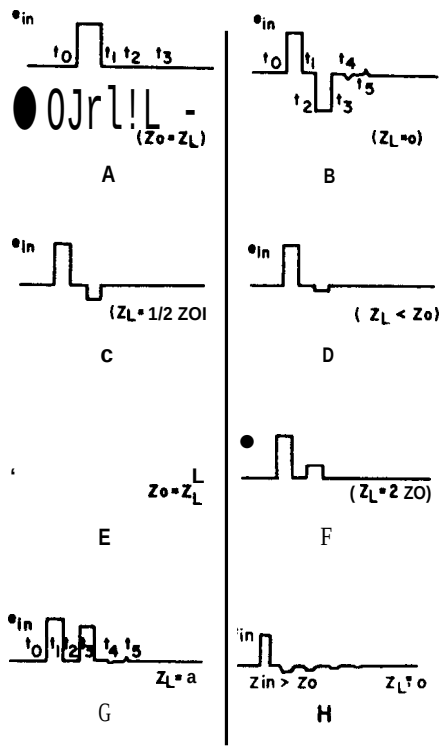
The current and voltage relationships for the short-circuited line are shown in the following figure. In this case, I_i is the step function, which at the closing of S1 jumps to its maximum value. Simultaneously, the applied voltage, E_i, does likewise. Because of voltage-divider action, E_o (the voltage across R_o) is half the source vrdue, or $E_i/2$. It remains at this value for the time of two delay periods, and returns to zero when the out-of-phase reflected pulse reaches the input and produces cancellation. Voltage E_L across R_L is produced at half amplitude since it is equal to the input voltage across R_O; it remains at this value for two delay periods and then rises to the source value at the termination of the pulse. The voltage e_{ref} is the reflected voltage, which does not exist until time T_2; it is negative and equal in amplitude to E_o. Once started by the reflection, it continues to flow back to the source until time T_3, when it reaches the start (T_1) and terminates output pulse E_o. Output pulse E_o originates at time T1 at half the amplitude of source voltage E_i continues for the time of two delay periods, and is then terminated,



Current and Voltage Relationships of Shorted Line

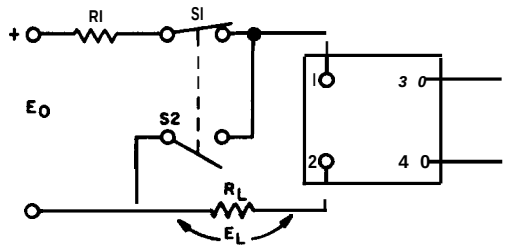
In the case of the shorted line, then, we can say - that it operates on a step function of current to produce a pulse of ***voltage*** equal in duration to twice the length of the line. The voltage produced has half the amplitude of the step of current multiplied by the characteristic impedance. Thus, there is complete duality between open lines charged from a constant-voltage source, and short-circuited lines charged from a constant-current source. The choice of the method depends upon the characteristics of the switch used to produce the step function. A thyratron switch has an impedance of less than 10 ohms and, therefore, effectively constitutes a constant voltage source. A pentode switch, on the other hand, may have an

impedance of a megohm when closed, and yet switch appreciable currents. While the discussion above has assumed ideal step function operation, in actual practice there is an effect produced by the steepness of the grid pulse and stray capacitance, which determine the slope of the leading edge of the pulse. Line attenuation also produces phase distortion; the characteristic impedance of the line and the line resistance produce a slope on the trailing edge of the pulse, and determine the total amplitude of the pulse. Accidentird resonances in the line can cause oscillation following both edges of the pulse. Unterminated open or shorted lines will tend to produce another reflection at the input end, and cause a following pulse of lower amplitude until attenuated by the losses in the line (this is effectively an oscillatory condition). The following figure shows some typical waveforms taken with different line terminations, and is indicative of typical responses of artificial delay lines. The pulse length is l-microsecond, and the delay time is also 1 microsecond. Part A of the figure shows both input (e_{in}) and output (e_o) waveforms with the delay line properly terminated both at the input and the output. Part B shows the input waveform with the input properly terminated and the output short-circuited. Note that between times T_1 and T_2 the output pulse is effectively cancelled by the negative inverted pulse, whose leading edge appears at T_2 and lasts until T_3. Since the amplitude of the inverted pulse is not exactly equal to that of the input pulse, slight pips appear at T_4 and T_5, even though the input is properly terminated. Part C shows a partially shorted line, that is, with the load only one-half the value of the line characteristic impedance, and with the input properly terminated. In this case, since the mismatch is approximately 50% there is a reflection of approximately l/4th the amplitude, with the remainder being absorbed. Note that because the resistance or impednace is lower than that of the line, the signal is inverted as with the short-circuited line. Part D shows a more nearly matched condition, at about 20% mismatch. While the reflection is still inverted, because the impedance of the load is lower than that of the line, its amplitude is very small. Part E shows the input waveform with the input and output both properly terminated. In this case the output is absorbed by the proper termination, and no reflection occurs; hence, the input pulse stands alone. Part F shows the condition for a 505% mismatch, with the load impedance twice the line impedance. In this case the reflected pulse is of the same polarity as the input, acting as an open line, since the load impedance is higher than the surge impedance of the line. The amplitude is not half of the input, but approximately one-quarter, exactly as in the opposite case of 50% mismatch shown in part C. Part G shows the waveform at the input with the output open-circuited and with the input properly terminated. In this case the open line creates a complete reflection, which is not quite equal in amplitude to the input signal because of line attentuation; therefore, there is a slight reflection, causing the minor pips at T_4 and T_5, even though the input is properly terminated. The final case is with the output short-circuited and the input terminated in a lower impedance than that of the line. Part H shows the input waveform for this case. Since the line is shorted, the reflected pulse is inverted, and since it is improperly terminated at the input, reflection occurs, with each succeeding waveform being further reduced in amplitude. This is equivalent t o an oscillatory condition or an undamped transient response.



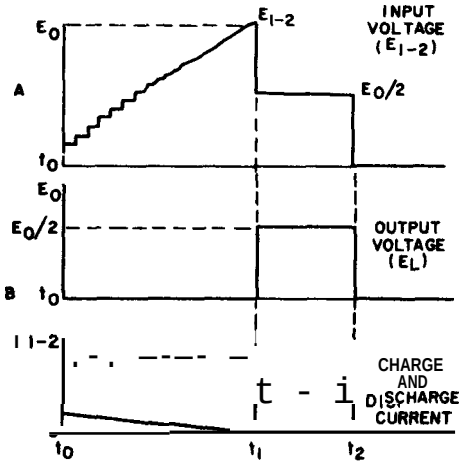
Typical Delay Waveforms for Various Terminations

Pulse-Forming Line. In the two preceding cases of open and shorted delay lines, the action was considered with the line discharged and a pulse applied. In the third and final case involving the use of a delay line, the line is first charged to a specific level, is then disconnected and discharged, and finally a pulse with steep leading and trailing edges and with a time duration equal to the delay time. The following figure shows a simple schematic equivalent of such a pulse-forming circuit. As shown, the line is connected through R1, S1, and R_L to the d-c source voltage, E.. Switch S2 is linked mechanically with S1 so that when S1 is closed S2 is open, and vice versa. The line is not terminated, but rather is open-circuited. At time T. switch S1 is closed and the line is permitted to charge until it reaches a steady-state condition with the line charged to voltage E_o. (This charge consists mostly of electrostatic energy stored in the capacitors.) At time T_1, switch S2 is closed, opening S1, and the line discharges through R_L. The discharge current through R_L produces voltage EL, which is the desired output voltage. The flow of current through R_L produces a voltage wave which travels from terminals 1-2 of the delay line toward open end 34. Since the load resistor is placed in series with the line and the line is now acting as the source of voltage, this voltage divides between the characteristic impedance of the line and R_L, which is of the same resistance. Therefore, the initial discharge voltage is half of the value to which the line is charged. Because the flow of current is now reversed, the polarity of the voltage wave is opposite that to which the line was initially charged. As this induced wave travels down the line, it cancels out the original charge by one-half the maximum charge voltage. Thus, the discharge current which flows through R_L is equal to $E_o/2R_o$. When the wave reaches terminals 3-4, reflection occurs. The reflected wave is now of the same polarity as the induced voltage wave and, since current cannot flow in an open circuit, the voltage doubles, becoming equal to E_o. The polarity of the *discharge (induced)* wave is opposite the original polarity of E.; thus both voltages are equal and cancel. Since the current cannot flow further, it is inverted in polarity and travels back to the source, wiping out the current wave as it travels. When the reflected wave reaches the input terminals, all the electrostatic energy stored in the line is completely discharged, and neither current nor voltage exists anywhere along the line. Switch S2 is then opened and S1 is closed, starting a new cycle of operation. In this instance the discharge of the line has resulted in a rectangular pulse with a duration equal to twice the delay time.



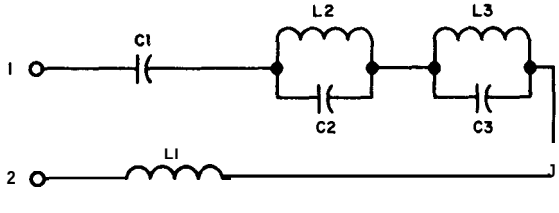
Line Discharge Equivalent Circuit

Current and voltage relationships for the charge and discharge of the delay line are shown in the following figure. At time To, when S1 is closed and S2 is open, the source voltage is applied to the line through charging resistor R_1 in series with R. and R_L. In the absence of R_1 the line would have half the source voltage applied. However, R_1 is a large-value resistor (where the 1^2R loss in this resistance is undesirable a choke is used instead), and only a small voltage is applied to the line. The initial voltage is reflected again and again (as shown in part A) until the line is finally charged up to the source voltage (assuming that the period of time between T. and T_1 is sufficient). At time T_1, when switch S1 is open and S2 is closed, the discharge commences and the charge voltage immediately drops to half the maximum value. The line voltage remains at this value until time T_2 is reached, when the discharge ceases. Thus, from part B of the figure it can be seen that between T_1 and T_2 the line discharges at a constant current with a voltage equal to one-half the initial charge voltage.



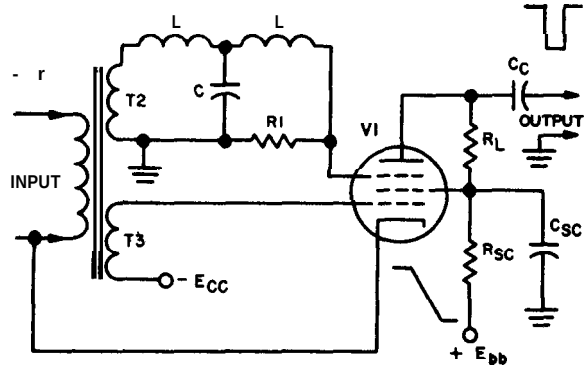
Current and Voltage Relationships for Discharge Line

The ladder-type LC networks used for the delay lines discussed previously are sometimes replaced by a more sophisticated type of line which uses a two-termirud series arrangement instead of the four-terminal parallel arrangement, as shown in the following simplified schematic. In this arrangement the two sections have different values of L and C. This type of construction is similar to the m-derived falter. The theory of operation is identical to that of the ladder-type of delay line; the different construction merely provides equivalent or better puke response characteristics with fewer sections.



Two-Terminal Delay Network

An artificial delay line used with a typical pulse generator to produce an output pulse equal to the delay time is shown in the following schematic. In this application a step function of voltage is applied to a delay line (which is connected to a tube element) at the same time the input pulse (step function) is applied to another tube element. The inverted and delayed pulse stops circuit action at the end of the delay period. Transformer T1 has two secondary windings, T2 and T3. Winding T3 is comected to the bias source and the control grid of the tube. When a positive input pulse is applied to the primary, the induced pulse in the secondary of T3 causes the tube to conduct. Secondary T2 is connected across the delay line, forming a shorted line, with the opposite end properly terminated by RI and connected to the suppressor grid. In the absence of a pulse and for the initial delay period, the suppressor is essentially at ground potential, being connected through the winding to ground. When the initird pulse is applied to primary T2, a positive pulse travels along the line, is inverted, and appears as a negative shut-off gate at the suppressor grid. Conduction occurs only during the time delay period. By tube action the plate current pulse produces an inversion of the positive input pulse, and provides a negative output pulse across R_L, which appears at C_c; this pulse is equal to the delay period. Because of the numerous variations in circuitry, no attempt will be made to cover any other practical circuits. The operation of the various circuits is essentially the same, with the output of the delay line controlling the circuit action.



Typical Pulse Generator

Failure Analysis.

Since the artificial delay line consists of inductors and capacitors, a simple resistance or continuity

check will determine whether the line is open or short-circuited. Basically, the line either works or it does not work. If it does not, the end result is that the controlled circuit produces a pulse of the wrong width and shape. Therefore, it is necessary to observe the circuit waveforms with an oscilloscope. Usually, the delay line is applied to the grid circuit of a tube, in which event the plate waveform, being an inverted and amplified replica, may be observed to avoid shunting the line with the oscilloscope input. If the rise time is slow, it may be because the input pulse shape has too much slope. If not, the line inductance is probably excessive. When the top of the pulse slopes excessively, the resistance in the line is excessive. Normally, a slight slope is expected since the line resistance can never be zero. Usually, the line resist. ance will also place a slight tail on the pulse in short-circuited lines. Adding additional sections will tend to sharpen the rise and fall time, but will also make the delay time longer. Therefore, in such case, the total inductance per section wiU necessarily have to be reduced. In practice, a defective delay line is usually replaced with a new one. Otherwise it will be necessary to accurately measure the individual components in inductance and capacitance bridges to determine whether they are defective. While insertion or removal of a component or section may temporarily restore the line to proper operating condition, this will be no assurance that other components have not been damaged by the cause of the previous failure, and will themselves soon fail and cause a similar condition. Failure of the associated tube and circuit is more common than delay line failure. Check the values of the resistors in the circuit. Failure of the terminating resistor is usually indicated by the presence of additionrd reflections or by an oscillatory condition.

SECTION 14

SYNCHROS AND SERVOS

PART 14-1. SERVOMECHANISMS

SERVOMECHANISM CIRCUITS

General

In radar systems, as well as in industrial and other widespread applications, it is often necessary to control the angular position of one shaft by the positioning of another shaft. When the two shafts are close together this control may be accomplished directly, by gears, or by some other mechanical means. However, when the controlled shaft is located some distance from the controlling shaft it is usually impractical to interconnect the two shafts mechanically and, as a consequence, some other method must be employed to move the controlled shaft in correspondence with the controlling shaft. Two systems used to transmit mechanical shaft angles to a remote location by means of electrical voltages are the synchro system, and the servomechanism. The synchro system accomplishes mechanical shaft transmission without power amplification. That is, mechanical power output is equal to mechanical power input, neglecting losses. In applications where the torque of the controlling shaft must be amplified before it is applied to the controlled shaft, the system used is known as a servomechanism. The synchro system employs two or more self synchronizing units, similar in appearance to small electric motors. Synchros are used extensively in remote indicator systems, where information is to be transmitted between two points. Such information includes antenna position data in azimuth, or in elevation, meter readings, and many types of computer data. Since the controlled shaft is usually fastened to a dial or pointer, the synchro system adequately supplies the small amount of torque required to move the shaft. In addition to remote indicator applications synchro devices are widely used as basic elements of servomechanisms. Synchro systems are discussed in detail in the following paragraph of this Handbook.

The servomechanism is essentially a high gain power amplifier operating on the closed loop, or error-sensitive principle. That is, the action of the power amplifier is governed by an error, which exists when there is an angular displacement between the controlling (or input) shaft, and the controlled (or output) shaft. Servomechanisms may be classified according to motive characteristics. Three types of motor drives are used extensively in positioning systems: the dc motor, the ac motor, and the hydraulic motor.

The dc servo motor is a high torque device widely used in servomechanisms where smooth control of heavy loads is desired. The dc servo motor is a specialized form of dc motor in that it is designed to provide nearly linear changes in speed with proportional changes in armature current. This feature permits the dc servo motor to change direction and speed of rotation smoothly, and with minimum mechanical stress on the controlled mechanism. A servomechanism utilizing a dc servo motor drive frequently uses a synchro system to produce an error voltage, which is indicative of the angular error between the input and output shaft. This error voltage is applied to a phase sensitive dc servo-amplifier, also called a dc servo motor-controller, which compares this error voltage to an ac reference voltage, and produces an output which drives the dc servo motor. The polarity of the servo-amplifier output is dependent upon the direction, either clockwise or counter-clockwise, of the angular displacement between the input and output shaft, and hence, the servo drive motor rotates the controlled devices in the desired direction. As the output shaft is rotated by the servo motor toward a position of alignment with the input shaft, the error voltage produced by the synchro control transformer (the synchro output device, which is mechanically coupled to the output shaft) decreases, since the amplitude of the error voltage is proportional to the amount of error between the input and output shafts.

The output of the dc servo motor-controller decreases and, therefore, the servo motor rotates slower. When the output shaft reaches a position of alignment with the input shaft, an error voltage is no longer produced, and the servo motor comes to rest. In systems where heavier loads must be positioned, thyratron servo motor-controllers are sometimes used because of their higher efficiency and power handling capabilities, which are necessary to drive the larger servo motors used with the heavier loads. In applications where very large loads are positioned, the

491-044 0 73 80

servo motor-controller does not directly drive the servo motor. Instead, it excites an electromechanical power amplifier, such as a dc generator, several cascaded dc generators, a Ward-Leonard system, or an Amplidyne, which is used to drive the dc servo motor. The Ward-Leonard system may be used, either with or without the electronic servo motor-controller. Electromechanical power amplifiers provide substantial gain, and in the AmpIidyne system, which provides the highest gain of them all, a power gain of 10,000 may be realized. An important refinement that is frequently found in servomechanisms is an anti-hunt circuit. Anti-hunt provisions are necessary because of the tendency of the load to coast past its ordered position due to inertia. When the load comes to rest, there ia an angular displacement between the input and output shaft in the direction opposite to the original error, and an error voltage is produced which causes the output shaft to be rotated back toward the ordered position. Again, due to inertia, the load coasts past its ordered position and again an error voltage is produced, which again causes the servo motor to rotate the load toward its ordered position. The load is now oscillating about the ordered position. Friction losses in the servomechanism would dampen out this oscillation, or hunting, as this condition is commonly referred to, if it were not for another factor. This factor is the existence of a time delay in the positioning system which tends to cause the applied torque to be proportional to a past error, rather than a present error. The torque applied to the load by the servo motor lags the error voltage by some angle, and is thereby applied in the wrong direction for a short period of time after the load coasts past the zero-error, or ordered position. Thus, the time delay in the controller creates a regenerative action, reinforcing the oscillations each time the ordered position is passed in much the same way that regenerative feedback in an oscillator sustains oscillations. Overshoot and hunting may be eliminated by increasing the friction of the mechanical drive, by decreasing the gain of the power amplifier, or by compensating electronically for the time delay of the servo motor-controller. The first two methods mentioned are usually unsatisfactory, since increasing the friction of the drive train decreases system efficiency, and decreasing power amplifier gain leads to sluggish response. Anti-hunt circuits, therefore, suppress oscillations by compensating for the effects of the time delay of the servo motor-controller. Anti-hunt devices for servomechanisms are many and varied. In small servos a simple inertia damper may suffice, whereas in larger applications various electronic anti-hunt circuits are used. In general, an anti-hunt circuit provides regenerative feedback when the error voltage is increasing, and degenerative feedback when the error voltage is decreasing.

Servomechanisms using ac servo motors are used where a rapid, accurate, and low cost servomechanism is required. The ac motor is, however, essentially a constant speed device and this characteristic makes it less desirable than the variable speed dc motor in some applications. A few advantages of the ac servo motor servomechanism are: no commutator or brush maintenance, and the ac servo motor-controllers, used with ac servomechanisms, are not subject to drift (development of an output signal with no signal input), which is sometimes encountered in dc servo motor-controllers. An ac servo motor servomechanism may be quite similar to the dc system. The only variations would be the type of servo motor-controller, and the servo motor itself. This system, like the dc servo motor system and all other servomechanisms, operates on the error-sensitive principle.

The servomechanism is one type of servo system. A servo system may or may not involve mechanical motion. Automatic frequency control and automatic gain control circuits are examples of non mechanical servo systems. In all cases, however, the output of the system is fed back for comparison with the input, and the error, or difference voltage is used for control of the system. By strict definition, a servomechanism is a servo system which includes mechanical motion. However, the terms servomechanism, servo system, and servo, are often used interchangeably.

The hydraulic servomechanism is a rugged power amplifying device operating on the hydromechanical principle. This system may be used to position very large loads, and has the advantage of relatively small physical size. Hydraulic servomechanism systems are beyond the scope of this Handbook, however, they deserve mention since they are frequently controlled by relatively small electrical servomechanisms.

SYNCHRO CONTROL SYSTEMS

Application.

Synchro control systems are used in radar sets, computers, and in any other system where it is necessary to indicate the angular position of a shaft, or to

4

transmit mechanical shaft angles to some remote location.

Characteristics.

Electrically transmits mechanical shaft data (angular position) from one point to another.

Does not provide power amplification, i.e., mechanical power output is equal to mechanical power input.

Circuit Analysis.

General. Synchros are known by a wide variety of trade names such as Selsyn, Autosyn, Telesyn, Teletorque and others which are not too frequently encountered. The preferred name however, is synchro, which applies to all the various types. Synchros are devices which convert mechanical shaft angular rotation to electrical signals and vice versa. When information is in the form of a shaft position so that it is expressed in terms of the angle between the actual shaft position and some zero or reference position, it can be converted by a synchro to a set of three voltages called synchro data. In this form such information can easily be transmitted to another point where a second synchro is used to set a second (repeater) shaft to a corresponding angular position. In some instances this second synchro, directly or indirectly through gears, mechanically positions the repeater shaft. In other instances where power amplification is required, the second synchro provides only a voltage output, which drives a servo system. It is important to note that there is no power gain in a pure synchro system. Neglecting friction losses the mechanical power output of the repeater (or receiver) synchro is equrd to the mechanical power input to the transmitter. There are five general types of synchro units, each classified according to function. These include transmitters, receivers, differential transmitters, differentird receivers, and control transformers.

The synchro transmitter, which is sometimes called a synchro generator consists of a rotor which carries a single winding, and a stator made up of three separate windings displaced 120°. The rotor is excited by an ac source and it is usually coupled directIy or through gears to a controlling shaft. The rotor is usually so restrained that it cannot turn except under the influence of the controlling shaft. The voltages induced in the stator windings as a result of the alternating field created by the rotor winding, are representative of the angular position of the rotor at any instant.

The synchro receiver, sometimes referred to as synchro motors are similar electrically to the synchro transmitter. The rotor of the synchro receiver is, in contrast to the synchro transmitter, free to turn and usually drives a light load, such as a pointer, dial, or some other indicating device. The drive is accomplished directly, or through a light gear train. The angular position that the rotor assumes is dependent upon the stator voltages received from the syncbro transmitter.

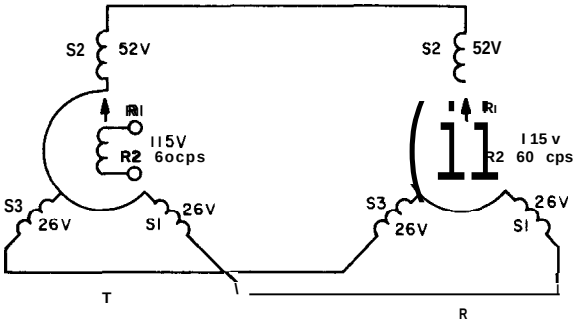
The differential synchro transmitter (abbreviated DT), resembles the regular synchro transmitter in that the rotor is mechanically driven, and the stator is similar. However, there are three separate windings on the rotor, and these windings are electrically displaced 120 degrees. Differential transmitters are used to compensate for errors existing in various parts of a synchro system. With the insertion of a differential synchro transmitter in a synchro system, the angular position of the receiver rotor with respect to the transmitter rotor may be varied by turning the rotor of the differential transmitter.

The differential synchro receiver is similar in design to the differential transmitter, but the rotor is free to turn. It is used when it is desired to interpret the sum or difference of two angular positions. If the differential synchro receiver is connected to two synchro transmitters, the differential synchro receiver assumes a position corresponding to the angular sum or difference (depending on the connections) of the transmitter rotor positions.

The synchro control transmitter is somewhat similar to the synchro receiver. The windings of the control transformer have a higher impedance than the windings of the other synchro units, and the rotor of the control transformer is not free to turn. Voltages from a synchro transmitter produce a voltage in the rotor of the control transformer, which is representative of the angular displacement of the transmitter rotor. The control transformer is used where it is desired to obtain a voltage output only, which is indicative of angular position.

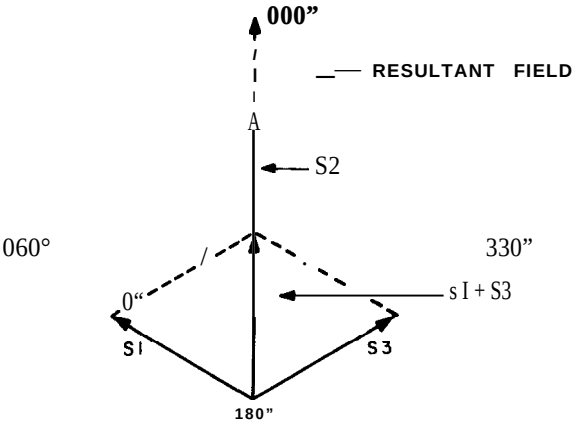
Circuit Operation. The synchro transmitter operates as a variable transformer with its rotor as the primary and the stator windings as **secondaries.** The voltages induced in each stator winding are proportional to the cosine of the angle between the rotor and the individual stator winding. The following

diagram illustrates a typical synchro circuit consisting of a synchro transmitter and receiver.



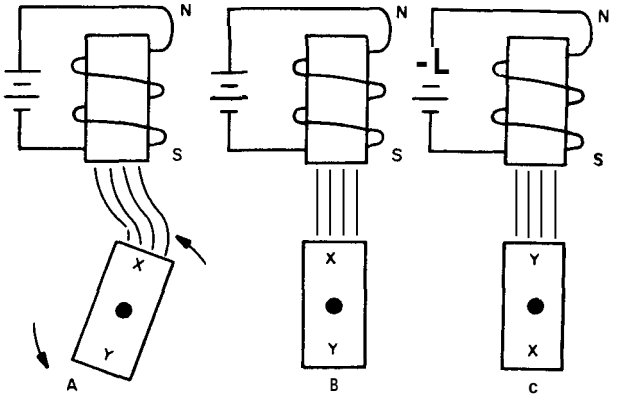
Synchro Transmitter-Receiver Circuit

When ac voltage is applied to the rotor of the synchro transmitter, voltages are induced in the stator windings (S1, S2, and S3), and the magnitude and phase of these voltages are dependent upon the position of the synchro rotor. The turns ratio between the synchro rotor and stator is generally 2.2:1, so that the maximum voltage that can be induced across an individual stator winding is 52 volts when standard 115V, 60 Hz, ac is applied to the rotor. The rotor of the synchro illustrated is, by convention, in the 0° position. This reference is used throughout synchro systems. Designations S1, S2, S3, R1, and R2 are also standard designations for all synchros. When the rotor of the synchro transmitter is in the 0° position flux linkage between the rotor and winding S2 is maximum, and 52 volts is inducted across S2. Stator windings S1 and S3, however, are at 60° angles to the rotor and only half as much voltage (26 volts) is induced across S1 and across S3, since the cosine of 60° is 0.5. At this point, circuit operation can be more easily understood by assuming that the receiver rotor is removed. Since the stator windings of the transmitter are connected directly to the stator windings of the receiver, the voltage applied to each individual receiver stator winding corresponds to the voltages induced in each stator winding of the transmitter. Current flows from S2 of the transmitter through S2 of the receiver, and divides equally through S1 and S3, since equal voltages are applied to S3 and S1. Current flow will, of course, be reversed when the polarity of the input voltage reverses. Each suitor winding in me receiver generates a magneuc field, but the important point to consider is the resultant field. The following vector diagram illustrates the direction and magnitude of each receiver stator field and the resultant field.



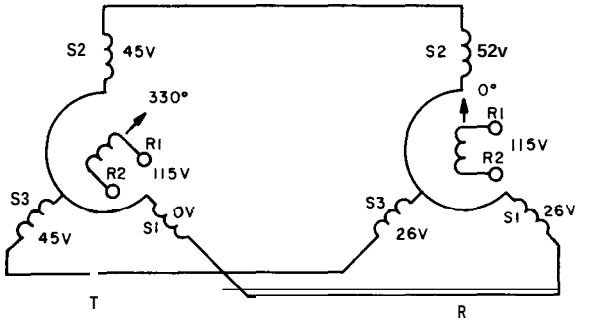
Resultant Receiver Field Vector Analysis (Transmitter Rotor At 0°)

As can be seen from the vector diagram, the resultant field points in the same direction as the transmitter rotor. Should an iron bar rotor be placed in the receiver field it tends to line itself up with the resultant field; however, the iron bar rotor can align itself in either of two positions 180° apart as shown in the following illustration.



Behavior of Electromagnet and Iron Bar

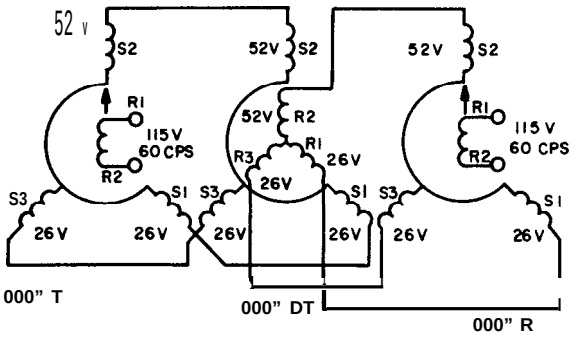
In figure A the iron bar rotor is held in the position illustrated. The paths of the magnetic lines of force are lengthened and when the bar is released it quickly rotates to position B in accordance with the stretched rubber band concept for the behavior of magnetic lines of force. Figure C illustrates the position that the rotor would assume if it is rotated to a position, where the "Y" end of the bar is nearer to the electromagnet than the X end, and is released. Thus a synchro receiver with an iron bar rotor displays ambiguity, that is, it has two stable positions 180° apart. To avoid the possibility of this 180° error the rotors on synchro receivers are energized by the same ac source as the transmitter rotor. This makes the receiver rotor an electromagnet, and there is now only one stable condition. In addition to the advantage of having only one stable condition, the energized rotor provides much greater torque, and synchro receivers with energized rotors do not have constant stator current as an iron bar receiver would have. The following is a standard synchro transmitter receiver system with the transnutter rotor positioned at 330° and the receiver rotor held at O°.



Transmitter 330°, Receiver Held At 0°

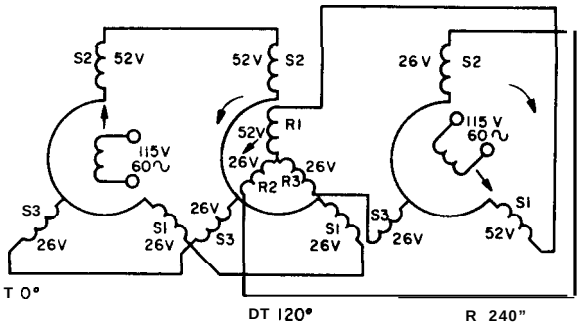
Voltages are induced in the synchro transmitter stator windings which are proportional to the cosine of the angle between the rotor and the stator windings. S2 and S3 are each displaced 30° from the rotor and the voltage induced in S2 and S3 is, therefore, 45 volts. S1 is now at right angles to the rotor and no voltage is induced in S1. The receiver rotor, which is being held at 0°, induces voltages in the synchro receiver stator windings, which are again proportional to the cosine of the angle between the receiver rotor and the receiver stator windings. Receiver stator winding S2 is parallel to the rotor and 52 volts is induced in S2. S1 and S3 are displaced 60° from the rotor and 26 volts is induced across S1 and S3. The synchro transmitter receiver circuit is now unbalanced, that is, voltage differences exist between the stator windings of the transmitter and receiver, and stator current flows, setting up a stator field in the receiver in such a direction as to exert a clockwise torque on the receiver rotor. Remember that the transmitter is so constructed that the transmitter rotor cannot rotate except under the influence of the controlling shaft. When the synchro receiver rotor, which is being held at 0°, is released it rotates in a clockwise direction due to the clockwise torque applied to it as a result of the receiver stator field, generated by a stator current. As the receiver rotor approaches 330° the degree of unbalance between the transmitter and receiver diminishes, and hence, stator current decreases, since the voltages induced in the receiver stator windings by the receiver rotor approach the voltages induced in the transrnittor stator windings by the transmitter rotor. When the receiver rotor reaches the same bearing as the transmitter rotor (in this case 330°) the voltages induced in the receiver stator windings are equal to the voltage induced in the transmitter stator windings. A balanced condition now exists, and stator current no longer flows, hence, torque is no longer produced, and the receiver rotor ceases to turn. It can be seen, then, that the transmitter supplies stator current to establish a field in the receiver, and produces torque only when the receiver is out of alignment with the transmitter. Torque produced in the receiver is proportional to the amount of error between the transmitter rotor and the receiver rotor. At very small error angles, the torque produced in the synchro receiver is insufficient to overcome the friction of the bearings and load. For this reason, friction is made as low as possible in the synchro receiver, and the maximum error in synchro receivers is generally less than 1°. Another important synchro unit frequently encountered is the differential transmitter. The differential synchro transmitter is used in circumstances where a correction must be inserted in the angular information being transmitted, or where the sum or difference of two angles must be transmitted. An

example of this is the conversion of the relative bearing of a target to true bearing. It has been previously stated that synchros operate as variable transformers. This statement applies to the synchro differential transmitter as well as all synchro units. In the case of the synchro differential transmitter, the stator is the primary of the variable transformer, while the rotor windings serve as the secondary. The following schematic diagram illustrates a differential transmitter inserted between a synchro transmitting and receiver.



Differential Transmitter Connections

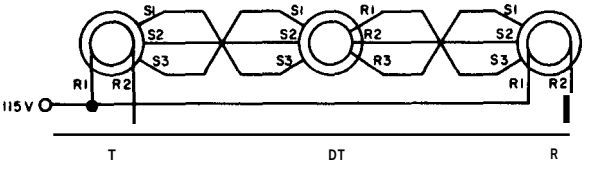
In a differential synchro transmitter the voltage ratio is one to one. With the differential transmitter at its electrical zero (0°) synchro data is passed from the transmitter to the synchro receiver without alteration. In the above illustration both the synchro transmitter and differential transmitter are mechanically positioned to O°. Since the rotor of the synchro transmitter is at 0°, 26 volts is induced in transmitter stator windings S1 and S3, and 52 volts is induced in stator winding S2. The stator windings of the synchro transmitter are directly comected to the stator windings of the synchro differential transmitter, and the voltages induced across the transmitter stator windings are developed across the differential transmitter stator windings. The differential transmitter rotor windings are directly connected to the stator windings of the synchro receiver and whatever voltages are induced in the differential rotor windings are applied to the stator windings of the receiver. When the differential transmitter rotor is positioned at 0° all three rotor windings, which are positioned electrically 120° apart, form an angle of 0° with their respective stator winding .(R1 with S1, R2 with S2, etc) and maximum voltage is induced in each rotor winding. Since the effective turns ratio is 1:1, 52 volts is induced in R2, and 26 volts is induced in R1 and R3. Therefore, 52 volts are applied to receiver stator winding S2, and 26 volts are applied to stator windings S1 and S3. The resultant receiver stator field is in the same direction as the transmitter rotor, and the receiver rotor aligns itself with this field. As long as the DT is positioned at 0° the receiver rotor positions itself at the same bearing as the transmitter rotor. If the differential transmitter is positioned to some bearing other than 0° the receiver indicates the position equal to the transmitter bearing minus the DT bearing, or in other words, the receiver indicates the difference between the transmitter and differential positions.



Effect of Changing Differential Transmitter Position

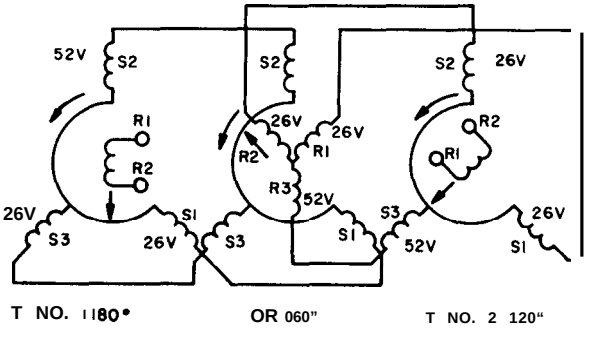
In the preceding illustration the synchro transmitter is positioned at 0° and the differential transmitter rotor has been rotated to a position of 120°. Maximum voltage is now induced in rotor winding R1 which is connected to stator winding S1 of the receiver. Twenty six volts is induced in rotor windings R2 and R3, and is applied to the receiver stator windings. The resultant receiver stator field points toward 240° and the receiver rotor aligns itself toward 240°. In all cases, where the differential transnutter is directly connected between the transmitter and receiver, the receiver shaft position is equal to the position of the transmitter shaft minus the position of the differential. If it is desired to have the differential position added to the transmitter reading, it is necessary to reverse S1 - S3 and R1 - R3 of the differential. It has been stated that the DT is effectively a 1:1 transformer. Actually there is a slight step-up ratio since

extra turns are added to the rotor to bring the voltage ratio up to 1:1 to make up for transformations, copper, and core losses present in the differential transmitter. The fact that this ratio difference between the stator exists, gives rise to an electrical condition of unbalance, which occurs when a differential transformer is inserted in a synchro system. In a conventional synchro system there is no stator current when the transmitter and receiver are in a balanced data (in alignment). However, when a differential transmitter is inserted in the system, the no stator current condition no longer prevails when the system is in balance. The reason for this is that the differential stator windings can be designed to match the impedance of the transmitter stator windings, or the impedance of the differential rotor windings can be made to match that of the receiver stator windings. Since the differential transmitter cannot be made a one to one transformer in both directions, it is not possible to match both input and output impedances at the same time. As a consequence, there is current flow in both transmitter and receiver stator circuits even when the system is balanced, and the effect of this current is to reduce the accuracy of the system. Synchro capacitors may be used to reduce this stator current and hence, increase system accuracy. Synchro capacitors will be discussed in a subsequent paragraph. The differential synchro receiver is comected between two synchro transmitters, and it is used to indicate the angle between the two transmitter shaft positions.



Wiring Diagram of Synchro System Designed to ADD Transmitter Position to Differential Position

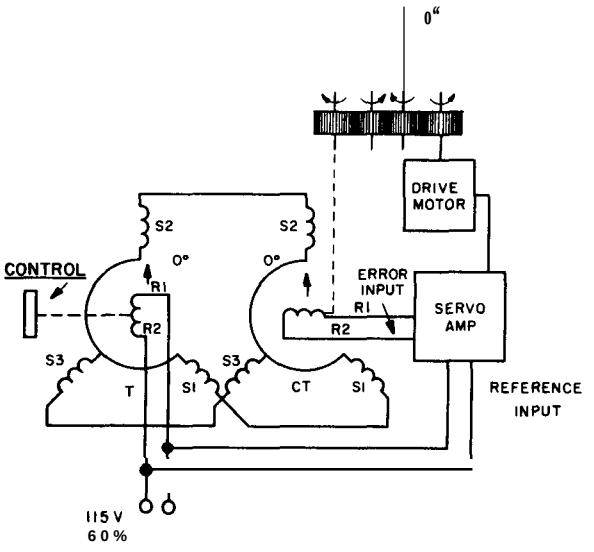
In the following illustration, synchro transmitter number 1 is mechanically positioned to a bearing of 180° and transmitter number 2 is positioned at 120°.



Synchro Differential Receiver Inserted Between Two Synchro Transmitters

The differential receiver is electrically similar to the differential transmitter, but the DR rotor unlike the differential transmitter, is free to turn. In a simple transmitter-receiver synchro system a balanced state is achieved when the voltages applied to the receiver stator windings by the transmitter are canceled by equal and opposing voltages induced across the receiver stator windings by the receiver rotor. The synchro system illustrated above attains a balanced state when the differential receiver assumes an angular position equal to the difference between the angular positions of the two transmitters. If either, or both, of the synchro transmitters are moved the synchro system becomes unbalanced, and stator current flows, creating torque which causes the differential receiver to rotate until once again a balanced condition is reached. The synchro control transformer (CT) is used to produce an output voltage which is indicative of the error between two shafts. This output voltage is called an error voltage because it exists only when the two shafts are not in alignment.

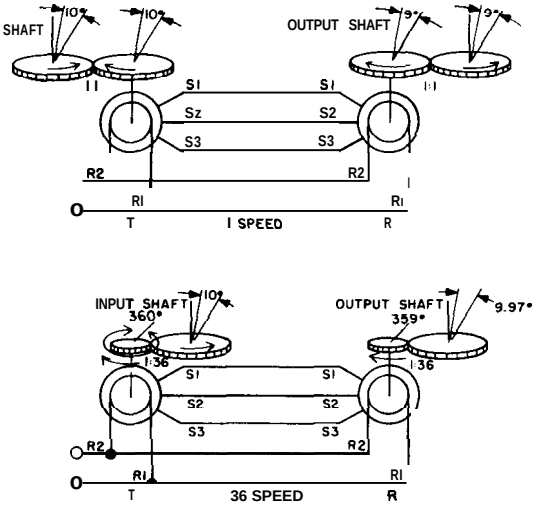
The following illustration depicts a simple synchro transmitter CT circuit and associated drive equipment.



Simple Antenna Control System

The synchro transmitter mechanically positioned by a hand crank. The synchro transrrdtter is connected to the synchro control transformer in the standard manner, that is, S1 of the transmitter to S1 of the receiver, etc. The control transformer rotor is comected to a servo amplifier and the servo amplifier drives a drive motor, which is geared to the device being controlled; in this case, it is an antenna. The antenna is mechanically connected back to the control transformer to provide feedback. When the CT rotor is in alignment with the transmitter rotor there is no error voltage produced, and hence there is no output from the servo amplifier and the drive motor does not operate. It is important to note that the CT rotor is considered to be in alignment with the transmitter rotor when the CT rotor is displaced 90° from the transmitter rotor. In this position no voltage is induced in the CT rotor since the CT rotor is now perpendicular to the resultant CT stator field. When the synchro transmitter rotor is timed to some new position, the resultant control transformer stator field also rotates to some new position, and this field is no longer perpendicular to the CT rotor so that a voltage is now induced across the CT rotor. his ac voltage is fed to the servo amplifier where it is compared with a reference voltage, which is of the same phase as the transmitter rotor excitation voltage, and an output is produced from the servo amplifier, which causes the antema drive motor to rotate the antenna. As the antenna rotates toward the desired position the error voltage produced by the CT diminishes, since the CT is mechanically coupled to the antenna. When the antenna reaches the desired position the rotor of the CT is now perpendicular to the resultant receiver stator field set up by the synchro transmitter and the CT output error voltage is zero. There is no longer an output from the servo amplifier and the drive motor ceases to rotate the antenna. The stator windings of a control transformer consists of many turns of fine wire, and presents a high impedance to current flow, thus reducing the load presented to the transmitter, and allowing several control transformers to be utilized in conjunction with a single transmitter. High impedance windings are also necessary since the rotor of the control transformer usually operates into a high impedance load such as a servo amplifier.

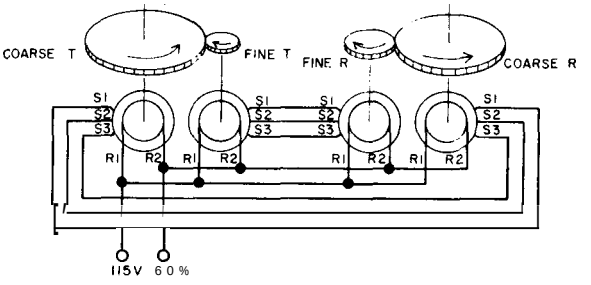
When the rotors of synchro devices turn in unison with their input and output shafts such devices are known as one-speed synchro systems. When a synchro receiver is in alignment with the transmitter no torque is developed, and with any movement of the transmitter rotor, the receiver must first overcome the restraining forces of the load before it can follow the transmitter. Even with no load the receiver must first overcome the restraining forces due to the friction of the receiver bearings before rotation occurs. This results in an angular displacement between the input and output shafts, called the no load error. Geared synchro systems are used when a high degree of accuracy is required. The following diagram illustrates the difference in error between l-speed and 36-speed systems.



Comparison of ERROR Between l-Speed and 36-Speed Synchro System

It can be seen in the preceding illustration that the 36-speed synchro system is far more accurate than the one-speed system. In both systems the error caused by bearing friction and resistance of the load amounts to one degree. In both systems the controlling shaft is rotated 1O°. In the l-speed system the transmitter is rotated 10° and the 1° error limits the receiver rotation to 9° and hence the output shaft rotates only 9°. In the 36-speed system, however, the transmitter is rotated 350° when the controlling shaft is rotated 10°, and the 1° error limits the receiver to 359° of rotation. This 359° of rotation causes the output shaft to rotate 9.97°. In other words, system error of the 36-speed system is only approximately .03° compared to 1° for the one-speed system. One disadvantage of geared synchro systems is that the self synchronous feature of the one-speed system is lost. When power to a one-speed system is interrupted, and the transmitter is turned the receiver of course does not follow, but when power is restored it aligns itself correctly with the transmitter. However, in a geared system, such as the 36-speed system used extensively in the Navy, 36-positions of the output shaft exist for which the receiver is in alignment with the transmitter.

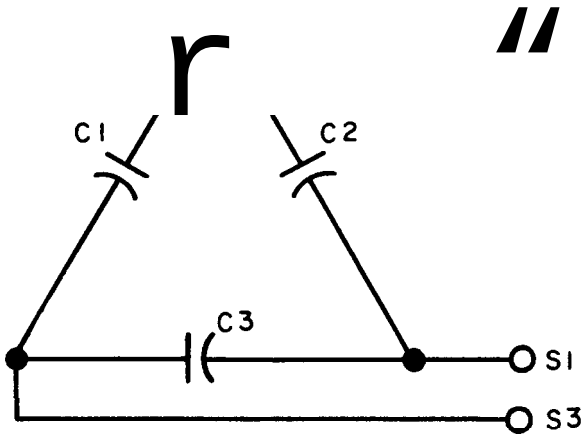
The self-synchronous feature of the one-speed system and the high accuracy of the 36 speed system can be combined by making use of coarse and fme synchros connected to the same input and output shaft. Following is an illustration of this system.



36-Speed Synchro System Using Coarse-Fine Synchros (Dual Speed System)

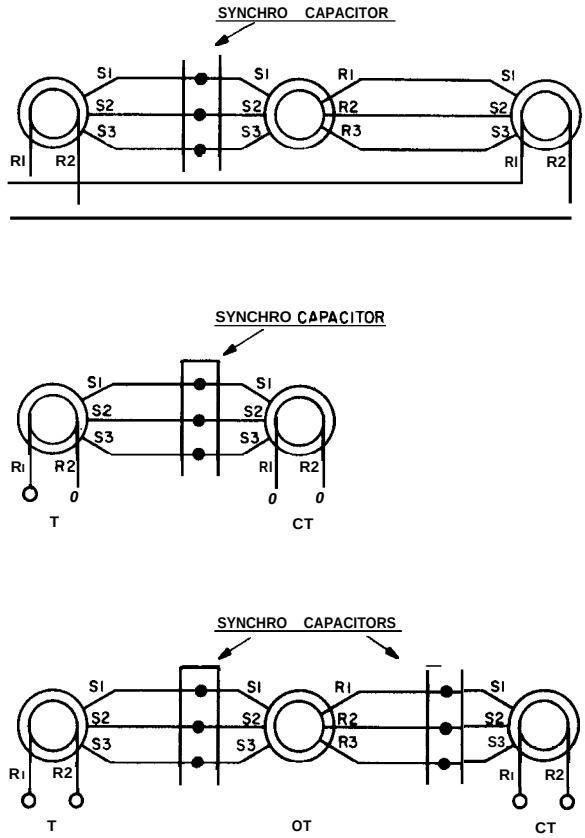
In the coarse-free synchro system, incorrect alignment of the 36-speed system is prevented, because when the shaft error is large the one-speed system has control, and reduces the error to a small value. At this point the 36-speed synchro takes over, and further reduces the error to a very small value. When a dual-speed synchro system utilizes a control transformer to drive a servomechanism a cross-over system or synchronizer must be used. The function of this system is to determine whether the coarse or tine CT error voltage is fed to the servo amplifier. When the input shaft of a 36-speed system is turned 2.5° the fme CT rotor is displaced 90° from its zero voltage position. This position provides maximum induced voltage in the fine CT rotor, but, more important, this is the first maximum voltage point since the zero error position. For this reason, corss-over systems are designed so that the fme CT has control for error angles less than 2.5°. For larger error angles the synchronizer or cross-over system cuts out the fme CT and the coarse CT takes control. There are a variety of cross-over circuits in use. One system utilizes a plate-circuit relay which normally allows the 36-speed CT to control the servo system. However, when the error angle increases beyond 2.5°, increasing the output of the coarse CT, the relay is energized and the coarse (1-speed) CT assumes control of the servomechanism. Some cross-over arrangements use purely electronic switching; these usually depend upon biasing and limiting circuits.

It has been pointed out that the differential synchro and the synchro control transformer both draw current from the transmitter, even when the system reaches a position of electrical and mechanical balance. The differential draws current because of the step-up turns ratio between stator and rotor. In the case of the control transformer current is drawn from the transmitter, because the CT rotor is not energized, and opposing voltages are not induced in the CT stator. In order to reduce the current flow when either or both of these units are used, synchro capacitors are connected into the circuit. Current flow in a synchro system is comprised of resistive and inductive current. If the inductive reactance of a differential stator winding is shunted by an equal capacitive reactance the inductive current is then effectively cancelled by the capacitive current. In this case all that the transmitter actually does is to supply power demanded by the resistive losses of the circuit. Synchro capacitors are manufactured with three capacitors contained in a single unit and are internally connected as shown in the following illustration.



Synchro Capacitor

The individual capacitors are matched to a tolerance of less than one percent to maintain proper current balance. Synchro capacitors are connected into various synchro systems as shown in the following illustration.



Synchro Capacitor Connections

Part A of the illustration shows the comections for a differential transformer as used with a transmitter and receiver, while Part B shows the connections for a control transformer and transmitter. In Part C both a differential transformer and a control transformer are used and each requires a separate capacitor unit.

Synchro capacitors are used only when it is desired to cancel or partially cancel existing current. The synchro capacitor is never used in simple transmitter-receiver circuits because in such a system the reactive component of stator current is assumed to be zero and insertion of a synchro capacitor only increases current and throws the system out of balance. However, exciting current in this type system may be reduced by connecting a capacitor across the rotor.

Failure Analysis.

No Output. Failure of a receiver rotor to rotate when the transmitter is rotated, or no-voltage output from a control transformer are considered no-output conditions. Frozen bearings or a jammed load could restrain a receiver rotor, and lack of excitation to the transmitter rotor would disable the synchro system. Existence of the first condition can be readily ascertained by attempting to manually rotate the receiver rotor. Existence of the second condition (no transmitter excitation) can be readily checked by measuring the voltage across the transmitter rotor. If no voltage is present check for a blown input line fuse, or an open input line. If voltage is present across the transmitter rotor, but the system is inoperative, reenergize the system and check the continuity of the transmitter rotor. If any two stator lines are open the synchro system will be inoperative. Resistance checks can be used to determine continuity of stator windings and stator leads.

Improper Operation. Improper operation is the result of incorrect wiring or an open or shorted winding in any of the synchro units, or excessive friction in bearings. If any of the stator windings are reversed, the units will not overheat and they will develop normal torque, but the receiver will turn in the direction opposite to that of the transmitter and a 120° bearing error will exist. If the rotor windings are reversed, operation will be normal except that a 180° bearing error will exist. An open receiver rotor results in weak torque, receiver hum, and possible ambiguous behavior, since the receiver rotor now operates as an iron bar rotor. The transmitter supplies excessive current when the receiver rotor is not energized, and may bum **out or** blow line fuses. An open or shorted stator winding results in erratic operation and could possibly overheat synchro units.

In general, if the synchro units operate smoothly, do not overheat, and produce normal torque, but do not rotate in the proper direction and/or an error which is some multiple of 60° exists, the probable cause is incorrect wiring. Since different units of a synchro system are usually located some distance from each other, and are connected by busses or cables which often pass through junction boxes, wiring errors are frequently made during repair or during new installations, or modifications to existing installations. Symptoms such as overheating, blown fuses, hum, or erratic operation are indicative of a short or open winding within the synchro units, or open or shorted interconnecting cables. Resistance measurements are valuable in locating shorts and opens in synchro to another it should be assumed that an ohmmeter will show the same reading across rotor or across stator windings of similar units, within close tolerances. **Be** certain that all power is disconnected before resistance or continuity measurements are attempted. Typical resistance values are low, ranging from a fraction of an ohm in the rotor of large synchros, to several hundred ohms in the stator windings of smaller units.

SERVO MOTOR-CONTROLLER-CIRCUIT

Application.

The dc servo motor-controller, also called a servo amplifier, is used in conjunction with a synchro system to control a servo motor which operates an indicator dial or rotates a load to a similar position.

Characteristics.

Drives dc servo motor.

Output is proportional to magnitude of error input.

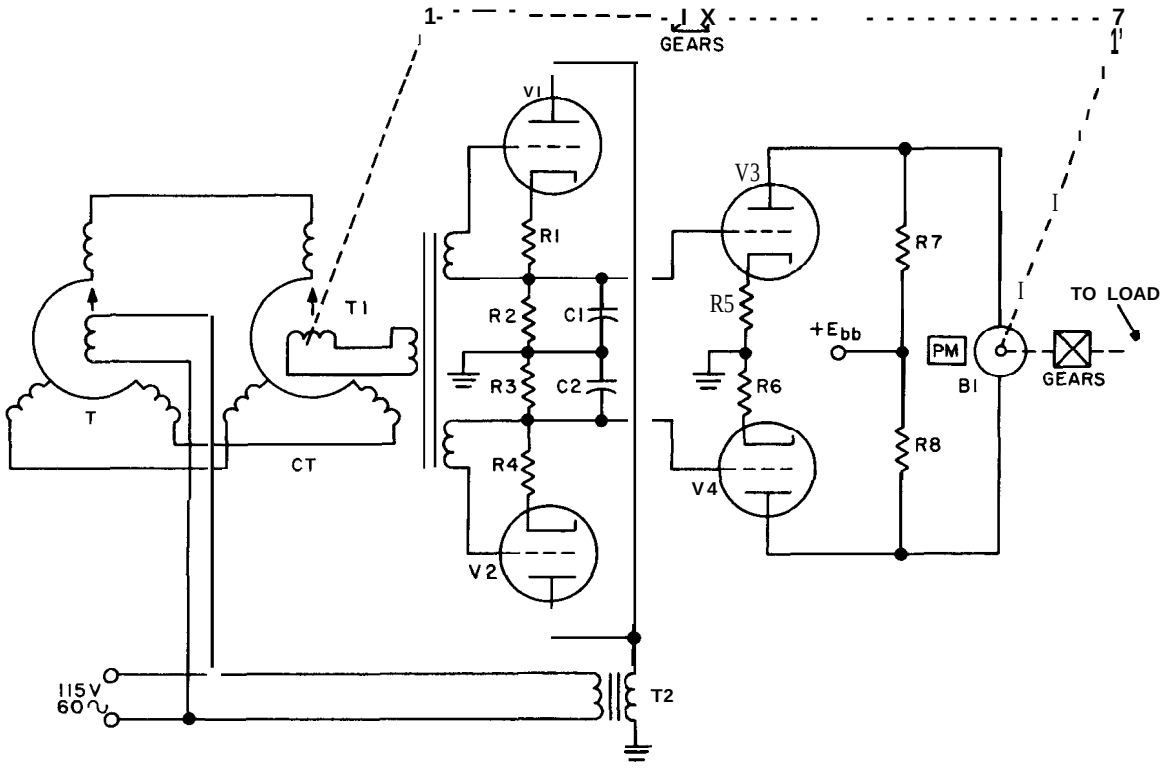
Is phase sensitive, direction of servo motor rotation is determined by phase of error input.

Use is limited to low power applications.

Circuit Analysis.

General. 'The dc servo motor-controller receives an error voltage input from a synchro control transformer (CT) and effectively compares this error voltage with an ac reference voltage to provide an amplified dc output which drives a dc servo motor. The dc servo motor-controller circuit consists of a phase sensitive detector-amplifier, with the ac reference voltage used as plate voltage, coupled to a dc amplifier, whose output drives a dc servo motor. The magnitude of the dc output, which determines the speed of the drive motor, is dependent upon the amplitude of the error voltage. The polarity of the dc output, which determines the direction of servomotor rotation, is dependent upon the phase relationship between the error voltage input and the ac reference voltage.

Circuit Operation. The following schematic diagram illustrates a typical dc servo motor-controller circuit and associated synchro and drive equipment.



Servo Motor-Controller Circuit

Transformer T1 couples the error voltage in push pull (180° out-of-phase), from the rotor of the synchro control transformer to the grids of detector amplifier tubes VI, and V2. Resistors R2 and R3 serve as load resistors for VI and V2, respectively. Resistors R1 and R4 provide degenerative feedback to the cathode of V1 and V2.

Transformer T2 applies the ac reference voltage in parallel (in-phase) to the plates of detector-amplifier tubes VI and V2. Capacitor Cl and C2 falter the pulsating dc developed across R2 and R3. V3 and V4 serve as dc amplifiers with R5 and R6 as their cathode resistor, and R7 and R8 as their plate load. Dc servo motor B1 is mechanically geared to the load to be positioned and is also mechanically coupled back to the synchro control transformer.

Tubes V1 and V2 conduct only on positive alternations of the ac reference voltage. When the synchro control transformer is in alignment with the synchro command transmitter there is no error signal input, and V1 and V2 conduct equally during the positive portion of the reference signal. Thus equal voltages are developed across R2 and R3. At this point V1 and V2 are functioning as rectifiers, and the voltage across R2 and R3 is pulsating dc, which is faltered by capacitors Cl and C2, and applied to the grids of V3 and V4. Dc amplifier tubes V3 and V4 conduct equally under this condition, and the voltage developed across R7 is equal to the voltage across R8. Therefore, no difference in potential exists between the plates of V3 and V4 and, hence, no current flows through the armature of servo motor B1, and the motor will not rotate. When the synchro command transmitter is moved to some new position, the synchro control transformer is no longer in alignment with the command transmitter rotor and an error voltage output is produced by the synchro control transformer and is applied to the servo motor-controller circuit. It is important to keep in mind that, the ac reference voltage applied to the plates of V1 and V2 is from the same source as the synchro excitation voltage, and any error voltage induced into

the control transformer rotor is either in-phase or 180° out-of-phase with the reference voltage. Assume that the angular displacement between the synchro command transmitter and the synchro control transformer is in such a direction that the error voltage induced across the CT rotor is in-phase with the reference voltage. When the reference voltage goes positive, a positive half cycle is applied to the grid of V1 and a negative half cycle of error voltage is applied to the grid of V2 (remember that TI is effectively a push-pull transformer). The conduction of V1 increases and, therefore, an increased voltage drop occurs across R2 and this voltage is faltered by Cl and applied to the grid of d-c amplifier V3, causing the conduction of V3 to increase. At the same time, the negative half cycle of error voltage applied to the grid of V2 decreases conduction of V2, causing a decreased voltage drop across R3, and consequently the d-c voltage coupled to the grid of V4 decreases, reducing the conduction of V4. Since the conduction of V3 increased, while the conduction of V4 decreased, a difference in potential now exists between the plates of V3 and V4 due to the increased voltage drop across R7, and the decreased voltage drop across R8. Current now flows from the plate of V3 through the armature of drive motor B1 to the plate of V4 and the motor rotates driving the load in the desired direction. VI and V2 conduct only during the positive half cycle of the ac reference input. Drive motor operation, however, is not erratic since filter capacitors Cl and C2 maintain fairly constant voltages across the grids of V3 and V4, causing the servo-motor-controller output to be fairly constant. The drive motor is also mechanically connected through gears to the synchro control transformer and rotates the synchro CT rotor toward the position of alignment with the synchro command transmitter. As the angular displacement between the CT rotor and the transmitter rotor diminishes the error voltage produced by the CT diminishes and the dc output of the servomotor-controller decreases, causing the drive motor to rotate slower. When the CT reaches the same bearing as the command transmitter, drive motor rotation ceases because no error voltage is produced by the CT, and consequently there is no longer an output from the servo motor-controller. If the synchro command transmitter is rotated in the other direction, the resulting error voltage produced by the synchro control transformer will be 180° out of phase with the reference voltage. Circuit operation will be the same, but the polarities are reversed, V1 is driven negative causing a negative voltage to be applied to the grid of V3, and the voltage on the plate of V3 increases. V2 is driven positive causing a positive voltage to be applied to the grid of V4, and the voltage at the plate of V4 decreases. Current flows from the plate of V4 through the armature of servo motor B1 to the plate of V3, causing the servo motor to rotate in the direction opposite to the direction that it rotated previously.

Failure Analysis.

No Output. Failure of the drive motor to rotate is considered to be a no-output condition. In a positioning system such as the dc servomotor system, no output could result from a defective synchro system, a defective servomotor-conroller or a defective servomotor, or associated mechanical drive equipment. The synchro system can be checked by measuring the voltage across the CT rotor with an ac voltmeter as the command transmitter is rotated 360°, and the servo motor-controller circuit disabled by removing V3 and V4. If the rotor voltage (called the error voltage) should vary smoothly from zero volts to about 55 volts the synchro system is operating normally. To check for a jammed gear train, load, or servo motor, attempt, with the power disconnected, to manually rotate the servo motor shaft. If the windings of the servomotor show the proper resistance when checked with an ohmmeter and there is not excessive leakage between windings the motor is most likely good. However, if a spare motor is available, substitution is a sure way of determining the merit of the servo motor. If the servo motor, gear train and synchro system is good, inability to position the load is most likely due to a defective servo motor-controller. Failure of error input transformer T1 and reference voltage transformer T2 would render the servo motor-controller inoperative. Using an ac voltmeter, check for 115 VAC on the plates of V1 and V2 to determine whether or not T2 is defective. T1 can be checked by observing the presence of an ac error voltage on the grid of VI and V2, while the synchro command transmitter is rotated. Check the voltage present at the junction of R7 and R8 to determine whether or not lack of plate supply voltage is the cause of no output. Failure of detector-amplifier tubes V1, V2, or failure of dc amplifiers V3, or V4, could cause no-output. Failure of an individual circuit component is not likely to cause a no-output

condition, but instead, an unbalanced condition would result between the output of dc amplifiers V3 and V4, and improper operation would most likely result.

Improper Operation. Improper operation is considered any type of operation other than proper operation, such as, sluggish or slow rotation of the drive motor, erratic or jerky rotation, or a tendency to rotate better in one direction than the other. Improper operation could result from a defective synchro system, excessive binding of the gear train or load, a defective servomotor, or defective servo motor-controller circuit. The synchro system, gear train, and servo motor can be checked as explained previously, and if these associated components are satisfactory, improper operation is likely due to a faulty servo motor-controller circuit. The servo motor-controller circuit can be thought of as consisting of two branches, V1, V3, and associated circuit components comprise the upper branch, and V2 and V4, together with their associated components, comprise the lower branch. Any component defect that alters the performance of one branch as compared to the other could result in improper operation, possibly manifesting itself as a tendency of the drive motor to rotate better in one direction than the other, or possibly continuous or erratic rotation in one direction. A possible cause of improper operation is defective tubes. It would also be advisable to check the dc power supply voltage, since low supply voltage could possibly cause sluggish operation. A change in value, short, or open of RI or R2 would, of course, affect the operation of detector amplifier V1 and, likewise, a defect in R3 or R4 would adversely affect V2. If Cl or C2 shorted, V3 or V4, respectively, would be inoperative as amplifiers and improper operation would result. A change in value or defect in either R5, R6, R7, R8, would destroy the balance between dc amplifiers V3 and V4, and improper operation could result. With the equipment deenergized all resistors can be checked for proper value with an ohmmeter, capacitors Cl and C2 can be checked w-ith an in-circuit capacitor checker.

RESOLVER-ORIVER CIRCUIT

Application.

The resolver-driver circuit is used to drive an ac resolver, which is used as a computing element in problems involving coordinate conversion, coordinate rotation, and resolution of vectors. Resolverdrivers are also used to drive sweep resolvers in radar indicators.

Characteristics.

Utilizes a pentode and a triode to drive a resolver.

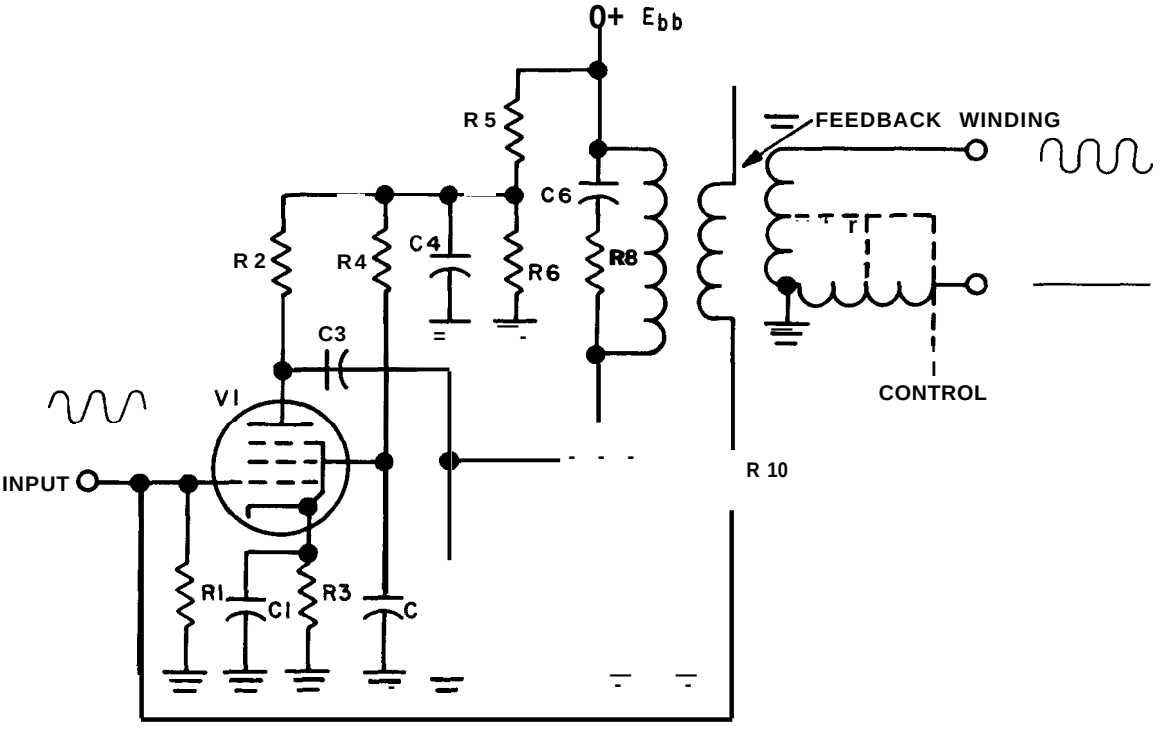
Operates on the principle of a feedback amplifier.

"Provides power amplification with minimum distortion, voltage gain is unity.

Circuit Analysis.

General. The resolver-driver circuit amplifies an ac synchro voltages to a power level sufficient to drive an ac resolver with a minimum of distortion. The resolver-driver is basically a feedback amplifier consisting of a pentode voltage amplifier, coupled to a triode amplifier which drives the resolver primary winding. R-C coupling is used between the first and second amplifier stage, and distortion is minimized by the use of degenerative feedback which is obtained from a feedback winding within the resolver and is coupled back to the grid of the first amplifier.

Circuit Operation. The following schematic - diagram illustrates a resolverdriver circuit.



Resolver Driver Circuit

Resistor RI is the input grid resistor for pentode amplifier V1. Resistor R2 is the plate load and R3, which is bypassed by Cl, provides cathode bias for VI. Resistor R4 is the screen dropping resistor for Vl, and C2 is the screen bypass capacitor. R-C coupling consisting of capacitor **C3** and resistor R7 is employed between V1 and V2. A voltage divider consisting of R5 and R6 is used to drop the pIate supply voltage to the proper value of plate voltage for V1. Capacitor C4 bypasses ac voltage variations to ground and prevents unwanted degeneration. Resistor R9 which is bypassed by C5 serves as the cathode bias resistor for triode amplifier V2. The plate load for V2 is the primary winding of the resolver. The primary winding of the resolver is shunted by a series r-c network, consisting of R8 and C6, which is intended to compensate for the inductive impedance of the resolver winding and thereby maintain the power factor near unity. Degenerative feedback is developed across the feedback winding within the resolver and applied to the grid of VI through resistor R1O.

When an ac input is applied to the input of the resolverdriver it is amplified by conventional ac amplifier stage V1, and is capacitively coupled to the grid of driver stage V2. The ac synchro voltage applied to the grid of V2 is amplified and developed across the primary of the resolver, and is inductively coupled to the resolver feedback winding and the resolver secondary windings. R-C network, R8-C6, cancels the effects of the inductive reactance of the resolver windings and makes the output load appear resistive, thus bringing the power factor of the output load to unity, Degenerative feedback developed by the resolver feedback winding is attenuated by resistor R1O and is applied to the grid of V1. The value of R1O is such that the amplitude of the degenerative feedback is great enough to reduce the closed loop voltage gain of the resolverdriver to unity. The degenerative feedback improves the fidelity and stability of the resolverdriver. Stability is improved since a decrease in emission of the tubes, which would normally reduce the output (if feedback

were not present), instead tends to decrease the magnitude of the present feedback and results in increased closed loop gain, since there is less degenerative feedback (which is 180° out-of-phase with the input) present at the grid of VI.

Failure Analysis

No Output. A no-output condition in the resolverdriver circuit could result from failure of the power supply or failure of one of the tubes. Check the power supply voltage with a voltmeter, and also check the tubes. If operation is not restored, a defective circuit component is most likely the cause of no output. Voltage checks of tube elements may be helpful in localizing the fault to a stage. Keep in mind that a fault in one tube element circuit such as the grid or cathode circuit, may effect the voltage present on other tube elements. Voltage checks are, therefore, only a means of localizing the trouble, and further resistance measurements are usually necessary to locate the component at fault. Improper plate and screen voltage on V1 could be caused by a defect in voltage divider **R5, R6** or capacitor C4. Check R5 and R6 for proper value and check C4 for a possible short with an ohmmeter. If either plate voltage or screen voltage is incorrect check for proper value plate load resistor R2 and also check C3 for a possible short. Also check screen resistor R4 and its bypass capacitor C2 for a possible short or excessive leakage with an ohmmeter. Improper cathode bias could be caused by a defect in cathode resistor R3 or bypass capacitor Cl. Check R3 for proper value with an ohmmeter, and check Cl for a possible short or excessive leakage, also with an ohmmeter. Improper grid bias could be caused by a defect in RI or possibly a defect in the feedback circuit, consisting of the feedback winding within the resolver and R1O, or by a defect in the output circuit of the preceding stage. Check the resistors in question with an ohmmeter and also check the continuity of the resolver winding. Improper grid bias on amplifier V2 would result if coupling capacitor C3 becomes shorted or if there is a significant change in the value of grid resistor R7. No output would also result if capacitor C3 opens, since the ac signal would not reach the grid of V2. Check R7 for proper value with an ohmmeter and check C3 with an in-circuit capacitor checker, since both a short or an open could cause a no-output condition. Improper cathode voltage on V2 could be caused by a defect in R9 or a short in bypass capacitor C5. Check R9 for proper vrdue and check C5 for possible leakage or a short. If the primary of the resolver opened there would be a no-output condition. This can easily be detected since there would be no plate voltage on V2. Various defects within the resolver could cause a no-output condition to exist. The resolver may be checked by measuring the resistance of its windings and by checking for excessive leakage between windings.

Low Output. The resolver-driver is basically a feedback amplifier. A prime characteristic of a feedback amplifier is the ability to maintain their gain at a predetermined level regardless of variations in tube characteristics with age. This characteristic exists because a tendency for the output amplitude to decrease also results in a decrease in the amplitude of the degenerative feedback, which is developed in the output circuit. This decrease in degenerative feedback has the same effect as increasing the input amplitude, and the overall effect is for the gain to remain constant. However, if the components deteriorate beyond the limits of feedback control low output could result. Check the power supply voltage and adjust if necessary. If proper operation is not restored a defective circuit component is most likely the cause of decreased output. A decrease in value of R1O would result in a greater amount of negative feedback reaching the grid of VI and result in decreased closed loop gain, hence, decreased output would result. Check R1O for proper value with an ohmmeter. Voltage checks of tube elements should reveal whether or not a change in operating levels caused by a defective component is the cause of low output. Any discrepancies found during voltage checks can be followed up with resistance measurements of suspected components, as explained in the previous paragraph, to locate the component at fault. A decrease in value of R8 or a shorted C6 could shunt a portion of the output signal around the primary of the resolver, resulting in decreased output. Check R8, with an ohmmeter, for proper value and C6 with an incircuit capacitor checker. A defective resolver can also cause a low output condition to exist. Measure the resistance of all resolver windings being alert for a lower than normal reading which would indicate that some of the turns on the winding in question are shorted. Also check for excessive leakage between windings and to ground.

Distorted Output. A defect in the feedback circuit is a prime cause of distorted output in resolver-driver

circuits. Measure the resistance of the resolver feedback winding and check the ungrounded end of the feedback winding for a possible short to ground. Also check feedback resistor R1O and V1 grid resistor RI for proper value. If the feedback circuit checks out good, check the power supply voltage and check the tubes by exchanging them with tubes which are known to be good. If the resolver-driver output is still distorted a defective component could be altering the operating level of one of the stages and causing distortion to occur. Voltage and resistance checks may be made, as explained previously, to locate the component at fault.

PHASE SENSITIVE NULL DETECTOR CIRCUIT

Application.

The phase sensitive null detector is used in servo control circuits to operate a dc relay when the input error voltage is in phase with the reference voltage.

Characteristics,

Output (position of dc relay) is dependent upon phase relationship between an input error voltage and a reference voltage.

Circuit may be connected so that the output relay is energized when both signals are in-phase, or when they are out-of-phase.

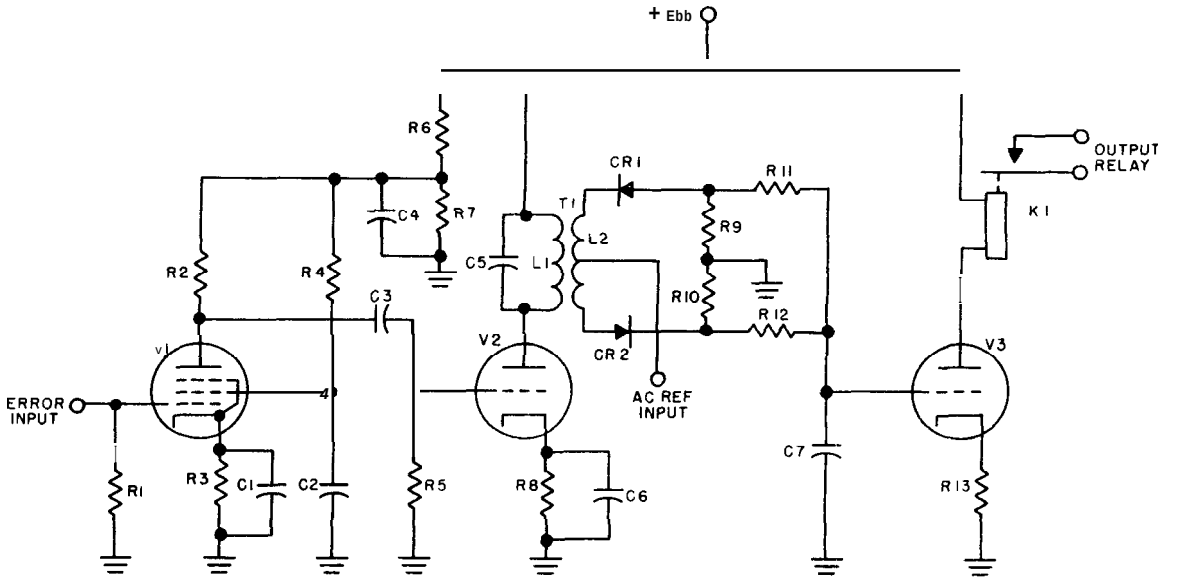
Use a pentode and two triodes.

Circuit Analysis.

General. The phase sensitive null detector consists of a two stage ac amplifier, a phase sensitive detector, and a relay control tube with a dc relay in its plate circuit. Basically the phase sensitive null detector compares ac error voltage to a reference ac voltage and determines whether or not they are in phase. The ac amplifiers provide sufficient gain so that very small error voltages may be effectively compared with the reference voltage, allowing an output to be produced almost immediately after the error voltage becomes in phase with the reference voltage. The amplified ac error voltage is applied to the phase sensitive detector stage through a transformer. The amplitude and polarity of the phase detector output is dependant upon the amplitude of the error voltage input and the phase of the error input with respect to the reference voltage. With the circuit connected in the standard manner the phase sensitive detector stage produces a positive voltage output when the error signal and reference signal voltages are in phase. The detector stage output voltage is faltered and applied to the grid of the final stage, a dc relay control tube. When the detector output voltage is positive, as it is when the error and reference voltages are in phase, conduction of the relay control tube is increased and the relay becomes energized. If the error voltage is out-of-phase with the reference voltage, the detector output voltage is negative and the relay control tube does not energize the output relay.

Circuit Operation. The following schematic diagram illustrates a phase sensitive null detector.

491-044 0 73 81



A-1034
Phase Sensitive Null Detector

Resistor R1 serves as the input grid resistor for pentode amplifier VI. Resistor R2 serves as the plate load for VI while R3 which is bypassed by Cl functions as the cathode bias resistor for VI. Resistor R4 is a series screen dropping resistor, and capacitor C2 is the screen bypass for V1. R-C coupling between V1 and triode amplifier V2 is pronded by capacitor C3 and grid resistor R5. Resistor R8 which is bypassed by C6 serves as the cathode bias resistor for V2, while the primary L1, of transformer T1 which is shunted by C5 serves as the plate load for V2. Resistors R6 and R7 form a voltage divider between the plate supply and ground to provide the proper plate voltage to V1 with capacitor C4 functioning as a bypass capacitor. Transformer T1 couples the error voltage to a phase sensitive detector consisting of diodes CR1 and CR2 and resistors R9 and R1O. The reference voltage is coupled to the phase detector stage via a centertap on the secondary of T1. The output of the phase detector is applied to a filter network "consisting of resistors R11, R12 and capacitor C7. The filtered phase detector output is applied to the grid of relay control tube V3. Resistor R13 serves as an unbypassed (degenerative) cathode bias resistor for V3, while dc relay K1 forms the output load for V3.

The ac error voltage is applied to the grid of amplifier VI, and the large amplitude error voltage developed across plate resistor R2 of amplifier V1 is coupled through capacitor C3 to the grid of amplifier V2. Amplified error voltage is developed across the primary of transformer T1 and is inductively coupled to the secondary of T1. The ac reference voltage is applied to the phase sensitive null detector through a center top on the secondary of T1. For ease of explanation assume for a moment that only the ac reference voltage is applied to the phase detector stage. During the positive half cycle of the ac reference voltage, current flows from ground, through R1O, through CR2, and back to its source, the secondary of T1. Diode CRI is reverse-biased for the positive half cycle of ac reference voltage and does not conduct. Voltage is developed across R1O and the junction of R1O, and R12 is above ground potential. During the negative half cycle of the reference voltage, reference diode CR2 is reverse-biased and does not conduct: However, diode CR1 is forward biased and current flows from the transformer centertop through the top half of the winding, through CR1 and through R9 to ground. A voltage is developed across R9 and the junctionofR9andR11 is below ground potential. The positive voltage produced by the rectifying action of CR2, and the negative voltage, produced by the rectifying action of CR1 , deviate since CR1 and CR2 have the same

4

operational characteristics and resistors R9 and R1O are of equal value. The negative voltage is filtered by RI 1 and C7 and the positive voltage is filtered by R12 and C7. The dc level applied to the grid of relay tube V3 is, therefore, zero volts, when only the reference voltage is applied to circuit. The relay control tube V3 is self biased by its cathode resistor to a conduction level insufficient to energize output relay K1. Since in effect there is no output from the phase detector portion of the phase sensitive null detector when only the ac reference voltage is applied, conduction of V3 does not increaae and the output relay remains deenergized. When an ac error voltage is applied in addition to the ac referenced voltage, there is an output from the detector circuit. The polarity of this output is dependent upon the phase relationship between the error and reference signals. Only a positive output from the detector causes the output relay to become energized. When the a-c reference voltage and the error voltage are in phase the output relay becomes energized in the following manner. During the period of the positive half cycle of input signal, a positive half cycle of reference voltage is applied to the centertop of T1, and is applied equally to both diodes. The error voltage, after being amplified by V1 and V2, is applied to primary winding L1 of T1. A negative half cycle of error voltage is induced across the top half of L2 while a positive half cycle of error voltage is induced across the bottom half of L2. The ac reference voltage and the ac error voltage add across the bottom half of L2 while across the top half of L2 they oppose. The result is a positive detector output during the positive half cycle of inputs, since diode CR2 conducts more heavily than CRI and the resultant voltage drop across RIO exceeds that of R9. When the input signal swings negative, the voltages across the top half of L2 again oppose while across the bottom half they add, but they are of such a polarity that CR2 is back biased and does not conduct. There is therefore a positive output from the detector portion of the phase sensitive null detector when the input signals (error and reference) are in phase. After being faltered by R12 and C7 this positive voltage is applied to the grid to relay control tube V3, causing conduction of V3 to increase, and thereby energizing output relay KI. If the error voltage developed across T1 is of greater amplitude than the reference voltage, a negative voltage is developed across R9 during the positive alternation of the error input. However, the positive voltage developed across R1 O due to the conduction of CR2, is of greater magnitude than the voltage developed across R9 since the reference voltage opposes the error voltage applied to CR1 while it aids the error voltage applied to CR2. The dc level after faltering remains positive and the output relay remains energized. When the error voltage is out-of-phase with the reference voltage, circuit operation is basically the same, except that a negative output is produced by the detector stage and is applied to the grid of V3. The negative output is produced because the two signals applied to the detector stage now add across the top half of L2, and oppose across the bottom hrdf. The magnitude of the current through R9 exceeds that of RIO, and the resultant negative voltage developed across R9 exceeds the positive voltage developed across R1O. The negative voltage applied to the grid of V3 reduces rather than increases conduction of V3 and output relay K1 is not energized. The phase sensitive null detector may also be connected so that the relay becomes energized when the error voltage and the reference voltage are out-of-phase. This may be done simply by reversing either the primary or secondary windings of T1 or by reversing the diodes.

Failure Analysis.

No Output. Failure of the output relay to become energized when the proper conditions are met, i.e., error and references voltages either in or out-of-phase depending upon how the circuit is connected, is considered to be a no-output condition. Failure of any of the three stages (the ac amplifier, the phase detector, or the relay control tube) of the phase sensitive null detector could cause a no-output condition to exist. Failure of the power supply would of course disable the circuit and no output also would result. Check the plate supply with a high resistance voltmeter and likewise check the tubes. If the power supply voltage is satisfactory and the tubes are good, a defective circuit component is most likely the cause of no-output. With an error voltage applied to the input and the reference voltage removed check with an oscilloscope for presence of amplified error voltage on the secondary winding L2 of T1. Also observe the waveform present at the grid of V1 to make sure that the no-output condition is not caused by no input. If there is no error voltage present at the secondary of T1 check the primary of TI to determine whether or not T1 is defective. If the ac error voltage is present

in sufficient amplitude at the plate of V2 the ac amplifier stages may be assumed to be good. If the error voltage is not present at the plate of V2 a defect likely exists in the ac amplifier stages. Voltage checks of tube' elements, which should give an indication of the locality of the faulty components may be made, and then with the circuit deenergized, resistance measurements of suspected components may be made to determine the component at fault. Improper grid bias on V1 could be caused by a defect in R1, or in the output circuit of the preceding stage, while improper cathode bias could be caused by a defect in R3 or a shorted Cl. A defect in voltage divider R6, R7 or a shorted or leaky bypass capacitor C4 would rdter both plate and screen voltage on V1. A change or defect in R2 would alter the plate voltage on V1, and a defect in R4, or a short in C2, would affect screen voltage on VI. Keep in mind that improper grid or cathode bias would also alter plate voltage on an amplifier stage. Improper grid bias on ac amplifier stage V2 could be caused by a shorted coupling capacitor C3 or a defective grid resistor R5, while improper cathode bias could be caused by a defect in cathode resistor R8, or a shorted cathode by pass capacitor C6. Lack of plate voltage on V2 could be caused by an open primary winding, L1 of T1. Capacitor C5 should be checked since the ac error signal would be shunted around T1 if C5 shorted. If the ac reference voltage is not present check the source of the ac reference. If the ac amplifier is operating normally, and the reference voltage is applied to the detector stage, a no-output condition could be caused by a defective phase detector stage or relay control stage. The relay control stage may be easily checked by measuring the resistance of R13, the cathode resistor for V3, and by checking the continuity of relay coil K1. Also check the mechanical action of relay K1 since it could become jammed. Diodes CRI and CR2 of the phase detector stage should be checked by disconnecting one lead of each diode and measuring the front to back ratio of each diode. In general the back ratio of most diodes should be greater than 10:1. The other components of the phase detector stage, resistors R9, R1O, R11, and R12, may be checked by measuring their resistance. Filter capacitor C7 may be checked for proper value with an in-circuit capacitor checker.

Improper Operation. Erratic operation, failure of the output relay to energize, or any type of operation rather than proper operation could be caused by improper plate voltage, a decrease of gain of the ac amplifiers, an unbalance of the phase detector stage, or it could be caused by decreased emission of the relay control tube, or a mechanical defect in output relay K1. Check the power supply voltage and adjust or repair it if necessary. If proper operation is not restored, the tubes may be at fault. If the phase sensitive null detector still does not function properly, the various stages may be checked individually to localize the trouble. The gain of the ac amplifier may be checked .by comparing the amplitude of the error voltage input with the amplitude of the error voltage developed across the primary, L1 of T1 using an oscilloscope. For small error voltages the gain should be around 3000. Be sure to remove the reference voltage when making the previous check since the reference voltage applied to the secondary of T1 could be inductively coupled to the primary of T1 and cause a possible erroneous reading. If the ac amplifier is determined to be defective, the faulty component may be located as explained in the preceding paragraph. The phase detector stage may be checked by removing either V1 or V2 (this disables the ac amplifier) and measuring the voltage on the grid of V3. Any voltage reading other than zero volts indicates an unbalance of the phase detector stage. Check the components as explained in the previous paragraph paying particular attention to the front to back ratio of CR1 compared to CR2 and the resistance of R9 compared to R1O and R11 compared to R12. Filter capacitor C7 should be checked for proper value with an in-circuit capacitor checker, since a change in value of C7 can adversely affect circuit performance. Relay control stage V3 may be checked by measuring the dc resistance of the output relay winding and by checking the mechanical operation of the relay and also checking the resistance of cathode resistor R13.

SECTION 15
COUNTERS

PART 15-1. DIODE

POSITIVE OIODE COUNTER (ELECTRON TUBE)

Application,

The positive diode-counter circuit is supplied uniform input pulses, representing units to be counted, and produces a positive output voltage, the average value of which is proportional to the frequency of the applied pulses. Counter circuits are employed in the frequency-indicator circuits of electronic timing or counting devices.

Characteristics.

input pulses must be of constant amplitude and of equal time duration; a counter circuit must be preceded by limiting and shaping circuits to ensure uniform amplitude and width of input pulses.

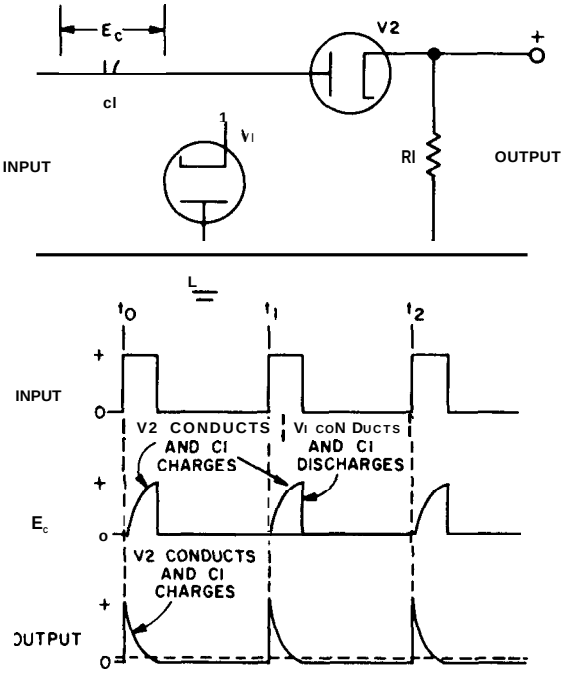
Output-pulse polarity is positive; average dc output voltage level is determined by input pulse-repetition frequency.

Circuit Analysis.

General. The positive counter circuit is used in frequency-indicator (timing or counting) circuits which depend upon the output pulse amplitude and time duration for accurate indications; therefore, the input pulses applied to the counter circuit must be of constant pulse amplitude and pulse width (time duration). The counter circuit is preceded by limiting and shaping circuits so that the only variable element in the counter-circuit output is the repetition frequency of the input signal, enabling input-frequency variations to be measured accurately. A relationship is thereby established between input frequency and average output voltage; as the input frequency increases the output voltage also increases and, conversely, as the input frequency decreases the output voltage decreases. Thus, the positive counter circuit, in effect, "counts" the number of positive-going input pulses and produces an average dc output voltage which is proportional to the input repetition frequency.

The output of the positive counter circuit can also be used to produce positive trigger pulses to synchronize the frequency of blocking-oscillator or multivibrator circuits with the input pulse-repetition frequency. The basic positive counter circuit can be easily modified to change it to a step-by-step counter circuit (described later in this section) by substituting a capacitor for the resistor across the output terminals. This modified circuit is referred to as a frequency divider, because the output trigger frequency is usually made a submultiple of the input pulse-repetition frequency; the circuit is used in trigger-generator circuits of radar modulators and indicators.

Circuit Operation. A basic positive diode counter circuit is shown in the following illustration, together with typical input and output waveforms. Capacitor Cl is the input coupling capacitor and also serves as a dc blocking capacitor; resistor RI is the load resistor across which the output voltage is developed. Electron tubes VI and V2 are indirectly heated diodes; the filament (heater) circuit for the diodes is not shown on the schematic,



Basic Positive-Diode Counter Circuit and Waveforms

Initially, capacitor Cl assumes a charge (reference level) which is determined by the dc voltage (if present) of the preceding stage. Once capacitor Cl is charged to the level of the applied dc voltage, the circuit remains in a quiescent condition until an input is applied; the output voltage at this time is zero.

Pulses applied to the input of the counter circuit must have constant amplitude and equal time duration, since the counter circuit is intended to produce an output voltage which is proportional to the input pulse-repetition frequency. For the purpose of this discussion, assume that the input waveform shown in the accompanying illustration is applied to the input of the counter circuit.

When the positive-going leading edge of the input waveform occurs, the voltage rises suddenly. The charge on coupling capacitor Cl cannot change instantaneously; therefore, the plate of diode V2 becomes positive with respect to its cathode, and the diode conducts. Current flows through the series circuit consisting of load resistor R1 and diode V2 to charge the capacitor, Cl. Since the charging current flows through the load resistor, RI, a pulse voltage is developed across the resistor and is supplied as the output of the counter circuit.

When the negative-going trailing edge of the input waveform occurs, the voltage drops suddenly. Once again the charge on coupling capacitor Cl cannot change instantaneously; therefore, a negative voltage appears across diode VI. (This negative voltage is equal to the charge previously obtained by capacitor Cl from the conduction of diode V2.) Since the cathode of diode VI is now negative with respect to its plate, the diode conducts and discharges capacitor Cl to its initial value. The circuit then remains in a quiescent condition until another pulse is applied to the input.

If it were not for the fact that diode V1 discharges the capacitor each time a pulse is applied to the input, capacitor Cl would soon charge to the peak value of the input waveform as consecutive positive pulses were applied. As a result, no output would be obtained because the circuit would be rendered inoperative.

The charge time of capacitor Cl is determined by the value of resistor R1 and the low internal resistance of diode V2 when conducting. The discharge time of capacitor Cl is determined primarily by the low internal resistance of diode VI when conducting. Thus, the time constant of the discharge path is always less than that of the charge path; therefore, within certain limits imposed by the R-C time constant and the applied pulse-repetition frequencies, the circuit is always in condition to accept the next positive-going input pulse.

From the discussion given in the previous paragraphs, it is evident that there is an average current flowing through resistor RI whenever pulses are applied to the input of the circuit; also, a pulse voltage is produced across resistor R1 for each input pulse applied to the circuit. Thus, an average voltage is produced across resistor R1 which varies in accordance with the repetition rate of the input pulses; the average voltage increases as the input frequency increases, and vice versa. Since the output voltage level changes in proportion to changes in the repetition frequency of the applied input pulses, the output voltage can be fed to a succeeding stage which controls a suitable indicating device. The indicating device, in turn, can be calibrated in units of time, frequency, revolutions per minute, etc., based upon the relationship of output voltage to input frequency.

Failure Analysis.

General. The positive diode counter circuit is a relatively simple circuit consisting of only four components–diodes VI and .V2, capacitor Cl, and resistor R1. For this reason, failure analysis is somewhat limited.

initially, the input signal to the counter circuit should be checked to determine whether it is present and has the correct amplitude and pulse width.

A visual check should be made to determine whether the filaments (heaters) of diodes V1 and V2 are lit and whether the filament circuit is complete. The diodes should be checked in a tube tester. If diode V1 is open and fails to conduct, capacitor Cl will charge to the peak value of the applied input pulse and, once the capacitor is fully charged, no output will be developed across the load resistor, R1; if diode V1 shorts, no output will be developed across the load resistor. If diode V2 is open or fails to conduct, no output will be developed across the load resistor; if diode V2 shorts, a positive output pulse will be developed across the load resistor, together with a small negative output pulse which will coincide with the negative-going trailing edge of the input waveform.

The counter circuit is normally preceded by limiter-shaper stages; therefore, in some cases a dc

potential exists at the input to the circuit. If coupling capacitor Cl should become leaky (or shorted), a voltage-divider action will occur. For this condition, it is likely that diode V2 will conduct at all times, and a dc potential which is above normal will be developed across resistor RI. Capacitor Cl can be checked with a suitable capacitance analyzer; resistor R1 can be measured with an ohmmeter to determine its resistance.

POSITIVE DIOOE COUNTER (SEMICONDUCTOR)

Application

The positive diode-counter circuit is used to count pulses and provide frequency indication. It is mainly used in electronic timing and counting devices, but it is sometimes employed as a frequency divider and in elementary types of computers.

Characteristics.

Requires an input pulse of constant amplitude and time duration.

Provides a positive output voltage with an average dc level that is proportional to the input pulse repetition frequency.

May be used to synchronize a blocking oscillator at a submultiple of original frequency.

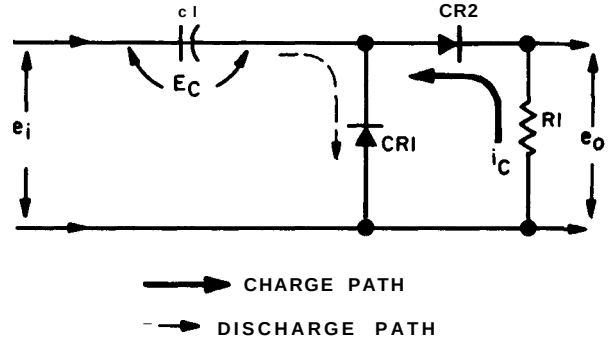
Requires an output circuit to provide a direct-reading output indication.

Requires that limiting and shaping circuits precede it.

Circuit Analysis.

General. The positive diode-counter circuit is used in timing or counting circuits which depend upon a proportional relationship between the output voltage and the number of input pulses. It may indicate frequency, it may count the rpm of a shaft or other device, or it may even register the number of operations. (This circuit is not the same as the binary or decade counter which is used in computers.) The counter establishes a direct relationship between the input frequency and the average d-c output voltage. As the input frequency increases the output voltage also increases; conversely, as the input frequency decreases the output voltage decreases. In effect, the positive diode-counter counts the number of positive input pulses by producing an average d-c output voltage which is proportional to the repetition frequency of the input signal. For accurate counting, the pulse repetition frequency must be the only variable parameter in the input signal. Therefore, careful shaping and limiting of the input signal is essential to ensure that the pulses are of uniform width, or time duration, and that the amplitude is constant. When properly faltered and smoothed, the dc output voltage of the counter may be used to operate a direct-reading indicator. With slight modifications, the circuit can also be used to control a blocking oscillator and cause it to provide a trigger output which is synchronized at a submultiple of the original repetition frequency. (This modification is discussed under the Step-by-Step Counter circuit, which appears later in this section.)

Circuit Operation. The basic positive diode-counter circuit is shown in the following illustration. Capacitor Cl is the input coupling and d-c blocking capacitor. CR1 and CR2 are semiconductor diodes, and resistor RI is the load resistor, across which the output voltage is developed. For the purpose of circuit discussion, it is assumed that the input pulses are of constant amplitude and time duration, and that only the pulse repetition frequency changes.



Positive Diode Counter

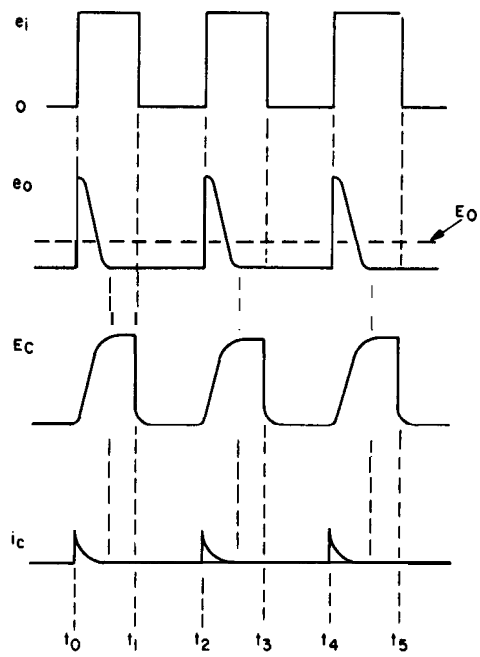
Once capacitor Cl is charged, it assumes a reference level as determined by the dc voltage applied to the preceding stage, and the circuit remains in a quiescent condition until an input signal is applied. Prior to the application of the input pulse, the output voltage is zero.

As shown in the following illustration, at time t. the positive-going input pulse is applied to Cl and causes the anode of CR2 to go positive. As a result,

CR2 conducts and current i_c flows through RI and CR2 to charge Cl. Current i_c develops an output voltage (e_o) across R1 as shown in the illustration.

The initial heavy flow of current produces a large voltage across R1, which tapers off exponentially as Cl charges. The charge on Cl is determined by the time constant of load resistor RI and the forward diode resistance, in series, times the capacitance of C_1. For ease of explanation, it is assumed that Cl is charged to the peak value before time t_1.

At time t_1 the input signal reverses polarity and becomes negative-going. Although the charge on Cl cannot change instantly, the applied negative voltage is equal to or greater than the charge on Cl so that the anode of CR2 is made negative, and conduction ceases. When CR2 stops conducting, output pulse e_o is at zero, and Cl quickly discharges through CR1, since its cathode is now negative with respect to ground (anode is grounded). Between times t_1 and t_2 the input pulse is again at zero level, and CR2 remains in a non-conducting state. Since the very short time constant offered by the forward resistance of CR1 and Cl is much less than the long time constant offered by CR2 and R1 during the conduction period, Cl is always completely discharged between pulses. Thus, for each input pulse there is an exact amount of charge deposited in Cl. For each charge of Cl an identical output pulse is produced by the flow of i_c through R1. Since this current flow always occurs in the direction indicated by the solid arrow, the dc output voltage is positively polarized.



W

At time t_2 the input signal again goes positive, and the cycle repeats. The time duration between pulses is the interval represented by the period between t_1 and t_2 or between t_3 and t_4. If the input pulse frequency is reduced, these time periods become longer. On the other hand, if the frequency is increased, these time

intervals become shorter. With shorter periods, more pulses occur in a given time and a higher average (de) output voltage is produced; with longer periods, fewer pulses occur and a lower output voltage is produced. Thus, the dc output is directly proportional to the repetition frequency of the input-pulses. If the current and voltage are sufficiently large, a direct-reading meter can be used to indicate the count; if they are not large enough to actuate a meter directly, a dc amplifier may be added. In the latter case, a Pi-type smoothing falter is inserted at the output of RI, to absorb the instantaneous pulse variations and produce a smooth direct current for amplification.

Consider now some of the limits imposed on circuit operation. Since the semiconductor diode has a finite reverse resistance, there is a flow of reverse current during the periods when the diode is supposedly in a nonconducting condition. Although this reverse flow is small at normal temperatures (on the order of microampere), it increases as the temperature rises. Therefore, at high temperatures and high repetition rates, the average output voltage will tend to decrease because of the effects of diode CR2. Similarly, diode CR1 will tend to shunt some of the input signal to ground. Thus, the net over-all effect with increasing frequency is a progressive decrease in the linearity (that is, a reduction in the proportionality of input frequency to output voltage), and at very high repetition rates the circuit may become inoperative. Fundamentally this is a design problem which can be minimized by proper choice of components; it is mentioned here merely to indicate why semiconductor circuits sometimes do not perform as well as their electron tube counterparts.

Failure Analysis.

No Output. A no-output condition maybe caused by an open-circuited coupling capacitor, by defective diode CR2, or by a short-circuited condition (defective diode CR1, grounded CR2, or shorted load resistor RI). This condition can be easily resolved by a resistance check. Observing the proper polarity, check the diodes for a high reverse resistance and a low forward resistance. As a general rule, the reverse resistance should be 50K or greater, and the forward resistance should not be more than 10 ohms (these values vary with different types of diodes). Also, observe the input signal with an oscilloscope to make certain that it is present; the point at which the signal disappears will generally locate the defective component.

Low Output. If CR2 develops a high forward resistance, the output voltage will be reduced. If coupling capacitor C_1 becomes leaky, either a negative or a positive bias will be placed on CR2, depending upon the polarity of the previous stage collector or plate voltage. A negative bias on CR2 will prevent it from conducting, and will also act as a forward bias for CR1, causing it to conduct continually. Under these conditions, C_1 will constantly be discharging and the pulse will be reduced in amplitude (depending on the amount of leakage). Heavy leakage may result in no output at all, but it is more likely that the leakage will be light and only reduce the output. To check Cl for leakage, connect a dc voltmeter between the output terminal of Cl and ground. If Cl is leaky, a constant negative or positive voltage will be present.

High Output. (For a positive leakage voltage through C_1, CR2 will conduct continually, and a higher-than-normal voltage will most probably be indicated.) If CR1 develops a high forward resistance, Cl will not be completely discharged at the termination of the input pulse. As a result, the output voltage will rise to a value equal to the dc potential applied to Cl and remain constant regardless of pulse frequency changes.

NEGATIVE DIODE COUNTER (ELECTRON TUBE)

Application.

The negative diode counter supplies a negative voltage output directly proportional to the repetition rate of incoming pulses. The negative diode counter is commonly employed in radar timing circuitry.

Characteristics.

Input pulses must have uniform width and amplitude; only repetition rate may vary.

Usually preceded by limiting and shaping circuitry.

Develops a negative voltage output directly proportional to the repetition rate of incoming pulses.

Always returns to quiescent state between pulses.

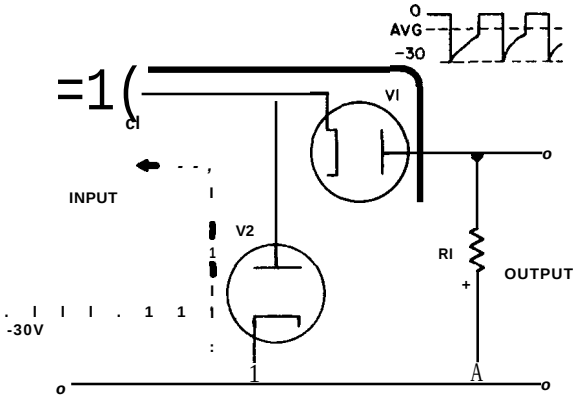
Circuit Analysis.

General. The negative diode counter circuit is used as a frequency indicating device in radar timing circuitry. With some modification, the diode counter may also be used as an f-m detector, a frequency divider or, when used in conjunction with a blocking oscillator or multivibrator, as a synchronizer.

Briefly, the negative diode counter furnishes a negative voltage output directly proportional to the repetition rate of the incoming pulses, provided pulse width and amplitude does not vary. If the repetition rate of the pulses increases, current flow through the load resistor also increases (occurs more times per second) and consequently the total voltage developed also increases.

Basically the diode counter utilizes the characteristics of a capacitor and diode to perform its function. The fact that a capacitor takes a finite time to charge and that a diode only conducts when its cathode is negative with respect to its plate, allows a voltage to be developed across the load resistor which is proportional to the repetition rate.

Circuit Operation. A basic negative diode counter, along with input and output waveforms, is shown in the following schematic diagram.



Basic Negative Diode Counter

Capacitor Cl is the input coupling capacitor and RI is the load resistor. Diode VI is in series with the load resistor and it can easily be seen that as long as V1 conducts there will be an ouput, conversely, diode V2 is connected in parallel with the load, and as long as V2 conducts there will not be an output. Thus, V1 acts as an off-on switch, while V2 operates as a discharging diode. Since the circuit is to function as a frequency indicating device, it is necessary that pulse amplitude and duration remains the same for each pulse, with only the time between pulses (or repetition rate) being allowed to change. Hence, the negative diode counter is usually preceded by limiting and shaping circuits to ensure that each pulse is uniform.

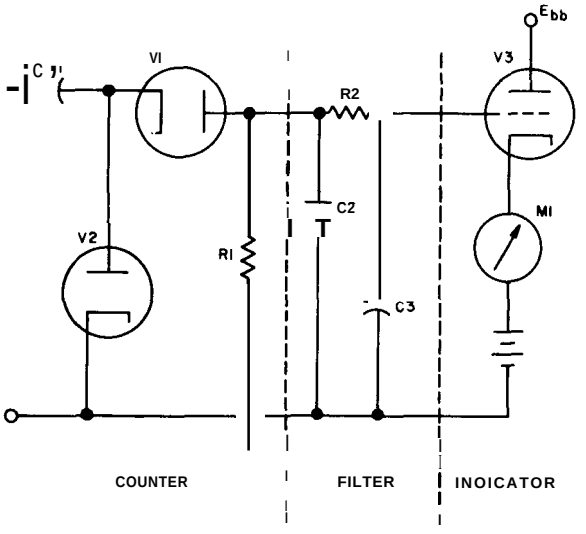
As the negative leading edge of the initial incoming pulse appears at the input, capacitor Cl begins to charge; however, it is known from basic theory that a capacitor is unable to charge instantaneously. Consequently, at the first instant the signal is applied, the peak negative voltage appears on the cathode of V1, causing the tube to conduct. As the tube conducts, current flows through the load resistor, R1 to ground, developing a negative output voltage. As Cl charges, the voltage applied to the cathode of VI becomes less negative and tube condition decreases, causing less voltage to be developed across load resistor R1, forming the curved portion of the output waveform as the capacitor charges.

As the positive going trailing edge of the pulse is applied to the input, Cl again cannot instantly change in potential. Consequently, the cathode of V1 instantaneously becomes positive with respect to its plate (because of the charge on Cl) and current flow through the diode and series load resistor ceases, instantly dropping the output voltage level to zero. Simultaneously; since V2 plate is now positive, V2 conducts discharging the capacitor. The circuit is returned to the initial quiescent condition with a discharged capacitor awaiting the next input pulse.

It is essential to remember that the circuit is returned to a quiescent condition each time the incoming input pulse returns to zero level, regardless of the pulse repetition rate. Referring to the schematic diagram it can easily be seen that charge current, (current flowing in the circuit whale Cl is charging) flows through the combined resistance of V1 and R1, while discharge current (current flowing in the circuit while Cl is discharging) flows only through the conducting resistance of V2. For example, if we assign the load resistor and the conducting resistance of the identical diodes a resistance of 10 thousand ohms and 100 ohms, respectively, it may easily be seen that charge current flows through 10,100 ohms, while discharge current flows through a mere 100 ohms. Hence, the time constant of the charging cycle is very large with

respect to that of the discharging cycle (approximately 100 to 1), and any voltage stored in Cl during change is immediately discharged through V2, returning the circuit to its quiescent state.

From the preceding discussion it is evident that the voltage across the output varies in direct proportion to the input pulse repetition rate. Hence if the repetition rate (frequency) if the incoming pulses increases, the voltage across RI also increases. In order for the circuit to function as a frequency counter, some method must be employed to utilize this frequency – voltage variation to operate an indicator. The following schematic diagram represents one simple circuit which may be used to perform this function. In this circuit the basic counter is fed into a low pass smoothing falter, which controls an electron tube with a cathode current meter calibrated is units of frequency.



Circuit Application

The negative output voltage developed across counter load resistor R1 is applied to the grid of V3 through a pi-falter network consisting of C2, R2 and C3. In this application the purpose of the falter is to smooth out any rapid increase or decrease in output voltage thus providing continuously smooth operation.

The faltered negative counter voltage is applied as bias to the grid of V3 and varies the plate current which flows through a meter in the cathode of V3. The meter is linearly calibrated on the front panel to indicate changes in current as a linear frequency change. For example, assume the circuit is operating and a specific frequency is indicated on the front panel meter. As the repetition rate of the pulses increases, the average voltage across the load resistor also increases and a larger bias is applied to V3. Plate current through V3 decreases, and as current through the meter decreases, a higher frequency indication is evident on the calibrated meter scale on the front panel of the equipment. If the applied frequency were to decrease, the opposite effect would occur and a greater plate current flow would produce a lower frequency indication on the meter.

Failure Analysis.

No Output. Because the basic circuit only incorporates four components and operation is relatively simple, detailed trouble analysis is not necessary. If trouble is experienced with the circuit use an oscilloscope to check the input pulse train for uniform width and amplitude. Also check both diodes. If the trouble persists, check the dc resistance of R1 with an ohmmeter. Also check the coupling capacitor Cl with an in-circuit capacitor checker.

Weak Output. If a weak (or incorrect) output condition exists, check the input pulse train for uniform width and amplitude using an oscilloscope. Also check both diodes. Check the dc resistance of R1 using an ohmmeter and also check Cl with an in-circuit capacitor checker.

NEGATIVE DIODE COUNTER (SEMICONDUCTOR)

Application.

The negative diode-counter circuit is used to count pulses and provide frequency indication. It is mainly used in electronic timing and counting devices, but it is sometimes employed as a frequency divider and in elementary types of computers.

Characteristics.

Requires an input pulse of constant amplitude and time duration.

Provides a negative output voltage with an average dc level that is proportional to the input pulse repetition frequency.

May be used to synchronize a blocking oscillator at a submultiple of original frequency.

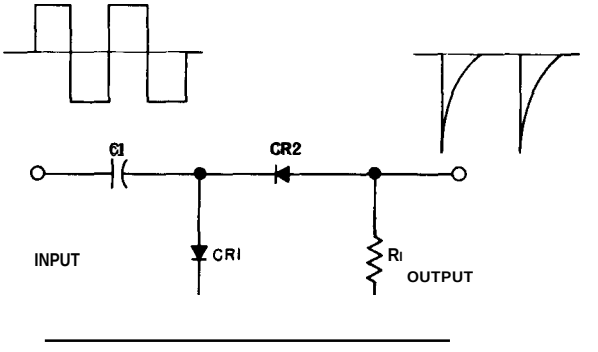
Requires an output circuit to provide a direct. reading output indication.

Requires that limiting and shaping circuits precede it.

Circuit Analysis.

General. The negative diode-counter circuit is used in timing or counting circuits which depend upon a proportional relationship between the output voltage and the number of input pulses. It may indicate frequency, it may count the rpm of a shaft or other device, or it may even register the number of operations. The diode counter establishes a direct relationship between the input frequency and the average dc output voltage. As the input frequency increases the output voltage also increases; conversely, as the input frequency decreases; the output voltage also decreases. In effect, the negative diode-counter counts the number of negative input pulses by producing an average dc output voltage which is proportional to the repetition frequency of the input signal. For accurate counting, the pulse repetition frequency must be the only variable in the input signal. Therefore, careful shaping and limiting of the input signal is essential to ensure that the pulses are of uniform width, or time duration, and that the amplitude is constant. When properly faltered and smoothed, the dc output voltage of the counter may be used to operate a direct-reading indicator. With slight modifications, the circuit can also be used to control a blocking oscillator and cause it to provide a trigger output which is synchronized at a submultiple of the original repetition frequency. (This modification is discussed under the Step-by-Step Counter circuit, which appears later in this section.)

Circuit Operetion. The basic negative diode-counter is shown in the following illustration. Capacitor C 1 is the input coupling and dc blocking capacitor.

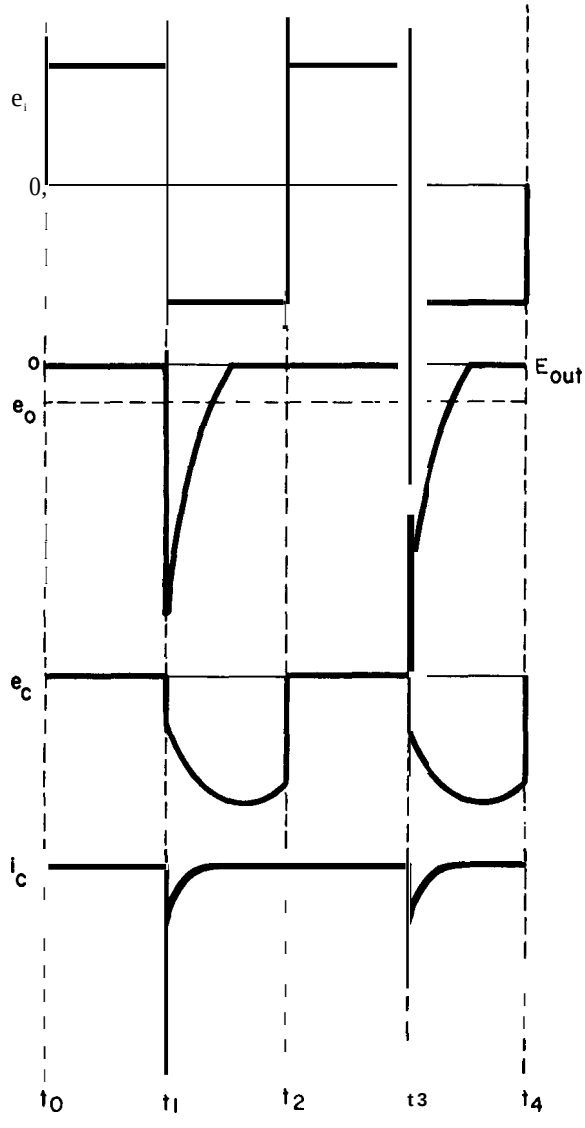


Negative Diode Counter

CR1 and CR2 are semiconductor diodes, and resistor R1 is the load resistor, across which the output voltage is developed. For the purpose of circuit discussion, it is assumed that the input pulses are of constant amplitude and time duration, and that only the pulse repetition frequency changes.

Once capacitor Cl is charged, it assumes a reference level as determined by the dc voltage applied to the preceding stage, and the circuit remains in a quiescent condition until an input signal is applied. Prior to the application of the input pulse, the output voltage is zero.

As shown in the following illustration, at time t. the positive-going input pulse is applied to Cl and causes the anode of CRI to go positive. As a result, CR1 conducts and charges Cl.



Circuit Waveforms

Cl charges very rapidly because of its short time constant with CR1, but there is no output at this time because there is no current flow through R1. At time t_1, the input amplitude suddenly drops from maximum positive to maximum negative. The capacitor cannot discharge through CR1, because the anode of the diode is negative with respect to its cathode. The anode of CR2, however, is now positive with respect to its cathode and begins to conduct. The capacitor voltage and the applied voltage now aid each other, and they produce a current flow through CR2, down through RI, to ground, the result being as illustrated in the diagram. As Cl begins charging through RI, the voltage across RI, and hence the output voltage, begins to decrease towards zero at an RC rate, and at some time between t_1 and t_2, the capacitor is charged to the new voltage, producing zero volts at the output.

At time t_2 the input signal again goes positive, and the cycle repeats. The time duration between pulses is the interval represented by the period between t_1 and t_2, or between t_3 and t_4, If the input pulse frequency is reduced, these time periods become longer. On the other hand, if the frequency is increased, these time intervals become shorter. With shorter periods, more pulses occur in a given time and a higher average (de) output voltage is produced; with longer periods, fewer pulses occur and a lower output voltage is produced. Thus, the dc output is directly proportional to the repetition frequency of the input pulses. If the current and voltage are sufficiently large, a direct-reading meter can be used to indicate the count; if they are not large enough to actuate a meter directly, a dc amplifier may be added. In the latter case, a Pi-type smoothing falter is inserted at the output of Rl, to absorb the instantaneous pulse variations and produce a smooth direct current for amplification.

Consider now some of the limits imposed on circuit operation. Since the semiconductor diode has a finite reverse resistance, there is a flow of reverse current during the periods when the diode is supposedly in a nonconducting condition. Although this reverse flow is small at normal temperatures (on the order of microampere), it increases as the temperature rises. Therefore, at high temperatures and high repetition rates, the average output voltage will tend to decrease because of the effects of diode CR2. Similarly, diode CRI will tend to shunt some of the input signal to ground. Thus, the net over-all effect with increasing frequency is a progressive decrease in the linearity (that is, a reduction in the proportionality of input frequency to output voltage), and at very high repetition rates the circuit may become inoperative. Fundamentally this is a design problem which can be minimized by proper choice of components; it is mentioned here merely to indicate why semiconductor circuits sometimes do not perform as well as their electron tube counterparts.

Failure Analysis.

No Output. A no-output condition maybe caused by an open coupling capacitor, by defective diode CR2, or by a short-circuited condition (defective diode CR1, grounded CR2, or shorted load resistor Rl). These conditions can be easily resolved by a resistance check. Observe the proper polarity, and check the diodes for a high reverse resistance and a low forward resistance. As a general rule, the reverse resistance should be 50K or greater, and the forward resistance should not be more than 10 ohms (these values vary with different types of diodes). Also, observe the input signal with an oscilloscope to make certain that it is present; the point at which the signal disappears will generally locate the defective component.

Low Output. If CR2 develops a high forward resistance, the output voltage will be reduced. If coupling capacitor Cl becomes leaky, either a negative or a positive bias will be placed on CR2, depending upon the polarity of the previous stage collector or plate voltage. A positive bias on CR2 will prevent it from conducting, and will also act as a forward bias for CR1, causing it to conduct continually. Under these conditions, Cl will constantly be discharging and the pulse will be reduced in amplitude (depending on the amount of leakage). Heavy leakage may result in no output at all, but it is more likely that the leakage will be light and only reduce the output. To check Cl for leakage, connect a dc voltmeter between the output terminal of Cl and ground. If Cl is leaky, a constant negative or positive voltage will be present.

High Output. (For a negative leakage voltage through Cl, CR2 will conduct continually, and a higher-than-normal voltage will most probably be indicated.) If CR1 develops a high forward resistance, Cl will not be completely discharged at the termination of the input pulse. As a result, the output voltage will rise to a value equal to the dc potential applied to Cl and remain constant regardless of pulse frequency changes.

STEP-BY-STEP COUNTER (ELECTRON TUBE)

Application.

The step-by-step counter is used as a voltage divider in electronic equipment when it is necessary to provide a stepped voltage output to a relaxation oscillator or any other device requiring a stepped voltage trigger.

Characteristics.

Provides a stepped voltage output.

As the number of input pulses increases for one pulse of output, the counting accuracy decreases.

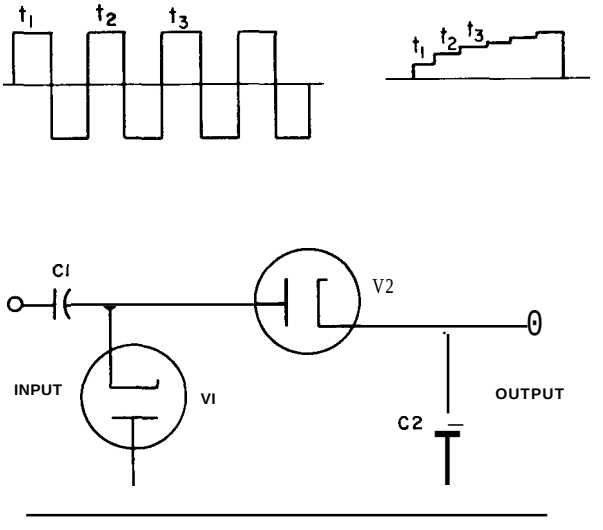
Utilizes two diodes.

One step out occurs for each cycle of input.

Circuit Analysis.

General. The step-by-step counter (commonly referred to as simply a step counter) provides an output which increases exponentially in such a way that the output increases by a one step increment for each cycle of input. At a predetermined level, the output voltage reaches a point which causes some circuit, such as a relaxation oscillator, to be triggered.

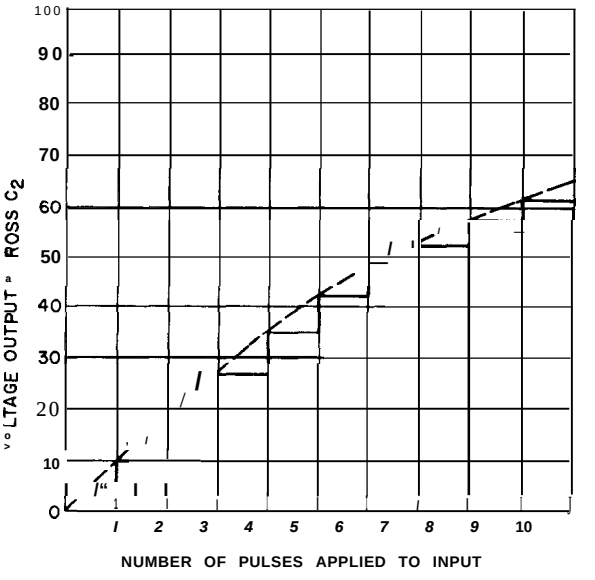
Circuit Operation. A schematic diagram of a step counter is illustrated in the following figure.



Basic Step-by-Step Counter Circuit

With no signal applied at the input, there is no output. As the input signrd is applied, and increases in a positive direction, the plate of V2 becomes more positive than its cathode, and the tube conducts, When V2 conducts, capacitors Cl and C2 begin

charging. The action of the counter can be best understood by referring to the following figure. Since C2 is larger than Cl (for the sake of explanation, we will assume it to be ten times as large, and that the peak voltage of the input is 100 volts), Cl assumes nine tenths of the input voltage and C2 assumes only one tenth, or in this example, 10 volts. At time t_2, the input drops to a negative value, and V2 is driven into cutoff. At the same time, the cathode of V1 becomes more negative than its plate, and conducts, discharging Cl. The charge on C2 remains, however, because it has no discharge path. Thus, there is a dc voltage at the output which is equal to one tenth of the input. At time t_2, the input again increases positively, but this time V2 cannot conduct until the input becomes greater than 10 volts, the charge on C2. At this level, V2 conducts and C2 again charges to one tenth of the total available voltage. The total available voltage at this time, however, is no longer 100 volts, but 100 volts minus the 10 volt charge on C2. Thus, the first cycle of input produced a ten volt charge on C2, but the second cycle added only an additional 9 volts, which is one tenth the quantity of 100 volts minus the 10 volt charge on C2. By the same token, the third cycle adds only one tenth of 81 volts, which results from 100 volts minus the 19 volt charge on C2. Each additional cycle provides an exponential increase in the same manner. It is for this reason that the accuracy decreases as the ratio increases, because as the ratio becomes too great, the higher steps become almost indiscernible.



Waveform of Step Voltage

When the counter is used to trigger a relaxation oscillator, the oscillator bias is adjusted to cause triggering at a specific step. When the relaxation oscillator draws grid current, it discharges C2 and the cycle repeats. The step counter therefore becomes a frequency divider, supplying one output trigger for a number of input triggers,

As previously mentioned counting stability is dependent upon the exponential charging rate of capacitor C2. When it is desired to count by a large number, for example, 24, a 6:1 counter and a 4:1 counter connected in cascade may be used. A more stable method of counting 24 would be to use a 2:1, a 3:1, and a 4:1 counter in cascade. Most step counters operate on ratios of 5:1 or less.

Failure Analysis.

No Output, A shorted VI, a non-conducting V2, an open or shorted C2, or a shorted Cl may cause a no-output condition to exist. Check both capacitors with an in-circuit capacitor checker.

Inaccurate **Output Ratio.** A low emission or shorted tube V1 or V2, or a leaky Cl or C2, can produce an inaccurate count. Check the tubes and if an accurate count still exists, check both capacitors with an in-circuit-capacitor checker.

STEP-BY-STEP COUNTER (SEMICONDUCTOR)

Application.

The step-by-step counter is used as a voltage divider in transistorized equipment when it is necessary to provide a stepped voltage output to a relaxation oscillator or any other device requiring a stepped voltage trigger.

Characteristics.

Provides a stepped voltage output which increases exponentially.

As the number of input pulses increases for one output pulse, the counting accuracy decreases.

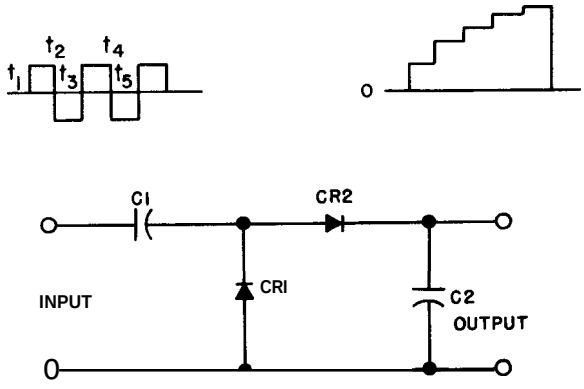
Utilizes two semiconductor diodes.

One step of output voltage is obtained for each cycle of input voltage.

Circuit Analysis.

General. The step-by-step counter (commonly referred to as simply a step-counter) provides an output which increases exponentially in such a way that the output increases by one-step increments for each cycle of input. At a predetermined level, the output voltage reaches a firing point which causes some circuit, such as a relaxation oscillator, to be triggered.

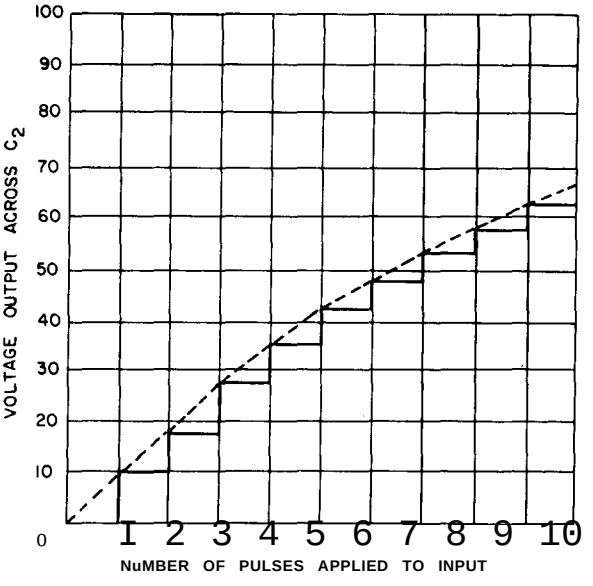
Circuit Operation. A schematic diagram of a step-counter is shown in the following illustration.



Basic Step-Counter Circuit

With no signal applied to the input, there is no output. As the input signal is applied, and increases in a positive direction, the anode of CR2 becomes more positive than its cathode, and the diode conducts. When CR2 conducts, capacitors Cl and C2 begin charging. The action of the counter can be best understood by referring to the following figure. Since C2 is larger than Cl (for the sake of explanation, we will assume it to be ten times as large, and the peak voltage of the input is 100 volts), Cl assumed nine tenths of the input voltage while C2 assumes only one tenth, or in this example, 10 volts. At time t_2, the input drops to a negative value, and CR2 is driven into cut-off. At the same time, the cathode of CR1 becomes more negative than its anode, and conducts, discharging Cl. The charge on C2 remains, however, because it has no discharge path. Thus, there is a dc voltage at the output which is equal to one tenth of the input. At time t_2, the input again increases positively, but this time CR2 cannot conduct until the input becomes greater than 10 volts, the charge on C2. At this level, CR2 conducts and C2 again charges to one tenth of the total available voltage. The total available voltage at this time, however, is no longer 100 volts, but 100 volts minus the 10 volt charge on C2. Thus, the first cycle of input produced a ten volt charge on C2, but the second cycle added only an additional 9 volts, which is one tenth the quantity of 100 volts minus the 10 volt charge on C2. By the same token, the third cycle adds only one tenth of 81 volts. which results from 100 volts minus the 19 volt

charge on C2. Each additional cycle provides an exponential increase in the same manner. It is for this reason that the accuracy decreases as the ratio increases, because as the ratio becomes too great, the higher steps become almost indiscernible.



Waveform of Step Voltage

When the counter is used to trigger a relaxation oscillator, the oscillator bias is adjusted to cause triggering at a specific step. When the relaxation oscillator draws grid current, it discharges C2 and the cycle repeats. The step-counter, therefore, becomes a frequency divider, supplying one output trigger for a number of input triggers.

As previously mentioned, counting stability is dependent upon the exponential charging rate of capacitor C2. When it is desired to count by a large number, for example, 24, a 6:1 counter and a 4:1 counter connected in cascade may be used. A more stable method of counting 24 would be to use a 2:1, a 3:1 and a 4:1 counter in cascade. Most step counters operate on ratios of 5: 1 or less.

In actual theory, the reverse resistance of the diode will allow a portion of the charge of C2 to leak off. This leakage, however, in a practical circuit, will be negligible, because the diodes which are selected for use are types which will have a very high reverse resistance, so that the ratio between the charge time and the discharge time will be very large.

Failure Analysis.

No Output. A shorted CR1, a non-conducting (open) CR2, an open or shorted output capacitor C2, or a shorted coupling capacitor Cl, may cause a no-output condition to exist. Check both capacitors with an in-circuit capacitor checker. Check the diodes with an ohmmeter, being sure to observe the proper polarities, since an erroneous indication may otherwise be obtained. For the special case where the diode is not completely shorted, but reads a very low reverse resistance of, say 2000 -obms or less, the diode may be considered defective. In good condition, the diode reverse resistance should be 50,000 -ohms or better, with a forward resistance of about 10 ohms (these values will vary from type to type).

Inaccurate Output Ratio. A low conducting, or a complete or partial short of CRI or CR2, or a leaky Cl or C2, can produce an inaccurate count. Check both capacitors with an in-circuit capacitor checker. If an inaccurate count still exists, check both diodes with an ohmmeter, being sure to observe the proper polarities, since an erroneous indication may otherwise be obtained. For the special case where the diode is not completely shorted, but reads a very low reverse resistance of, say 2000-ohms or less, the diode may be considered defective.

SECTION 16
LOGIC CIRCUITS

PART 16-0. INTRODUCTION

LOGIC POLARITY

General.

Computer logic is expressed by a form of two-value logic which is easily adaptable to the binary number system. Thus computer elements (circuits) have only two states, such as: the conduction or non-conduction of a circuit, the presence or absence of a hole on a card or paper, or the presence or absence of a magnetic field. The use of two-value logic also means that, basically, these states may assume a value of either O or 1. (While true or false could also be used, the numeric values lend themselves readily to computations and algebraic manipulations.)

In any electrical circuit, any two distinct voltages or currents can be used to represent the two logic states of O and 1. For example, a negative voltage could indicate O and a positive voltage could indicate 1, or vise versa. Likewise, current flow into the circuit could indicate O, and current flow out of the circuit could indicate 1. Similar results could be obtained with amplitude control, using small and large voltages or currents. Pulses could also be used in a like fashion, with a negative pulse indicating O and a positive pulse indicating 1; or O could be indicated by the absence of a pulse, in which case the presence of a pulse could signify 1. Many combinations of logic expressions are possible; they can also be used interchangeably, since each logic element (circuit) or operating entity can actually function independently as long as the desired result is achieved. Mixed logic systems are not used in large computers, however, since this practice would cause expensive circuit complications. Most presentday logic systems utilize polarity to define the circuit state, since positive and negative voltages are easily obtained and manipulated, regardless of whether the actual logic element (circuit) employs relays, switches, diodes, or transistors. Logic circuits can be divided into two generrd classes, according to polarity, namely positive and negative logic. As employed on logic diagrams, a signal may assume either the “active (or true)” state (logic 1), or the “inactive (or flase)” state (logic O). The electrical signal levels used and a statement concerning whether positive or negative logic applies are usually specified explicitly on the individual logic diagrams by the manufacturer of the logic designer.

In practice, many variations of logic polarity are employed: for example, from a high-positive to a low-positive voltage, or from positive to ground; from a high-negative to a low-negative voltage, or from negative to ground; and mixed polarity, from a high positive to a negative (below ground) potential, and vice versa. A brief discussion of the two general classes of polarity is presented in the following paragraphs. Each of the logic circuit discussions also given in this section will be based upon the form of logic polarity best suited for simple explanation of the circuit action.

Positive Logic.

Positive logic polarity is defined as follows: when the logic 1 state has relatively more positive electrical level than the logic O state, and the circuit is activated (operated) by the logic 1 signal, the logic polarity is considered to be positive. The following typical examples illustrate the manner in which positive logic may be employed.

Example 1: Logic 1 = +10 volts
Logic O = 0 volts

Example 2: Logic 1 = 0 volts
Logic O = -10 volts

In both examples the logic 1 state is always more positive than the logic O state, even though in example 2 the logic O state is negative. The previous statements and definitions are particularly appropriate for dc switching circuits, but also apply to ac circuits as well. For example, a positive pulse can be used to simulate a positive voltage, and a negative pulse can be used to simulate a negative voltage. However, such complexity is unnecessary, since the absence of a pulse can signify the logic O state and the original definition of positive polarity will still apply. That is, the logic 1 state is more positive than the no signal (or logic O) state.

As normally used, positive logic is more adaptable to NPN type transistors because of the NPN polarity requirements. Since a positive collector voltage is

required to reverse-bias the NPN transistor, operation of the transistor produces either a low or a high positive output voltage. Thus by using direct coupling, a fully transistm-ized, positively polarized 'dc system can be developed, thereby eliminating interstage coupling capacitors and any possible waveform distortion effects. The functioning of direct-coupled transistor logic (DCTL) circuits is discussed later in this section. The use of positive logic, however, is not restricted to NPN transistors, since PNP transistors can be used in ac systems using the common-emitter (CE) configuration, which inverts the input polarity in the output circuit. The use of NPN transistors merely makes the design of dc positive logic circuits easier and simpler, so that normally positive logic is associated with NPN transistors, while negative logic is associated with PNP transistors. At present, however, it is unimportant which type of logic polarity (positive or negative) is used, since logic components and circuits are available for all types. In fact, by using a form of mnemonic (symbolic) notation, such as H for the high or active state (l), and L for the low or inactive state (0), logic design may be completed and circuitry devised without concern for the polarity or levels used. Once the logic design is completed, standard circuits of the proper type and polarity for the components and level to be used are selected, and the unit is constructed.

Negative Logic.

Negative logic polarity is defined as follows: when the logic 1 state has relatively more negative electrical level than the logic O state, and the circuit is activated (operated] by the logic 1 signal, the logic polarity is considered to be negative. The following typical examples illustrate the manner in which negative logic can be employed.

Example 1:	Logic 1 = O volts
	Logic *o* = +10 volts
Example 2:	Logic 1 = –lo volts
	Logic *o* = *o* volts

In both examples the logic 1 state is always more negative than the logic O state, even though in example 1 both states are in the positive region. While the above definitions of logic polarity are particularly applicable for dc switching circuits, they also apply to ac circuits as well. For example, a negative pulse can be used to simulate a negative voltage, and a positive pulse can be used to simulate a positive voltage. Such complexity is unnecessary, however, since the absence of a pulse can be assumed to indicate the logic O state. Thus only a negative pulse is necessary, and the above definitions will still apply.

As normally used, negative logic is more adaptable to PNP type transistors because of the PNP polarity requirements. Since a negative collector voltage is required to reverse-bias the PNP transistor, operation of the transistor produces either a low or a high negative output voltage. By using direct coupling, a completely negatively polarized dc system can be developed, and interstage coupling capacitors can be eliminated. Thus, besides the saving of the cost of a component, waveform distortion due to phase shift through the coupling capacitor can be minimized. Operation may also be speeded up, since it is no longer necessary to wait for the charge and discharge of the capacitor. Direct-coupled transistor logic (DCTL) circuits are discussed later in this section. Negative logic is not limited to PNP transistors, since the common emitter configuration (in an ac coupled circuit) can invert the polarity of the input signal and provide a negative output from an NPN transistor. The use of PNP transistors merely makes the design of dc negative logic circuits easier and simpler, so that negative logic is normally associated with PNP transistors, while positive logic is associated with NPN transistors. Since logic circuits and components are available for all types of polarity, there is no particular reason why negative logic should be used in preference to positive logic. In fact, for design reasons some special computers use both (mixed) positive and negative polarity. The usual practice is to design the logic without regard to polarity or levels. Once designed, the proper type of polarity and levels for the standard logic circuit and components to be used is selected, and the unit is constructed.

GATING CIRCUITS

General.

A gating circuit is a switch with two or more inputs that allows information to flow when certain input signals are present. The input signals may be in the form of numbers, control instructions, and timing pulses. Gating circuits are used to perform AND, OR, INHIBIT, and NOR operations of logic. *AND-gate* circuits produce an output ordy when signals are

present at all inputs. When signals are not present at all inputs, no output is obtained from an AND-gate circuit. ***OR-gate*** circuits produce an output when one or more input signals are present. When signals are not present at any of the OR-gate circuit inputs, no output signal is obtained. *INHIBIT-gate* circuits allow a signal to pass only when certain signals are present and other specific signals are not present at the inputs. Thus, an INHIBIT-gate is the same as an AND-gate with one or more inputs inverted. ***NOR-gate*** circuits pass a signal only when no signals are present at the inputs. The NOR operation can therefore be obtained by using an OR-gate circuit with an inverted output.

The polarity and level of AND-gate and OR-gate output signals are generally the same as the polarity and level of the input signals. For example, when a negative 10-volt output signal is to be obtained from an AND gate or OR gate, negative 10-volt signals are applied to the gate inputs. The time durations of the input signals can vary greatly, and combinations of signal levels and pulses are often applied to a gate circuit.

Gate circuits usually include one or more of the following circuit parts: relays, semiconductor or electron-tube diodes, electron-tube triodes or pentodes, transistors, and magnetic cores.

LOGIC COMPUTATION

General.

The flow of information through computer equipment and control of the computer arithmetic section are accomplished by gating circuits in conjunction with inverter circuits. These circuits are called ***logic circuits*** because their operation can be described by simple statements of formal logic using the connective words ***and, or,*** and ***not.*** In computer equipment, the basic logic circuits are AND-gate, OR-gate, and NOT circuits.

Statements of formal logic can be written in symbol form and manipulated in a manner similar to the mathematical operation of ordinary algebraic symbols. The branch of symbolic logic that is used extensively for binary computer applications is called ***Boolean algebra. In*** ordinary algebra the following four basic operations are used: addition, subtraction, multiplication, and division. Only the three basic operations of AND, OR, and NOT are necessary for Boolean algebra. In statements of logic in mathematical form, the AND operation is indicated by the multiplication sign (0), the OR operation is indicated by the addition sign (+), and the NOT operation is indicated by a bar over a symbol. Thus, these operations of logic are written as follows:

A •B'means A AND B

A + A means A OR B

A • $\overline{B}$ means A AND (NOT B)

$\overline{A}$ + B means (NOT A) OR B

The symbols 1 and O are used in Boolean algebra to indicate logic actions that are binary in nature. Common binary logic actions that can be represented are: yes or no, true or false, and on or off. You must remember that the symbols 1 and O used for Boolean algebra and the symbols 1 and O used for binary arithmetic are handled differently. The relationships for the AND operation are as follows:

0◦0 = 0

0•1 = 0

1“o ⁼o

1•1 = 1

The relationships for the OR function are as follows:

0 + 0 = 0

0 + 1 = 1

1 + 0 = 1

1 + 1 = 1

In binary logic any digit must be either of two symbols; therefore, the condition NOT 1 is the same as the condition O, and the condition NOT O is the

same as the condition 1. This relationship is as follows:

$$\overline{1} = 0$$

$$\overline{0} = 1$$

Logic circuits do not perform the actual computer computations, but only control the flow of information through the computer circuits. Counter, accumulator, and adder circuits are used for arithmetic computations.

INPUT SIGNALS

General.

For operation of logic circuits, the conditions 1 and O can be represented by two different values of voltage or current. For example, the condition 1 may be represented by a positive 10 volts, and the condition O may be represented by a negative 6 volts. Input signals are usually referred to as either ***pulses*** or levels. Pulses are electrical signals of short duration, and levels are signals of relatively long duration. For example, if 1-microsecond timing signals occur at l-millisecond intervals, the l-microsecond timing signal may be called a ***pulse,*** and any signal lasting 1 millisecond or longer maybe called a level.

In a digital computer, numbers and instructions are represented by trains of pulses. In a pulse train, the individual pulses are referred to as ***bits*** or ***characters,*** and the entire pulse train is referred to as a word. Large digital computers may use words that contain many bits of information. The bits in such words can be divided into groups, with each group containing information or control data.

FAILURE ANALYSIS

General.

Since logic circuits, as used in modem computers, generally are modularized, failure analysis of logic circuits requires a quite different approach than that for the other types of circuits discussed in this Handbook. No failure analysis is provided for circuits in this section of the Handbook on an individual basis; it is given very briefly here only for general discussion.

By the use of lights and special programming in modern military computers, the operator quickly can determine in which area a failure exists, and substitute a new module, or group of modules, when needed. In some instances, it may be considered economical to throw away the module; in other instances, local or factory repairs are made.

In large computer repair centers, test jigs usually are available, and the module is inserted in the jig and simulated test signals are applied to the inputs; the outputs or lack of outputs are noted. Thus the defective part and circuit are quickly located. For small computers, when authorized, a similar procedure may be followed. The computer can be used to supply the necessary inputs, and the outputs can be observed on either a voltmeter, a VTVM, or an oscilloscope. Lack of output when the proper trigger is applied, or a continuous output with no trigger applied, **usually will** isolate the trouble to the circuit and part at fault.

Many modules consist of several identical but independent circuits on the same printed-circuit board. Once it is determined which output is defective, failure analysis is required only for that single defective circuit. On the circuit level, semiconductor devices (both transistors and diodes) function as switches; they are either in a state of cutoff or saturation–on or off. This factor makes failure analysis much less complex than most other electronic circuits, as fewer voltage levels are involved; outputs from a logic circuit are generally at one of two levels – high or low (Logic 1 or logic O). Once it is determined, therefore, that an output is in a wrong state (with a known input), it is a relatively simple matter to trace back, component by componerit, to find at which point the voltage first appears at the wrong level. When a defective component is found, whether by test procedure or visual observation, it should never be replaced without first checking other related components of the circuit. Many times a defective component is not in reality the cause of the trouble, but the result of yet another undetected trouble, such as a cracked printed circuit board or a defective connector.

PART 16-1. SWITCH LOGIC

SWITCH LOGIC (GENERAL)

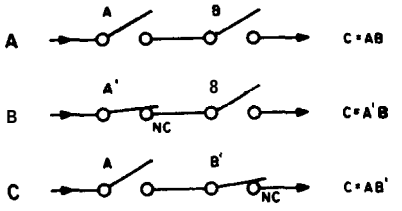
Switch logic presents basically two states of action; that is, a switch is either off or it is on. Thus the connected circuit is either inactive or it is activated, and it can represent either the logic state of O or 1. When the switch is off, the circuit is not energized (no voltage or current is present), and it represents the inactive state of O. When the switch is turned on, the circuit is energized (voltage or current is present), and it represents the active state of 1. The opposite condition may also be assumed, if desired.

Actually, switching logic has been used for years prior to the advent of computers and logic circuits. For example, when lights at different locations are operated by one-way, two-way, or three-way switches, a form of elementary switch control logic is represented. Likewise, elevators have been controlled for years by instructions from switches located on different floors. Not only is the elevator started and stopped, it is directed to go up or down and to proceed to different floors. When calied upon to operate in two different directions, it selects a sequence of' operation and carries it out, in turn, as each command is sequentially followed in accordance with the basic design.

Basically, there are three forms of switching used in logic circuits; the manually operated switch, the mechanically operated switch, and the electromagnetically operated switch. Manually operated switches included knife switches, toggle switches, push-button switches, key switches, rotary switches, and many other variations. Mechanically operated switches are similar to manually operated switches, but are operated by mechanisms such as cams, linkages, hydraulic or pneumatic cylinders, and other means. These are generally used in analog computers where the state of some physical quantity is indicated when the quantity is at a maximum or a minimum, or as it reaches a series of predetermined values. The electromagnetically operated switch is simply a mechanical switch operated by the passage of electric current through a magnet coil. This type of switch commonly known as a relay, finds widespread use today, if an additional set of contacts is added, it can also be used to control another relay; thus numerous combinations of open and closed circuits can be contrived and automatically controlled to produce logic operations. Relays and switches used in logic circuits differ from the basic electrical relay in construction and size because they need not carry heavy currents or break high voltages; they are usually operated at very low currents and voltages. As normally constructed, the armature of the relay is held in the open position by spring action and closed by the magnetic attraction of the coil for the armature when current is applied. The contacts may be numerous, either normally open or normally closed, or the relay may consist of a stack of contacts containing various combinations. While the selection of the type of coil and relay is basically an engineering problem, the logical designer must be familiar with the types of contacts and coils available for efficient design. There are about five standard types of contact arrangements available (types A, B, C, D, and E which are make, break, break and make, make before break, and break before make continuity-transfer, respectively). Similarly, there are about five different combinations of coils, such as the single coil, the two or more independent winding type, the two or more cooperative type (two or more windings must be energized simultaneously for operation), other combinations with holding windings, and differential types which can alternately energize or simultaneously reenergize the relay. Since this article is devoted to switch logic rather than component design, it is suggested that the interested reader, obtain further data on relays and contacts by consulting manufacturers' catalogs containing design and operating specifications. Further mention of contacts and coils will be made only when pertinent to the logic design or circuit operation.

Let us now consider simple switch logic. First, it must be understood that in applying switch logic all operations are treated first in elementary form, that is, as simple make and break contacts. Later, after the logic is firmed up, the contacts are counted and various relay contact stack arrangements are considered in order to determine the minimum number and types of contacts and relays. This summation is known as ***simplification,*** which will be discussed later in the section.

Examine the simple series switching circuit formed by two relay contacts connected in series, as shown in the following figure. For simplicity, actuating coils



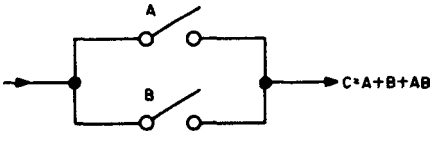
Series Switching Circuit

are not shown. Part A of the figure shows an elementary normally open circuit; when the coil of each contact is actuated, the relay switch is closed. Thus, in order for current to flow in the load circuit, coils A and B must both be actuated, thereby, closing contacts A and B and completing the circuit. If contact A is closed and contact B is open, no current flows. The same condition follows with B closed and A open (the closed condition is indicated by printing the contact, e.g., B' instead of B). With both contacts open a similar condition exists, so that one, and ordy one, condition will produce current flow into the load, namely when both contacts are closed. Let us tabulate these conditions using O to represent open contacts and 1 to represent closed contacts. Such a table, commonly called a ***truth table*** or a ***table of combinations*** is shown below. This truth table is easily identified as the typical AND logic operation (multiplication). In part B of the figure, contact A is normally closed when the relay is de-energized, and, since it is closed it is represented in logic notation by priming the letter, thus making it A' (indicating "not" open) instead of A. Forgetting for the present whether the coils are energized or not, consider only the contacts. For each opening and closing combination the AND truth table still applies. A similar condition exists for part C of the figure, except that B' is the primed contact (normally closed). Thus, we may say in general that a series arrangement of relay contacts produces the AND logical function. The circuit of part A is simpler to comprehend and follow in logic design, since the circuit operates only to produce current when both relay coils are energized; in parts B and C only one relay need be energized at a time to produce the desired condition.

A	B	C
0	0	0
0	1	0
?	0	0
1	1	1

AND Truth Table

Consider now a parallel arrangement of contacts, as shown in the following figure. It is evident from an examination of the figure that current flows in the load circuit when either contact A or contact B is closed, or when both contacts A and B are closed



Parallel Switching Circuit

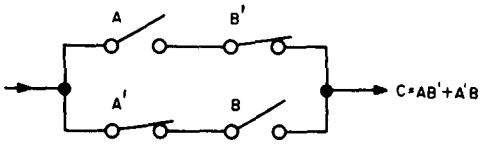
Note that current will flow when A is closed, regardless of whether B is closed, and vice versa. This action is indicated by logic notation as follows: C = B (A+ A') + A (B + B') which can be reduced to: C = AB + A'B + AB + AB'. As interpreted logically, this expression says that the load will draw current if A and B are closed, or if B is closed and A is not closed, or if A and B are closed, or if A is closed and B is not closed. Since AB + AB = AB, the expression for C may be simplified to: C = A'B + AB' + AB. A truth table for the preceding function follows: This table is

A	B	C
0	0	0
0	1	1
1	0	1
1	1	1

Inclusive OR Truth Table

recognized as a typical OR table. Since it includes operation when A and B are both closed, it also represents the inclusive OR logic state. In general, then, we may say that parallel switching contacts represent the logic OR state (addition). The exclusive OR logic state is indicated when either A or B activate the

circuit, but the circuit remains inactive when both A and B are operated. Such a condition is shown schematically in the following figure. A truth table for the



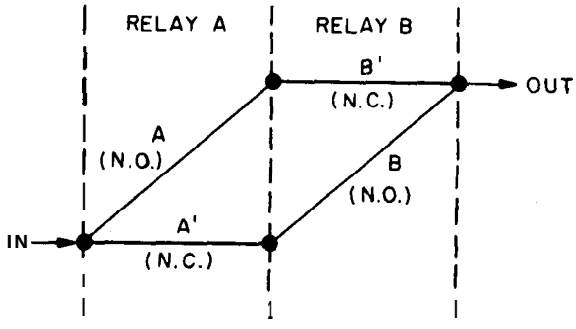
Exclusive OR Circuit

circuit above is shown below. It is recognized as the classic exclusive OR truth table, proving our contention that the schematic is that of the exclusive OR circuit by perfect induction.

A	B	c
o	0	0
0	1	1
1	0	1
1	1	0

Exclusive OR Truth Table

In addition to the schematic form of relay circuit drawings shown above, a kind of short-hand notation (diagram) is sometimes used, as shown in the following figure. In this form of notation the horizontal lines represent normally closed (or primed) contacts, while the diagonal lines represent the normally open (or unprimed) contacts. The contacts shown in a particular column are all operated by the same relay. The figure illustrates relay logic notation as applied to the circuit of the series-parallel switch contacts representing the exclusive OR circuit shown by the preceding schematic. The abbreviations N.C. (normally closed) and N.O. (normally open), shown in parentheses in the diagram, are not normally included.



Relay Logic Notation Diagram

While this discussion of switching logic has presented the basic AND and OR switching circuits, the discussion is limited to logic concepts alone. The circuit action of specific logic circuits is discussed in the latter part of this section.

OR CIRCUITS

Application.

The OR circuit is used in mechanical computers and switching circuits to perform logic addition.

Characteristics.

May use positive, negative, or combined logic.

Consists of a series of switching contacts connected in parallel.

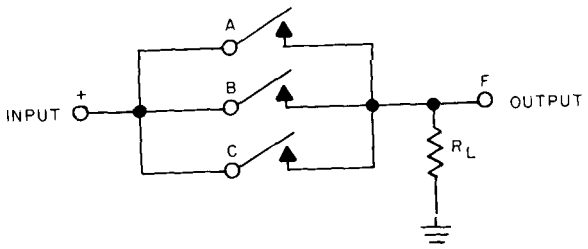
Performs logic addition.

Switch may be electrically or mechanically operated; usually consists of a group of relays.

No amplification is produced.

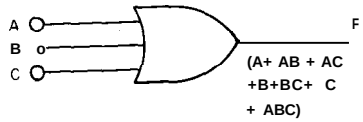
Circuit Analysis.

General. In switch logic, a basic OR circuit consists of a group of parallel connected single pole, single throw switches connecting the power source to the output load, as shown in the accompanying schematic.



Basic **OR Switching Circuit**

As can be seen from a study of the schematic, in the inactive condition all switches are open, and since the load and output are not connected to the power source there is no output, representing a logic O. Conversely, when any of the switches are turned on, either separately or in combination, the power is connected to the load and the output voltage is the same as the input voltage, representing a logic 1. The logic diagram for this circuit is shown symbolically in the following illustration, with a truth table.



INPUTS			OUTPUTS

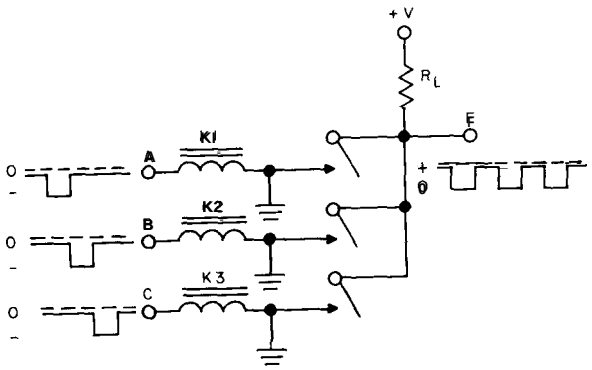
OR Logic Diagram **Truth Table**

From the symbolic logic diagram it is evident that there is no difference between the mechanical and electronic circuit, the symbol is functional. Since it is necessary to operate each switch by hand in the example given, and switches are not affected by polarity, the level indicators are omitted from the logic diagram. Because little advantage is obtained by requiring manual manipulation of the switches, the mechanical computer uses relays. Applying the proper potential to the relay coil pulls in the relay armature and closes the circuit. Thus by using another relay to control a series of switching operations, performed by groups of relays arranged in the proper switching sequence, electro-mechanical computers which operate at high rates of speed are formed. Speed of operation is limited by the time it takes the relays to open and close. Since relays are expensive and require more power and space than transistors or diodes, these types of computers find limited use.

Circuit Operation. The schematic of a typical relay-type of OR switching circuit is shown in the following illustration.

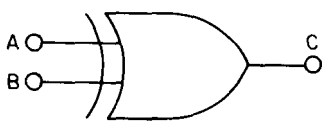


Three-Input OR Relay Circuit

The inputs are applied to the coils of relays K1, K2, and K3. When energized, these relays close and complete the circuit from the power source through common load resistor R_L to ground. When no input signal is applied either A, B, or C, the circuit through the load resistor to ground is open, no current flows through R_L, and the potential at the output is the relatively high positive level of the power source. Assuming a negative voltage (a positive voltage could also be used) representing a logic 1 is applied to input terminal A, relay K1 closes and the current flowing through R_L to ground produces a voltage drop which lowers the output to the zero level. The output stays at the zero level for the duration of the input pulse and

then returns to the normal high positive level when the input signal ceases and K1 opens. Thus, a negative output pulse is generated. If inputs B or C are activated the same sequence of operation occurs, except that relays K2 or K3 are energized instead of KI, In either case a negative output is developed. If two inputs are activated simultaneously, an output also will be generated. This represents the case of the ***inclusive OR*** where the output is A + B + C + AB + AC + BC + ABC. This type of OR circuit allows several independent signals of different origins to perform the same switching function without any interaction between the signal sources. The relay in the OR circuit thus acts as a buffer or isolating element. To perform logic addition, this circuit must be used together with other OR or AND circuits arranged to produce the desired logic function. Should inversion or the NOR type of operation be desired, it is only necessary to control these relays with another relay, which when activated temporarily shorts the second relay coil causing it to deactivate. In this special case, the input signal does not produce an output signal.

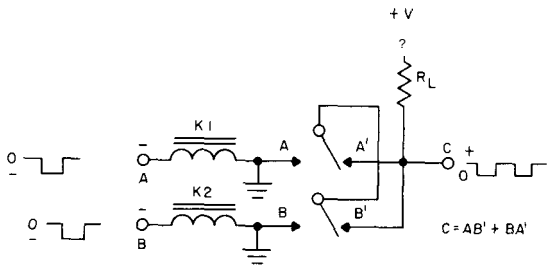
To accomplish the exchrsive OR operation it is necessary to prevent operation of the other relay when one relay is already activated.
This is accomplished by adding a back contact on each relay which is normally closed. The logic symbol and truth diagram for this circuit is shown in the following illustration.



INPUTS		OUTPUTS
A	B	C
0	0	0
0	1	1
1	0	1
1	1	0

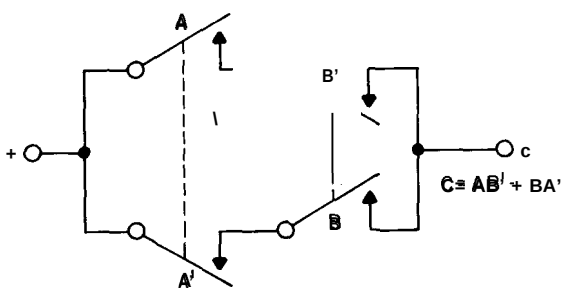
Exclusive-OR Logic Diagram **Truth Table**

In this instance, the logic symbol changes slightly to indicate that this is the exclusive-OR function and not the inclusive OR function. The circuitry, however, may be solid state, electron tube, or mechanical without change of symbol as long as the same function is achieved. The schematic of the mechanical exclusive-OR circuit is shown in the following illustration.



Exclusive-OR Relay Circuit

A simplified schematic of this circuit showing only the relay contacts is shown in the following illustration to simplify the discussion. Note that for any circuit to produce an output, the other relay must be resting in the normally closed position, as indicated by the primed symbols. Thus, when input A is activated, relay K1 closes and produces an output only if contact B' is closed.



Simplified Contact Arrangement

Likewise, when B is activated relay K2 closes and produces an output only if contact A' is closed. Since activating the relay opens the normally closed contact, whenever two relays are activated the circuit to the power supply, load, and output will be opened and an output cannot be produced. Thus, a negative pulse is generated only when one of the inputs is activated at a time, and never when more than one is activated simultaneously. Thus, the exclusive OR function is accomplished as shown in the truth table.

AND CIRCUITS

Application.

The AND circuit is used in mechanical computers and switching circuits to perform logic multiplication. It is sometimes called a coincidence circuit in other publications.

Characteristics.

May use positive, negative, or combined logic.

Consists of a group of switching contacts connected in series.

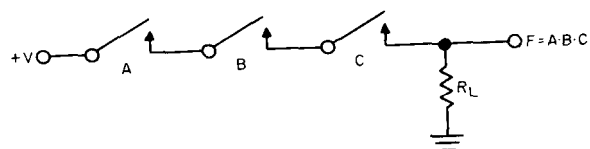
Switch may be mechanically or electrically operated, usually consists of a group of relays.

No amplification is provided.

Performs logic multiplication.

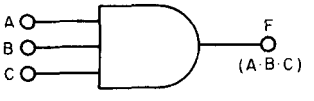
Circuit Analysis.

General. In switch logic, a basic AND circuit consists of a group of single pole, single throw switches connected in series, as shown in the accompanying schematic.



Basic AND Switching Circuit

As can be seen from the schematic, in the inactive condition all switches are open, and since the load and output are not connected to the power source there is not output, representing a logic O. Conversely, when all the switches are turned on, the load is connected to the power source, and an output is developed across load resistor RL by the current flowing through the circuit, representing a logic 1. The logic diagram for this circuit is shown symbolically in the following illustration, with a truth table.

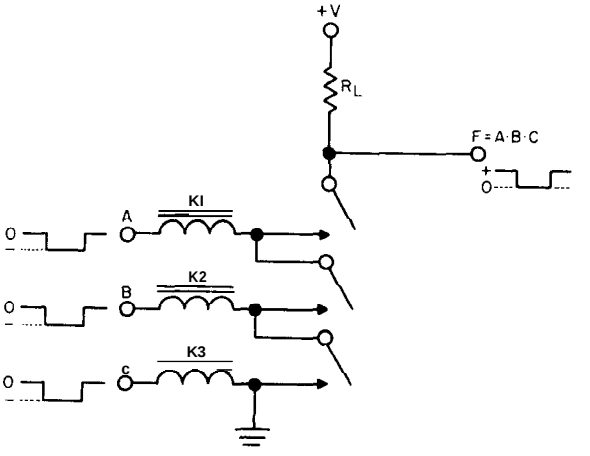


INPUTS			OUTPUTS
A	B	C	F
0	0	0	0
0	0	1	0
0	1	0	0
1	0	0	0
1	0	!	o
1	1	0	0
I	I	I	I

AND Logic Diagram **Truth Table**

From the symbolic logic diagram, it is evident that there is no difference between the mechanical and electronic circuit, the symbol is functional. Sinoe it is necessary to operate each switch by hand in the example shown, and switches are not affected by polarity, the level indicators are omitted from the logic diagram. Because advantage is obtained by requiring manual manipulation of the switches, the mechanical computer uses relays. Applying the proper potential to the relay coil pulls in the relay armature and closes the circuit. By using one relay to control a series of switching operations performed by groups of relays arranged in the proper switching sequence, electro-mechanical computers which operate at high rates of speed are formed. Operating speed is determined by the time it takes the relays to open and close (from 1 to milliseconds on the average). Since relays are expensive and require more power and space than transistors or diodes, these types of computers find limited use.

Circuit Operation. The schematic of a typical relay-type of AND switching circuit is shown in the following illustration.



Three-Input AND Relay Circuit

The inputs are applied to the coils of relays Kl, K2, and K3. When closed, these relays connect common load resistor RL to ground. In the deenergized position, the load circuit and output float at the supply voltage, and this high positive output level is considered to represent a logic O. When all three inputs are activated simultaneously, relays K1, K2, and K3 close and connect the load resistor and output to ground. The high positive output voltage is dropped to zero by the current flowing through the load resistor and the output is effectively a large negative-going pulse. For the duration of the input signal or pulse, the output remains at zero and then rises to its normal high positive level when the input terminates, completing the negative output pulse.

Because of the series arrangement of relay contacts the circuit is only completed when all contacts are closed. Thus, as shown in the truth table previously, all outputs are zero, except when all the inputs are simultaneously activated to produce a "one" signal.

FLIP-FLOP CIRCUITS

Application.

Relay type flip-flop circuits are used in mechanical computers and switching circuits to supply off-on

triggering pulses and provide a signal and its complement simultaneously, they are also used as storage elements. It forms the basic circuit used in most registers.

Characteristics.

May use positive, negative, or combined logic.

No amplification is produced.

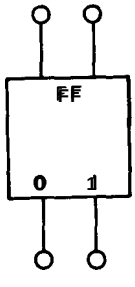
Consists of two operating and two control relays.

Provides two output signals (one is the inverse of the other).

Usually requires two inputs (an "off" trigger and an "on" trigger).

Circuit Analysis.

General. The relay type of flip-flop is the mechanical switching equivalent of the transistor or electron tube bistable multivibrator (it is sometimes known as a "toggle switch" circuit). It has two stable states, one the inactive or zero-state, and the other the active or one-state. Once triggered, one relay is held in the active position until it is released, meanwhile the other relay rests in the inactive condition until a trigger appears. Thus, this type of circuit provides a limited amount of storage. It will retain either a zero or a one indefinitely, and without attention, until it is triggered into the opposite state of operation. The logic diagram for this circuit is shown symbolically in the following illustration, together with a truth table.



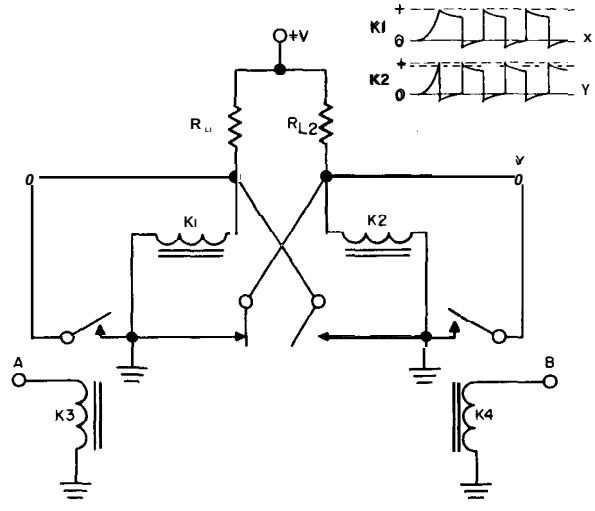
Flip-Flop Logic Diagram

INPUTS		OUTPUTS	
A	B	X	Y
0	1	0	1
1	0	1	0

Truth Table

It is evident there is no difference in the logic symbol between electronic and mechanical flip-flops, since the symbol is functional. When the symbol bears the designations C and Son the unidentified leads it indicates a clear (reset) input for C and a set input for S. The clear input always returns the flip-flop to the zero or inactive state, while the set input always triggers the flip-flop into the active or one condition. It is not necessary to label these inputs, but they may be labelled, if desired.

Circuit Operation. The schematic of a typical relay flip-flop is shown m the following illustration. The outputs are X and Y, and the inputs are A and B which operate control relays K3 and K4. The flip-flop operating relays are K1 and K2.



Relay Flip-Flop Circuit

When no power is applied, both relays K1 and K2 rest in the deenergized position and no output is produced. When power is applied, both relays will try to close since their coil is connected between the power source and ground. The first relay to close will lock out the other relay and prevent it from closing, and the circuit will rest in one of the two possible conditions. Assume for the moment that relay K1 is closed, then relay K2 is open and output Y is connected to ground via the contacts of KI. Current flow to ground through RL_2 will drop the voltage at terminal Y to zero and simulate a O. Meanwhile, RL_1 and the coil resistance of K1 form a voltage divider from +V to ground, and output X will be a positive voltage determined by the ratio of the resistances in the voltage divider, but is always less than the supply voltage. As long as K1 remains closed, the X output will be a positive voltage representing a 1. When input A is activated by a "set" signal, relay K3 closes and grounds the coil of K1 by shunting it to ground and

causing K1 to open. As soon as K1 opens, current flow through RL_2 and the coil of K2 to ground pulls in relay K2. The output of terminal X is now O, since it is grounded, while the Y output is the voltage developed across K2 coil (K2 and RL_2 form a voltage divider between +V and ground). The conditions are now exactly reversed, and the Y output is a positive voltage less than the source value, while the X output is O. When a "clear" pulse is applied to relay K4 by energizing B input terminal, relay K2 is shorted out and K1 operates and resumes control. Thus the flip-flop may be made to change state by alternately energizing control terminals A and B. (The trigger is only momentary it is not continuous.) As a result, the flip-flop produces two outputs, one the inverse of the other as shown in the waveforms, and will rest in one state until triggered into the opposite state.

Circuit arrangements may be made to produce negative output voltages if desired, and the control relays may be triggered by either positive or negative voltages, since the relays are not polarized. The output voltage will be determined by the values of relay coil resistance and load resistance used for a specific source voltage and will never exceed the source, except possibly for the switching transients shown by the pips on the output waveforms. With proper design these transients can be practically eliminated,

TWO-WAY AND THREE-WAY CIRCUITS

Application.

Two-way and three-way circuits are used in computers and switching devices to apply to outputs of two or three other logic circuits to the input of a single logic circuit, and control its output.

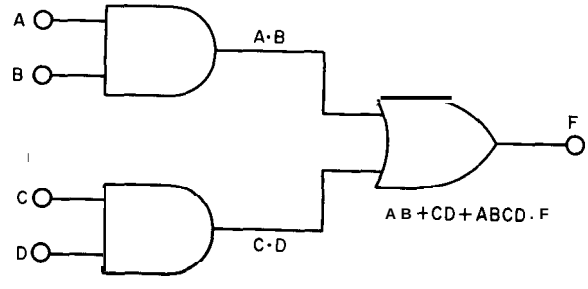
Characteristics.

May use positive, negative, or combined logic.
Uses combinations of OR and AND circuits.
Has a number of inputs, but only a single output.

Circuit Analysis.

General. Two-way and three-way circuits provide a means of combining logical operations so that the result can be handled by simple off-on switching circuits. Combinations of AND and OR gates offer a convenient and easy method of fanning-in a large number of inputs to a single output line. Besides being convenient for binary and digital use they are also useful for control functions. For example, if it is necessary for three switches to be placed "on" before another switch can be operated, a simple three-input AND circuit will control this operation. Likewise, the turning on of a transmitter from two separate locations is accomplished by a simple OR gate. In digital logic it is the arrangement of these two-way and three-way circuits (or four- or five-way circuits) which form the arithmetical or logic circuit used as an adder or subtracter, or otherwise to produce the desired function(s).

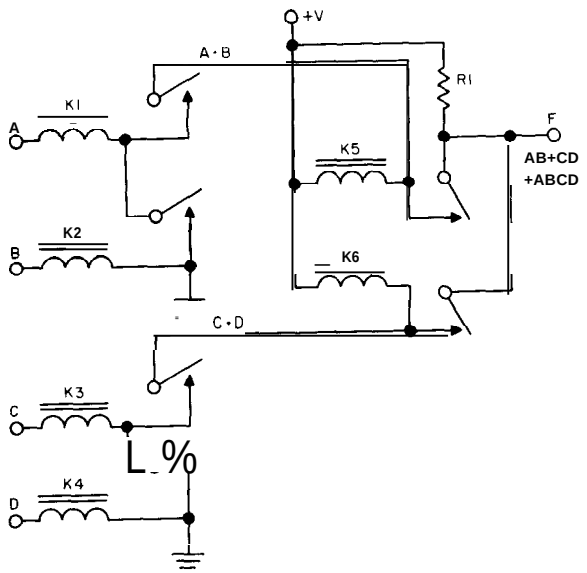
Circuit Operation. A basic two-way circuit consisting of two AND gates and an OR gate is shown in the following logic diagram.



Two-Way Circuit Logic Diagram

Note that the logic diagram is functional and does not indicate the actual circuit, so that diodes, transistors, relays or switches could be used as long as the proper function was performed. Note also, that the actual circuit diagram or schematic is not needed in understanding circuit logic. When inputs A AND B exist the first AND gate produces output AB. Likewise, when inputs C AND D exist the second AND gate produces output CD. These inputs can be at two different levels and supplied from separate logic circuits. When either input combination is applied to the OR gate a single output is produced, and, since it also represents the inclusive OR function, when both combinations simultaneously exist an output is also produced from the OR gate. Thus the output of this circuit is AB + CD + ABCD, and the two level input is expressed as a single-level output.

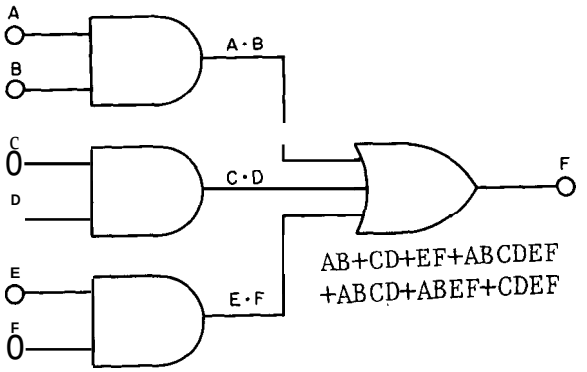
A typical schematic diagram using relay switching to accomplish the logic explained above is shown in the accompanying illustration.



Two-Way Circuit Schematic

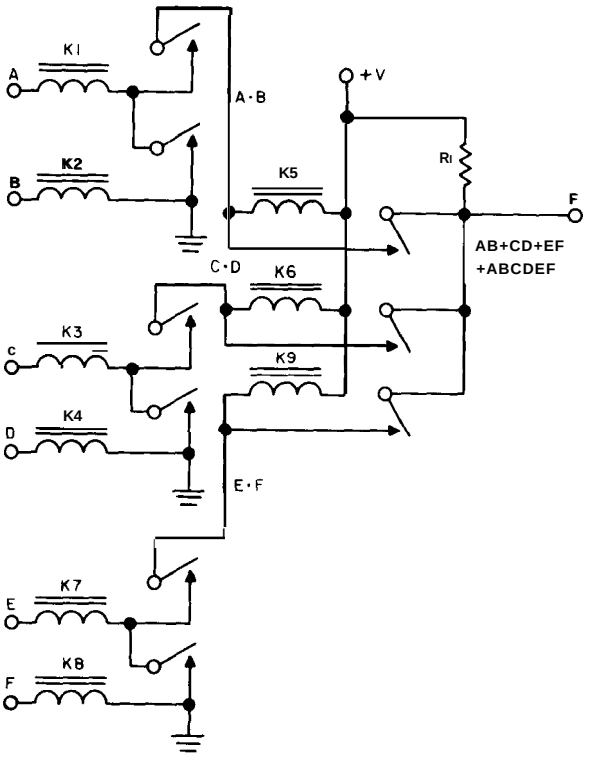
Relays K1 and K2 form one AND gate, while relays K3 and K4 form the other AND gate. Both AND gate relay contacts are connected in series to ground, and actuate relays K5 and K6 of the OR gate when appropriate inputs are applied. When either K1, K2, K3, or K4 alone are actuated, the circuit to ground for the OR gate relay coil is open since only one set of contacts is closed. However, when both K1 and K2, or K3 and K4, or all relays are activated simultaneously, the OR gate is activated. Therefore, when an output such as AB is obtained from the AND gate by closing relays K1 AND K2, relay KS is closed and output F is at ground potential. Normally, with KS and K6 open, output F is at a high positive level since no voltage drop occurs across RI. However, when K5 AND K6, or K5, or K6 is closed, current flow to ground through RI drops the output to zero. When these relays are released, output F again assumes a high positive level. Thus the OR gate output effectively is a negative pulse representing a 1, and negative logic is employed.

A three-way or three-level logic circuit merely provides an additional input level over the two-way circuit. Therefore, by adding another AND circuit as shown in the following logic diagram, a three-way circuit is obtained.



Three-Way Circuit Logic Diagram

Examination of the new logic diagram reveals that when input A AND B exist, the first AND gate produces output AB. Similarly, when inputs C AND D are present the second AND gate produces output CD; and finally, when inputs E AND F are present, the third AND gate produces output EF. When any of the AND gate outputs are applied to the OR Gate input a single output is produced. Since this circuit also includes the inclusive OR function, when all combinations simultaneously exist an output is also produced from the OR gate. Thus the output of the three-way circuit is AB + CD + EF + ABCDEF +ABCD+ABEF+CDEF, and the three-level input is expressed as a single-level output. The schematic diagram for the three-way circuit is shown in the following illustration, using relay switching to accomplish the logic indicated and explained above.



Three-Way Circuit

Relays K1, K2, K3, and K4 operate identically with the previously described two-way circuit and the new relays K7 and K8 have their contacts connected in series to ground, controlling new OR gate relay K9. Since the contacts of K9 are connected in parallel with those of KS and K6, operation of the OR gate drops output F to zero level when K9 is closed. Therefore, when relays K7 and K8 are simultaneously activated, relay K9 is closed, producing an effective negative output for a logic 1.

SIMPLIFICATION PRINCIPLES

Application.

Simplification is used to reduce the number of logic or switching circuits necessary to obtain a desired functional result.

Characteristics.

Circuit is reduced to simplest form.

Unnecessary or excessive components are eliminated.

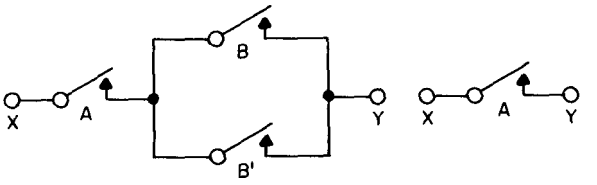
Usually employs Boolean Algebra.

Function is not changed.

Circuit Analysis.

General. The process of simplification is generally to reduce any given circuit to its simplest form without changing the logic. This is accomplished by eliminating unnecessary switches or by substituting one switch for duplicate switching. There are two basic methods which can be used; the first method involves pure reasoning, while the second method uses the mathematical manipulations of Boolean Algebra to reduce the unsimplified expression to its simplest form. Examples of each method will be given. Since simplification and the intricacies of Boolean logic are mainly of use to the logic designer, and the equipment encountered in Naval use will already be in simplified form, the subject is only briefly discussed in this Handbook in elementary form. For more information on this subject the interested technician should consult the text books on logic design available from commercial sources and public libraries.

Procedures. A simple switching circuit involving AND and OR operations is shown in the following illustration, with its simplified equivalent.

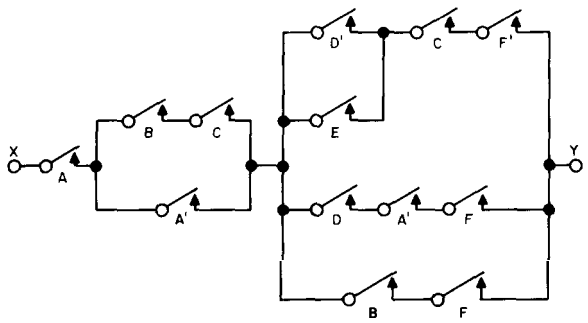


Switching Network Simplified Representation

Since switch NOT B (B') is normally closed, while switch B is normally open, the path from X to Y will always be completed when switch A is closed. Thus both B and B' switches may be removed and a closed wire connection made between switch A and output Y, leaving switch A as the only one in the circuit. When represented in Boolean notation, multiplication of A AND B or A AND B' is indicated because of the

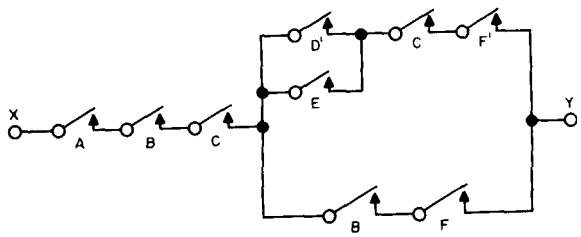
series ANDing of the switches, and the summing of these quantities is also indicated because of the parallel connection (ORing) of switches. Thus the original expression is (A •B) + (A • B'). If we factor A from both terms we can rewrite the expression as A • (B + B'). However, the quantity (B + B') is equal to 1 by the first law of complementation in the Boolean postulates. Therefore, we write expression as A(1) which is equal to A, proving the simplified version and reasoning are correct.

Let us now take a more complex switching arrangement where it is desired that point X be connected to point Y through independent elements A, B, C, D, E, AND F, as shown in the following illustration.



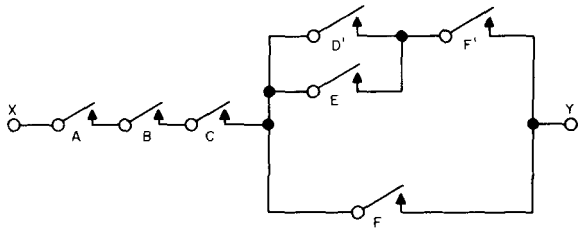
Complex Switching Circuit

We may now reason as follows. Since switch A' is normally closed and any path between X and Y must have switch A closed, switch A' will always be open and may be eliminated to produce the simpler circuit. (See following illustration.)



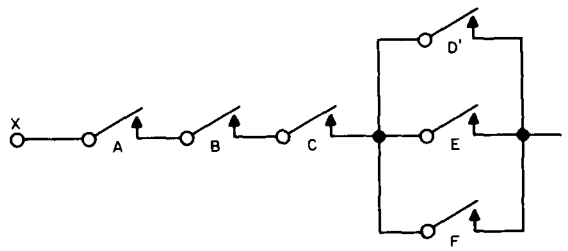
First Simplification

Note that the circuit now consists of a series group of switches forming an AND circuit, and feeding a group of series and parallel switches. Further simplification is desirable. Since B and C switches must be closed for the AND gate to operate, duplicate switches B and C may be eliminated and wired across, producing the second simplified circuit. (See following illustration.)



Second Simplification

Finally, we may reason that switch F provides an independent path, which if F is open has an alternative path offered through D' or E AND F'. Therefore, D' and E may be directly wired to Y and F' disposed of. Thus the final circuit version is obtained, as shown in the following illustration, consisting of an AND gate feeding an OR gate.



Final Simplification

By elementary reasoning the 13 switch circuit is reduced to 6 switches and retains the original desired function. This is proven with Boolean algebra as follows. The overall expression for the unsimplified network is:

A(A' + BC) [(D'+ E) • C • F'+ DA'F + BF] = F, - and F = 1

Combine the terms in the following manner:

$(AA' + ABC)\ [D'CF' + ECF' + DA'F + BF] = F$

since AA' in the first expression is equal to O, therefore

$$(ABC)\ [D'CF' + ECF' + DA'F + BF] = F$$

and we have by further combining

$$ABCD'F + ABCEF' + AA'BCDF + ABCF = F$$

but AA' in the third term is equal to O eliminating the term, and

$$ABCD'F + ABCEF' + ABCF = F$$

combining the last two terms gives

$$ABCD'F' + ABC\ (F+ F'E) = F$$

since F + F' equals 1 we have

$$ABCD'F' + ABC\ (F+ E) = F$$

eliminating the parentheses we get

$$ABCD'F' + ABCF + ABCE = F$$

combining the first two terms gives

$$ABC\ (F+ F'D') + ABCE = F$$

since F + F' equals 1 we have

$$ABC\ (F+ D') + ABCE = F$$

recombining terms we get

$$ABCF + ABCD' + ABCE = F$$

which can be written as

ABC (F + D' + E) = F), which agrees with the final simplification

arrived at by a simple reasoning.

PART 16-2. DIODE LOGIC

DIODE LOGIC (GENERAL)

Diode logic is the simplest type of logic, corresponding, in general, to switch operation. Either the switch is ON (diode conducting) or it is OFF (diode non-conducting). It is usually used where signals of only two levels are involved (the off level and the on level) although three-level circuits may be arranged, if desired. Either negative or positive logic maybe used with the same circuit arrangements, except that the diode connections must be reversed. While it is important that the forward resistance of the diode be low, it is more important that the reverse resistance be very high. Thus when diodes are parallel-connected their paralled reverse-resistance is still high, and leakage and operating power requirements are low; also, false triggering will not occur. Another advantage to the use of diode logic is that no inversion of the output signal occurs. Thus it may be unnecessary to add an inverter circuit to return the signal to its original polarity; this helps simplify computer design.

The diode also lends itself to multiple arrangements where a combination of inputs is used to produce a single output, usually called a decoding matrice or matrix. Conversely, an arrangement with single inputs producing a multiple output is known as an encoder matrice or matrix. In general, when arranged in a rectangular arrangement the matrice becomes a rectangular matrice, regardless of function, that is, it may be either an encoder or decoder. Each of these basic circuits and arrangements are fully discussed in the following paragraphs.

OR GATE

Application.

The diode OR gate is a basic logic circuit which produces an output when either input is activated, and when both inputs are simultaneously activated (inclusive OR). It replaces the relays and electron tubes used in earlier computers.

Characteristics.

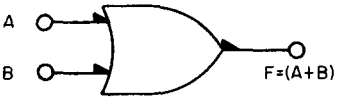
May use either positive or negative logic.

A signal at any of the inputs produces an output.

Output never exceeds the input (no amplification is obtained).

Circuit Analysis.

General. Logic circuits differ from basic electronic circuits in their general treatment. Through the use of standard logic symbols (see Graphic Symbols for Logic Diagrams, ASA Y32.14-1962 for a complete list), a block-diagram type of presentation may be used, instead of the conventional schematic representation with which the ET is more familiar. Thus the signal path and operation can be followed, or considered, without regard to the actual electronic circuit operation. Typicrd standard symbol used to represent a positive logic OR circuit are shown in the following illustration, accompanied by a truth table of possible combinations.

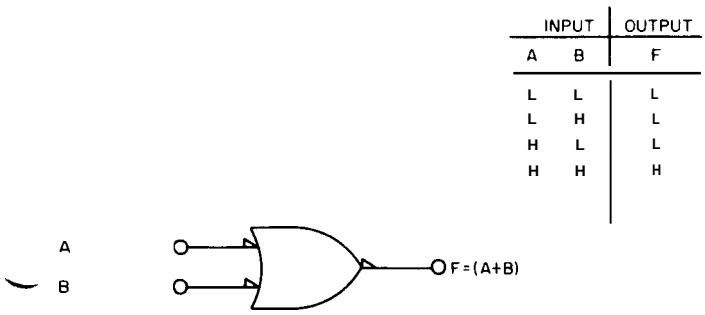


INPUT		OUTPUT
A	B	F
L	L	L
L	H	H
H	L	H
H	H	H

Positive OR Gate Symbols Table of Combinations

A high level or positive logic is indicated by the filled-in (or solid) right triangles in the symbol. The inputs are A or B. The output F shows in Boolean algebra notation the result (A+ B), where the + sign indicates OR (addition). The tabIe of combinations shows every possible combination of input and output and is therefore, called a truth table. When either input A or input B (or both) are at a relatively high level, the output, F, is also at a relatively high level. When both A and B are at a low level, so is output F.

When negative logic is used, the following symbol and truth table apply.

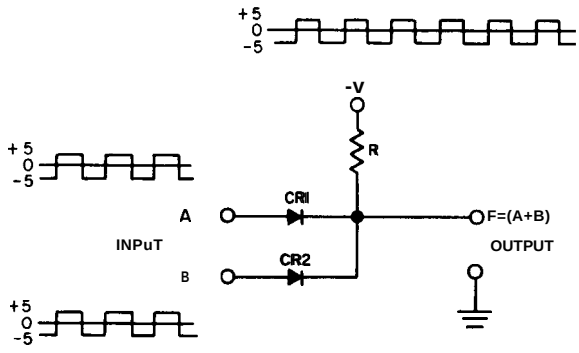


INPUT		OUTPUT
A	B	F
L	L	L
L	H	L
H	L	L
H	H	H

Negative OR Gate Symbol Table of Combinations

A low level or negative logic is indicated by the open right triangles in the symbol. The table of combinations shows that for all inputs but one, the output is low. When both inputs are high, then the output is also high.

Circuit Operation. A two-input positive OR gate is shown in the following illustration. The gate consists of two diodes, CR1 and CR2, and current limiting resistor, R, connected as shown in the schematic.



Two Input Positive OR Gate

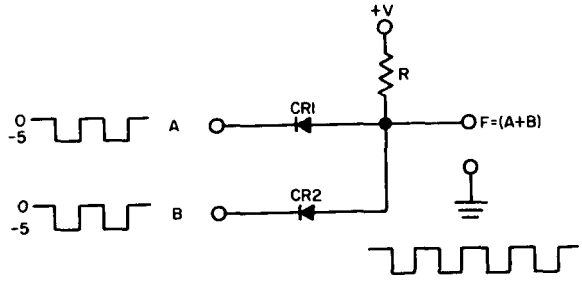
When the OR gate is inactive (no inputs) it is forward biased by the large negative voltage applied the cathode, and usually a small negative voltage, representing O, is applied to the anode and a small current flows through either CR1 or CR2. Actually, a reverse current may also flow depending upon the reverse leakage of the diode. This current, however, is so small in most cases that it may be neglected. Thus if sufficient diode current flow through R to drop the bias supply to zero, no output is produced at F. When an input is applied to either A or B, more current flows through R depending upon the amount of voltage applied, and its polarity. If a voltage of exactly –V, is applied both sides of the diode will be at equal potentials and no current will flow. If negative, but less than –V a current equal to that produced by an equivalent positive voltage will flow. That is with –20 volts applied and assuming V to be –30 volts the anode will be effectively 10 volts positive with respect to the cathode. Similarly, if 5 volts positive is applied to A or B, the effect will be as if the anode of the associated diode were at +35 volts. A larger current will flow and a greater voltage will be dropped across R. The output is taken from the diode end of R to ground. Thus, if sufficient voltage is applied to either A or B the entire bias source will be dissipated across R. Hence the only voltage existing as an output will be the input voltage applied the anode. If +5 volts is applied to either A or B, the output at F will be +5 volts, which is considered to be a logic 1 in this example. It can be seen that no gain results. Actually, the conducting diode has some slight resistance, and the examples discussed above are for the idealized case where the diode is considered to have zero resistance. Thus, at all times, the actual OR gate output is always slightly less in value than the input, when using diode logic. This is to be expected, since the diode itself has no inherent gain. Note, also that the input signal is not inverted (this is true of all diode logic circuits and helps simplify design).

When both diodes are activated simultaneously, the output will be the highest voltage applied to CR1 or CR2. Since in every case a positive input signal is required to produce an output, positive logic is used. The output pulse will continue for the duration of the trigger pulse and be of approximately the same shape. Because the input pulse appears as the output pulse, a reverse bias of this value is applied the nonconducting diode. Therefore, when signals are applied to inputs A and B, simultaneously, the larger amplitude signal determines which diode shall conduct. For exactly equal amplitude signals, both diodes will conduct. The difference between logic circuits and

conventional electronic circuits is that in the logic circuit, distortion which would be intolerable in the communications circuit is acceptable. Thus it is only necessary for the logic circuit to provide a signal of sufficient amplitude and of the proper phase (or polarity) for actuating the next logic circuit.

The positive OR circuit is sometimes referred to as a negative AND circuit, because if the polarity of the input trigger is reversed so that a negative signal represents a 1 and a positive signal a zero, a combined input will produce a negative output, but separate inputs will ***not.*** Because of the interchangeability of the OR and AND functions with polarity it is necessary to adopt certain conventions to avoid confusion. Therefore, if we assume that relatively positive signals produce a 1, and relatively negative signals produce a O, we may call the OR circuit previously discussed above a positive OR gate. Unless otherwise noted, we shall assume this convention throughout the remainder of the circuit discussions in this Chapter of the Handbook.

A two input negative OR gate is shown in the accompanying illustration. The gate consists of two diodes, CR1 and CR2, with current limiting resistor, R, comected as shown in the following schematic.



Two Input Negative OR Gate

The negative OR gate operates inversely to the positive OR gate. Thus, when inactive, it is held so by inputs approximately equal to +V and no conduction occurs. This represents the O state. When a negative 1 is applied either A or B, the respective diode is forward biased and current flows through R. Electron flow is in such a direction that the output end of resistor R is negative, and the input signal appears as the output. While one diode is conducting, the other diode is reverse biased by the amount of the output signal; thus it cannot conduct unless a greater negative voltage is applied its input. When both inputs are simultaneously activated with a negative signal, if equal in amplitude both diodes conduct. This is the case of the inclusive OR. If the polarities of the O and 1 are reversed, the negative OR gate will function as a positive AND gate. Thus the proper conventions must be used to produce the desired function. When the 1 input is relatively more negative than the O input, the above discussion, the symbol, the schematic, and the truth tabIe for the negative OR gate apply.

AND GATE

Application.

The diode AND gate is a basic logic circuit which produces an output only if all of its inputs are simultaneously activated. It represents the basic logic circuit for binary multiplication, and the dot symbol is used to indicate this (A B = C). It replaces the relays and electron tubes used in earlier computers.

Characteristics.

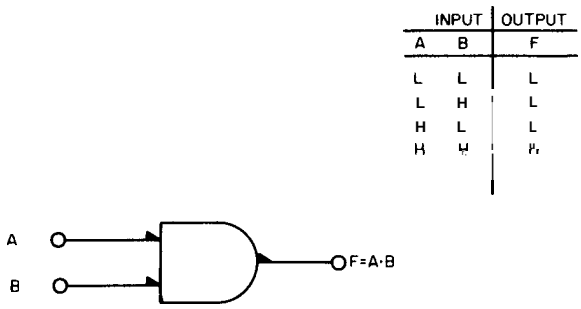
May use either positive or negative logic.

A signal is required at both inputs to produce an output.

Output never exceeds the input (no amplification is obtained).

Circuit Analysis.

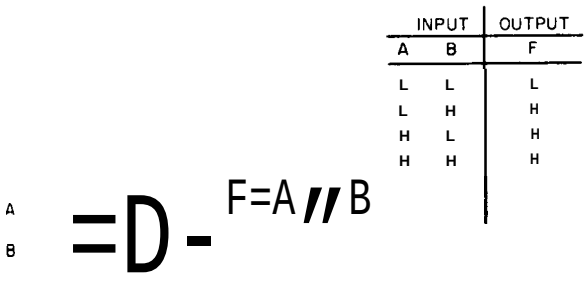
General. Logic circuits differ from basic electronic circuits in their general treatment. Through the use of standard logic symbols, a block diagram type of presentation may be used, instead of the conventional schematic circuit representation with which the ET is more familiar. Thus the signal path or operation may be followed, or considered without regard to the actual electronic circuit operation. Following is a typical standard symbol used to represent a positive logic AND circuit accompanied by a truth table of possible combinations.



Positive AND Gate Symbol — Table of Combinations

A high level or positive logic is indicated by the filled-in (or solid) right triangles in the symbol. The inputs are A and B. The output, F, shows in Boolean algebra notation the result **(A·B)**, where the dot sign indicates AND. The table of combinations shows every possible combination of input and output, and is, therefore, called a truth table. When inputs A and B are both at a relatively high level, the output, F, is also at a relatively high level. When both A and B are at a low level, so is F. For a single input the gate remains inactive.

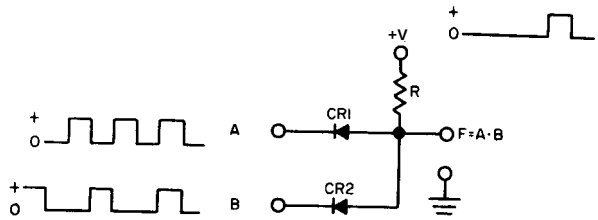
When negative logic is used, the following symbol and truth table apply.



Negative AND Gate Symbol – Table of Combinations

A low level or negative logic is indicated by the open right triangles in the symbol. The table of combinations shows that for all inputs but one, the output is low. When both inputs are low, then the output is low. For any single input, the gate remains inactive and rests in the high state.

Circuit Operation. A two-input positive AND gate is shown in the accompanying illustration. The gate consists of two diodes, CR1 and CR2, and current limiting resistor, R, connected as shown in the following schematic.



Two-Input Positive AND Gate

When no inputs are applied, the cathodes of CR1 and CR2 are at a relatively low level with respect to their anode. Thus the cathodes are effectively negative with respect to the anode and the diodes conduct. The diode current flowing through resistor R produces a voltage drop equrd to that of the supply and of opposite polarity. Therefore, at the output end of R the potential is zero, and no output signal exists between F and ground.

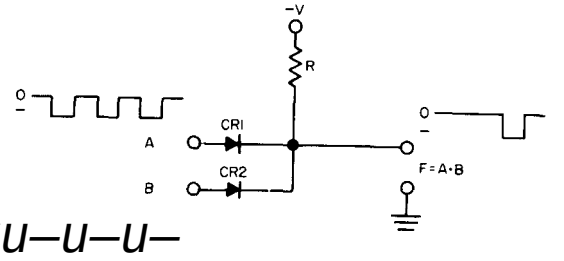
Should a positive input be applied to either A or B alone, either CR1 or CR2 will cease conducting. However, the other diode will then conduct more heavily and keep output F at zero. Thus if only one input is activated there will be no output. On the other hand, if both A and B inputs are activated simultaneously by a high level or positive signal, the cathodes become more positive than the anodes and both diodes cease conducting. When conduction ceases, the voltage drop across resistor R no longer exists, and output F rises to the full vahre of the

supply voltage (becomes highly positive). Thus a positive output is produced when both inputs are simultaneously activated by a relatively high level input representing a 1.

A positive AND gate is sometimes referred to as a negative OR gate, because if the polarity of the input trigger is reversed so that a negative signal represents a 1, and a positive signal represents a zero, a single input will produce a negative output, but combined inputs will not. Refer to the OR gate schematic in the previous discussion earlier in this Chapter and observe they are identical. Because of the interchangeability of the AND and OR functions with polarity it is necessary to adopt certain conventions to avoid confusion. Therefore, if we assume that relatively positive signals produce a 1, and relatively negative signals a O, we may call the AND circuit discussed previously above a positive **AND gate.** Unless otherwise noted, we shall assume this convention throughout the remainder of the circuit discussions in this Chapter of the Handbook.

In some systems, O's and 1's are represented by the absence or presence of a pulse. If the pulse is absent it represents a O, if present, a 1. The AND gate produces a pulse at its output only when all inputs are present. Thus in a three input AND gate, inputs A, B, and C must all be activated before an output can be produced. Where both d-c and pulse levels are used, all must also be activated. If two levels are dc and the third is a pulse, then both dc levels must be positive and a positive pulse must appear at the third level before the circuit will operate. Absence of the pulse would be a O exactly as though a negative signrd were applied instead, and the circuit would not operate.

A two input **negative AND gate is** shown in the accompanying illustration. The gate consists of two diodes, CR1 and CR2, with current limiting resistor, R, connected as shown in the following schematic.



Two Input Negative AND Gate

The negative AND gate operates inversely to the positive AND gate. Thus, when inactive, the anodes are at a relatively high level (positive) with respect to the cathodes, which are connected to the negative supply through R, and they conduct. The voltage drop across R is opposite the supply and equal so that no voltage exists at the output end of resistor R, thus no output is obtained from F. When either input A or B is activated (with a negative 1 signal) the associated diode stops conduction, but the other diode maintains the output at zero. However, when both inputs are simultaneously activated by a low level or relatively negative input the anodes become more negative than the cathode and the diodes cease conduction. Since no current now flows through R, the voltage at the output terminal rises to the value of the supply voltage, and a negative output representing a 1 is produced. When the inputs cease, the output again terminates and the gate is considered inactive, even though this is the period during which the diodes are active and conducting.

If the polarities of the O and 1 are reversed, the negative AND gate will function as a positive OR gate (see schematic in previous OR gate discussion in this section of the Handbook). Thus the proper conventions must be used to produce the desired function. When the 1 input is relatively more negative than the O input, the above discussion, the symbol, the schematic and the truth table for the **negative AND gate** apply.

RECTANGULAR MATRICES

Application.

A rectangular diode matrice (matrix) is used in computers to perform a specific function, such as supplying a single output when supplied with multi-inputs or vice versa. It may also be known by its functional name instead. Thus, although arranged as a rectangular array it may be known as an encoding or decoding matrice. Actually it is a generic name for a class of circuits which are also named for the function they represent.

Characteristics.

May use positive or negative logic.

Consists of an orderly rectangular array of diodes.

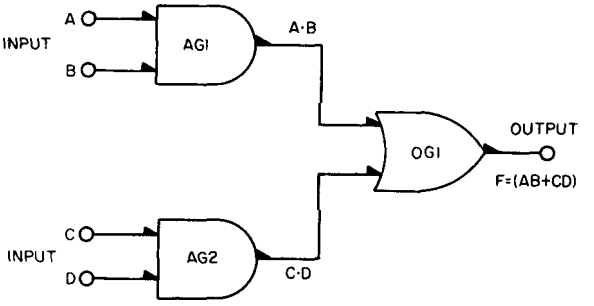
When many inputs are supplied only one or a very few outputs are produced, and vice versa.

Gain is less than 1 (no amplification is provided).

Circuit Analysis.

General. Rectangular diode matrices have no specird characteristics or functions of their own other than an ordered array of diodes. The matrix arrangement does not make it a logic circuit. It is the manner in which the matrix elements are connected that determines the logic function produced. Thus to describe a computer as containing a rectangular matrice is of no significance unless the associated function is also described.

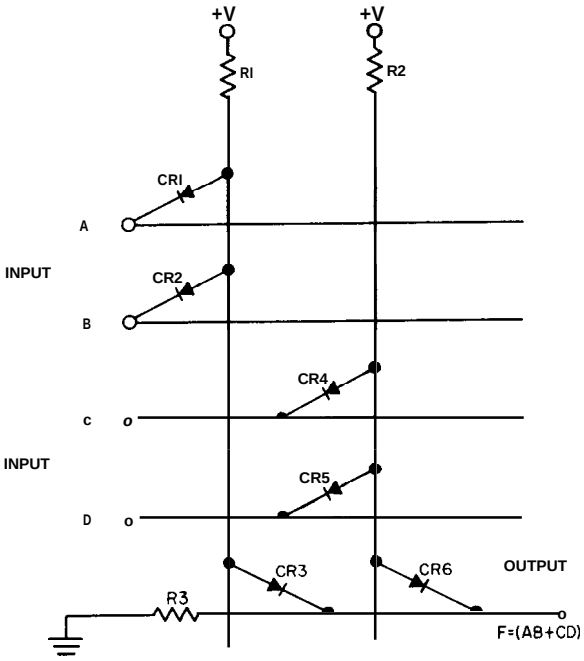
Circuit Operation. A simple rectangular matrice composed of two AND gates and one OR gate, which perform the logic function (AB + CD) are first shown symbolically, then as a matrix diagram, and finally, in schematic diagram form.



Logic Diagram of Matrice

As shown in the preceding logic diagram, the diode AND gates are AG1 and AG2, and the diode OR gate is OG1. Inputs A and B are provided for AGI, and C and D for AG2; the output of both circuits is combined by the OR gate at F. Thus output F is active whenever AGI output **(A·B)** is active, or when AG2 output (C"D) is active, or when both AG1 and AG2 are active. The output function is written symbolically as AB+CD, which is read as A AND B, or C AND D, or both A AND B and C AND D. The last mentioned condition is the inclusive OR function.

The diode matrix representation of the function, F = AB + CD is shown in the following illustration. AND gate AG1 consists of diodes CR1 and CR2, with current limiting resistor R1. AND gate AG2 consists of diodes CR4 and CR5, with current limiting resistor R2. OR gate OG1 consists of diodes CR3 and CR6, with current limiting resistor R3. h-r the drawing, zero volts represents a logic O and +V volts represents a logic 1, thus positive logic is used, and output F is active (logic 1) when it is at +V volts relative to ground. It is inactive (logic O) when it is at zero volts relative to ground.



Matrix Representation

Assume that all inputs (A,B,C, and D) are at zero volts (logic O). With the anodes of CR1, CR2, and CR4, CR5 connected to the positive bias supply through RI and R2, respectively, the diodes are forward biased and conduct. The supply voltage is dropped across resistors RI and R2 so that the anodes of OR gate diodes CR3 and CR6 are also at approximately zero volts. Because the cathodes of the OR gate diodes connect to ground via R3, there is no difference in potential across these diodes and no conduction occurs. Thus, the output of the OR gate remains at zero volts (a logic O). The conditions stated above are shown on line 1 of the table of combinations following. That is, all inputs and the output are at a low level (L).

LINE NO.	INPUT A	INPUT B	INPUT C	INPUT D	OUTPUT F = (AB + CD) (H)
1	L	L	L	L	L
2	L	L	L	H	L
3	L	L	H	L	L
4	L	L	H	H	H
5	L	H	L	L	L
6	L	H	L	H	L
7	L	H	H	L	L
8	L	H	H	H	H
9	H	L	L	L	L
10	H	L	L	H	L
11	H	L	H	L	L
12	H	L	H	H	H
13	H	H	L	L	H
14	H	H	L	H	H
15	H	H	H	L	H
16	H	H	H	H	H

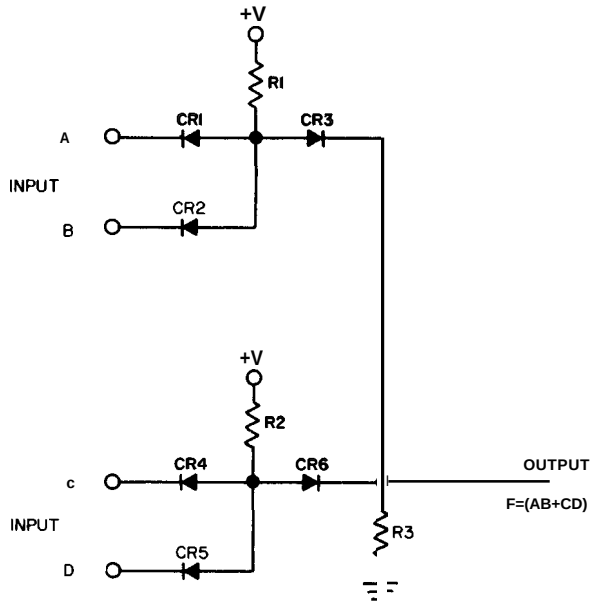
Table of Combinations

Assume now that the condition on line 13 is true. That is, inputs A and B are active at +V volts (relatively high), and inputs C and D are inactive at zero volts (relatively low). With inputs A and B both at +V volts, diodes CR1 and CR2 are held in the nonconducting state (reverse biased), while CR3 anode is positive with respect to ground and conducts, current flow is from ground through R3, diode CR3, and RI to the supply. Thus, output F is equal to the supply voltage minus the drop across R1, and the small drop through the diode, or approximately +V volts, a logic 1. Meanwhile, inputs C and D are inactive at zero volts, and diodes CR4 and CR5 conduct because of the high positive anode potential. The current flow through R2 drops the supply voltage to zero, with respect to ground, at the anode of diode CR6 (the OR gate). With the cathode of CR6 connected to ground through R3, no potential exists across the diode, it is reverse biased by the positive output voltage across R3, therefore CR6 does not conduct.

Assume now, that conditions are reversed, that is, inputs C and D are activated by a positive voltage, and inputs A and B are inactive at zero volts, this is combination number 4 in the table above. OR gate

diode CR6 now conducts, while CR3 remains nonconducting, and the output at F is again at +V volts, and produces a logic 1 while in this active state. It is evident from the table of combinations, above, that if each of the input combinations is performed, only combinations number 4, 8, 12, 13, 14, 15, and 16 will cause an active (high) output to be produced at F.

The schematic representation of the circuit described above is shown in the accompanying illustration. While this drawing and the matrix representation are identical, the arrangement is slightly different. Thus the schematic representation shows the more familiar AND and OR gate arrangements at a glance, However, the matrix drawing is usually used for matrices because it essentially conforms to the physical and wiring arrangement of the matrice, and it is clearer and easier to follow signal path flow when a large number of cascaded circuits are used. Both circuits are identical, however, so you may use whichever seems easier to follow or understand. The circuit explanation is applicable to both drawings. To fully understand operation of this circuit, you should apply each input condition shown in the table of combinations and verify that an identical result is obtained. Once established, the truth table makes it necessary to know how the circuit operates in determining a particular result. If the inputs are known, then the output can be determined at a glance.



Schematic Circuit

ENCODING MATRICES

Application.

Encoding matrices (matrix) are used to change data from one form into another. For example, the conversion of conventional decimal or english notation into a form usable in a digital computer. The decimal numbers, letters, and punctuation marks are converted to binary form for use in the digital computer.

Characteristics.

Consists of many input lines, but only a few output lines.

Only one input line is activated at a time to produce a unique output.

May use positive or negative logic, or combined logic,

Gain is less than 1 (no amplification is provided).

The matrix may be arranged in any suitable geometric form (rectangular, square, pyramid etc.).

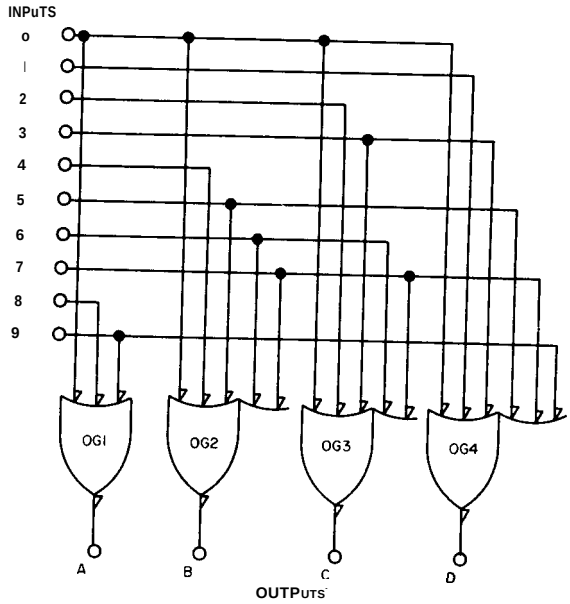
Circuit Analysis.

General. A decimal-to-binary encoder matrice changes a voltage level which represents a specific decimal number into a unique set of voltage levels representing the binary form of the decimal number. The following table shows decimal numbers from O through 9 with their binary equivrdents.

DECIMAL NUMBER	BINARY NUMBER			
o	0	0	0	0
1	0	0	0	1
2	0	0	1	0
3	0	0	1	1
4	0	1	0	0
5	0	1	0	1
6	0	1	1	0
7	0	1	1	1
8	1	0	0	0
9	1	0	0	1

Note that the decimal digit requires four binary digits (or bits) to represent it. Therefore, the circuit which performs the decimal to binary encoding must have 10 input lines, one for each decimal digit input, and 4 output lines, one for each binary output.

Circuit Operation. The logic diagram for a typical decimal-to-binary encoder is shown in the following illustration.



Decimal to Binary Encoder Logic Diagram

Examination of the logic diagram reveals that four OR gates are employed. OR gate number 1 has three inputs and one output. OR gates numbers 2 and 3 have five inputs and one output, and OR gate number 4 has six inputs with one output. The open triangles indicate that negative logic is used. Therefore, a logic O (inactive state) is represented by a relatively high voltage level (H), while logic 1 (the active state) is represented by a relatively low voltage level (L).

The following table of combinations shows the specific decimal number input and level, and the unique output level for each of the inputs.

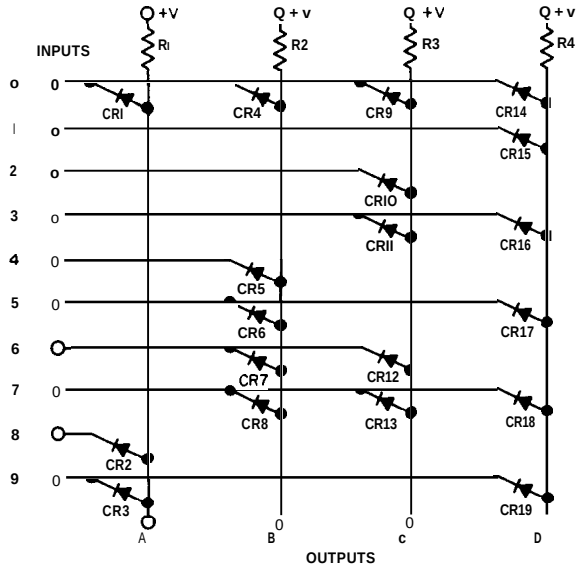
INPUT	OUTPUT			
F	A	B	C	D
0	L	L	L	L
1	H	H	H	L
2	H	H	L	H
3	H	H	L	L
4	H	L	H	I
5	H	L	H	L
6	H	L	L	H
7	H	L	L	L
B	L	H	H	I
9	L	H	H	L

Table of Combinations (Truth Table)

Examination of the table of combination reveals that the listed gate output is activated when the input is the decimal number(s) shown in the following matrix truth table; note that the number of inputs correspond to those shown on the logic diagram.

A = 0,8,9
8 = 0,4,5,6,7
C = 0,2, 3,6,7
D = O, 1,3,5,7,9

The following illustration shows the complete matrix schematic representation of the encoder.



Matrix Representation

Examination of the matrix schematic reveals that OR gate number 1 (output A) consists of diodes CR1 through CR3, with current limiting resistor R1. OR gate number 2 (output B) consists of diodes CR4 through CR8, with current limiting resistor R2. OR gate number 3 (output C) consists of diodes CR9 through CR13, with current limiting resistor R3. And OR gate number 4 (output D) consists of diodes CR14 through CR19, with current limiting resistor R4. As shown in the schematic, the anodes of all diodes are connected to a positive bias supply through the current limiting resistors. When their cathodes are connected to a less positive voltage, or placed at zero (ground) potential they will conduct. When left unterminated (no input) the circuit from the supply through the diode to ground is open, and no conduction occurs. When no conduction occurs, no current flows through the associated current limiting resistor and the gate output is +V, the supply voltage. Since negative logic is employed, a positive (relatively high) output represents a O and the circuit is then considered inactive. When a zero voltage (negative or relatively low) input is applied, all diodes on this line will conduct. The normally high (positive) output will be dropped to zero by the current flowing through the associated current limiting resistor, thus zero voltage or no output represents a 1, that is, an active negative output.

For example, assume the decimal number 7 is applied by grounding that input line (a relatively low (L) input is applied). The cathodes of diodes CR8, CR13, and CR18 are, therefore, more negative than their anodes, and these diodes will conduct. Thus at gate outputs B, C, and D, no voltage will appear, and these OR gates will all be at a relatively low (L) output. At the same time, since gate A output is not connected to line 7 it will remain highly positive at +V volts creating a relatively high (H) output. Thus by activating the number 7 line (through grounding it) the output will be **HLLL,** representing the binary number 0111 or the decimal number 7. By following the table of combinations, number for number, in a similar fashion and applying each input in turn, the outputs shown in the table of combinations will be obtained. Only one decimal number input at a time is permitted, with all the remaining lines resting in the inactive state. If two or more input ines were simultaneously activated, one of the numbers might be produced correctly and the others masked out, or else the wrong number would be produced. Thus in an encoder of this type a series input must be used, since a parallel input would produce a false indication. Conversely, the decoder which works just the opposite, requires a parallel input. Thus the coding time for a series of decimal digits in a simple computer represents a finite time, since only one can be produced at a time. However, the operating time for each digit is only a few microseconds, so that the coding is usually accomplished as fast as the information can be inserted, and appears to be instantaneous.

While the above explanation assumes the use of d-c voltage levels, the same action can be obtained with

pulses using appropriate coupling circuits, when needed. Because of the inherent loss in the diode (although assumed zero for ease of discussion in these paragraphs), when large numbers of diodes are used, considerable power is required. Thus diode logic is usually used together with transistors, and diode-transistor logic (DTL) circuits are used in large computers.

DECODING MATRICES

Application,

Decoding matrices (matrix) are used to change data from machine (computer) language to ordinary decimal or english notation. The binary representation of a decimal or an english character (machine language) is automatically converted by the matrix into a straight-forward reading character or digit easily recognized by the reader.

Characteristics.

Consists of many input lines, and many more output lines.

Several inputs are activated simultaneously to produce a unique output.

May use positive or negative logic, or combined logic.

Gain is less than 1 (no amplification is provided).

The matrix may be arranged in any suitable geometric form (rectangular, square etc.).

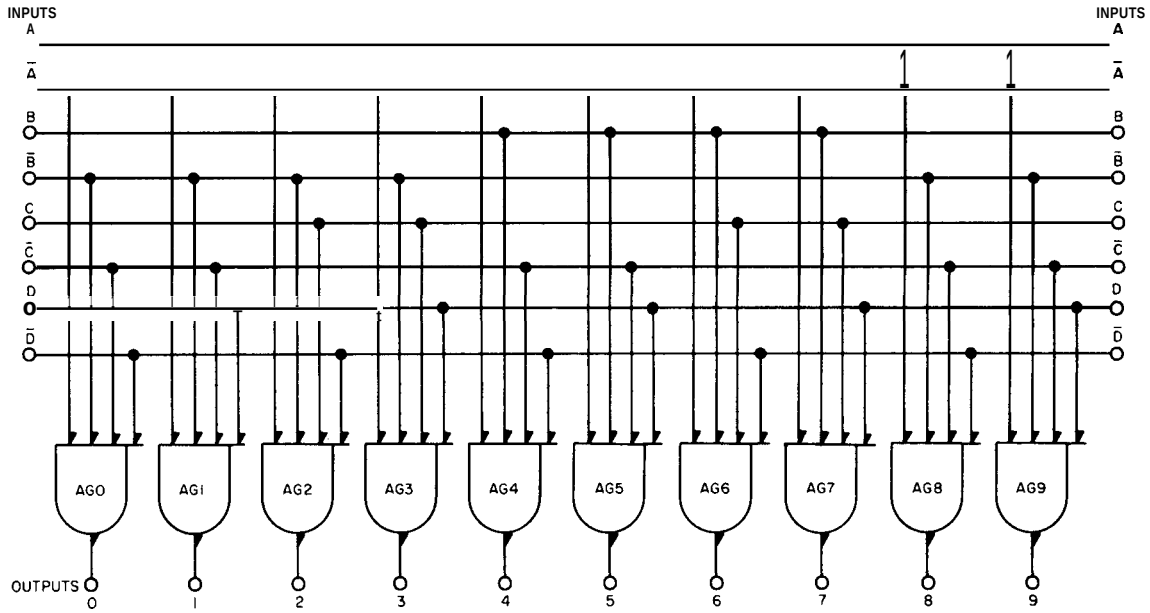
Circuit Analysis.

General. A binary-to-decimal decoder matrice changes a unique set of input voltage levels representing a binary number into an output which represents a single decimal number. The following table shows binary numbers from O through 9, with their decimal equivalents.

BINARY NUMBER	DECIMAL NUMBER
0 0 0 0	0
0 0 0 1	1
0 0 1 0	2
0 0 1 1	3
0 1 0 0	4
0 1 0 1	5
0 1 1 0	6
0 1 1 1	7
1 0 0 0	8
1 0 0 1	9

Note that each decimal digit requires four binary digits (bits) to represent it. Thus this type of decoder is sometimes called a “many-to-one” decoder, since many inputs are converted to a single output. To perform the binary decoding 8 inputs are required (four inputs for binary 1’s and four inputs for their complement, binary O), with 10 outputs representing the decimals from O through 9.

Circuit Operation. A logic diagram for a typical binary-to-decimal decoder is shown in the accompanying illustration.



Binary-to-Decimal Decoder Logic Diagram

Examination of the logic diagram shows that 1O-AND gates having 4-inputs and four diodes in each gate (AGO through AG9) are used. The closed triangles indicate that positive logic is employed. Therefore, the inactive state (a logic O) is represented by a relatively low voltage level (L), while the active state (a logic 1) is represented by a relatively high level (H). Thus, in the inactive state, logic O represents an (L) condition at inputs A, B, C, and D, and an (H) condition at inputs Ȧ, B, $\overline{C}$, and $\overline{D}$.

The following table of combinations shows the various binary input levels and the unique output level for each of the possible input combinations.

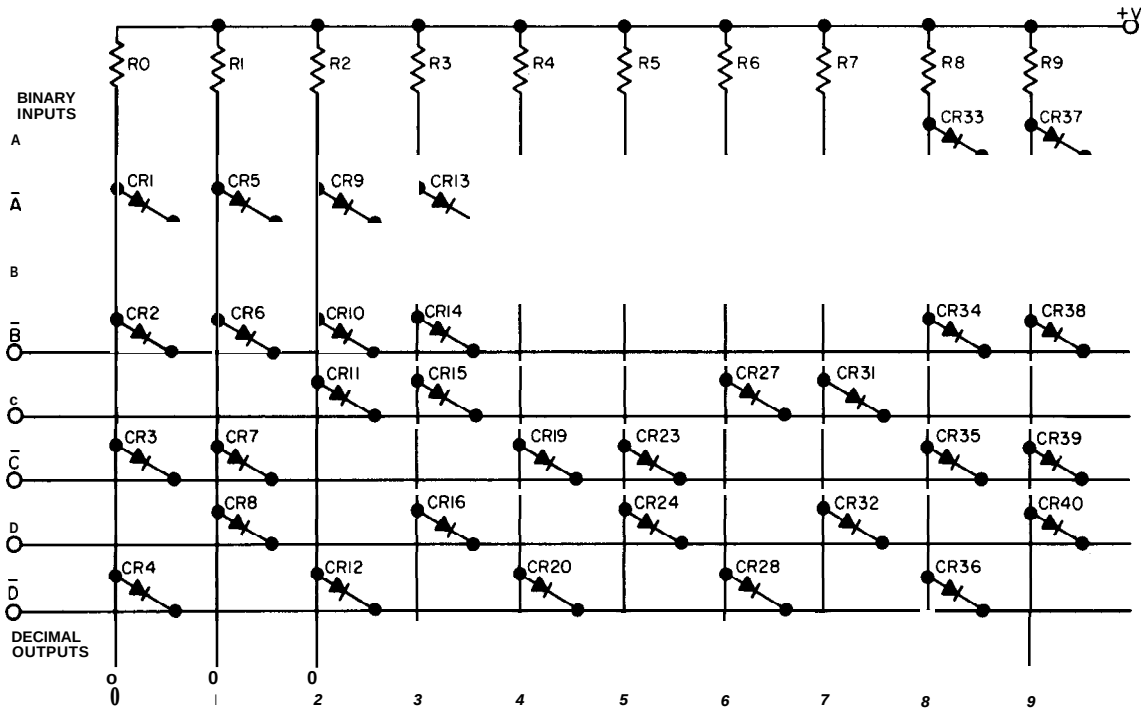
BINARY INPUT				DECIMAL OUTPUT	
A	B	C	D	F	
L	L	L	L	H	(0)
L	L	L	H	H	(1)
L	L	H	L	H	(2)
L	L	H	H	H	(3)
L	H	L	L	H	(4)
L	H	L	H	H	(5)
L	H	H	L	H	(6)
L	H	H	H	H	(7)
H	L	L	L	H	(8)
H	L	L	H	H	(9)

Table of Combinations

Examination of AG8 reveals that in the inactive condition, three of its inputs are in the (H) condition (inputs B, C, and $\overline{D}$); only the fourth input to AG8 (input A) need be activated to produce an output decimal number 8. While the gate that is activated for each binary input is shown by the preceding table of combinations, if it is converted into a Truth Table by substituting the O and 1's corresponding to the decimal number as shown in the following table, operation becomes easier to follow. It is also evident that this is the same as the binary-decimal equivalent numbers previously listed. When the gates are activated it is by means of a logic 1 signal. In the logic zero state the gate remains inactivated. When the gate input is activated, the input signal stops the associated gate diodes from conducting, and an output is produced as the output level rises to the +V supply voltage. When the gate input is inactivated, the cathode of the associated diode is at a lower potential than the anode and the diode conducts. The current flow through the associated current limiting resistor drops the supply voltage to zero so that no output is obtained. Thus when input A is activated a positive voltage is applied to block off or reverse bias any diodes connected to that line. When $\overline{A}$ (A-bar) is activated it is a "NOT A"; thus, it is not a logic 1 but a logic O, and all the diodes associated with that line conduct because of the forward bias applied by the relatively-low (L) input signal.

BINARY NUMBER				DECIMAL NUMBER
0	0	0	0	o
0	0	0	1	1
0	0	1	0	2
0	0	1	1	3
0	1	0	0	4
0	1	0	1	5
0	1	1	0	6
0	1	1	1	7
1	0	0	0	8
1	0	0	1	9

This operation may be followed more easily if the accompanying matrix schematic is examined in conjunction with the truth table inputs as the discussion continues.



Decoder Matrix Schematic

For example, assume that inputs B and D are active (H) and $\overline{A}$ and $\overline{C}$ are inactive (therefore also high (H)); this places a +V volts (H) at each of the four inputs to AG8. The truth table shows that the corresponding combination 0101 must activate gate number 5 and produce a high positive output. Examination of the matrix schematic shows that gate 5 consists of CR21 through CR24 with current limiting resistor R5. When input line $\overline{A}$ is inactive (H), diode CR21 ceases conduction; likewise, as B, $\overline{C}$ and D, respectively, are also made high the diodes CR22, CR23, and CR24 are also reverse biased. Thus all the diodes of AND gate 5 stop conduction simultaneously, and output F which is assigned the decimal number 5 rises to the supply voltage level creating a positive output pulse, as required by the table. Note that if any one of these inputs were not high (H), but were low (L) instead, then that one diode would conduct and the high output could not occur. Thus one, and only one particular combination will activate each of the AND gates. To prove this, examine each of the input lines which are at a relatively low value. We find, then, that line A forward biases diodes CR33 and CR37 and decimrd outputs 8 and 9 are, therefore, at zero. Likewise, for input line $\overline{B}$ diodes CR2, CR6, CR1O, and CR14 conduct and outputs O, 1, 2, and 3 are low or zero. For line C diodesCR11, CR15, CR27, and CR31 conduct so that outputs 2,3, 6, and 7 are zero. Finally, input $\overline{D}$ causes conduction of diodes CR4, CR12, CR20, CR28, and CR36, with outputs O, 2, 4, 6, and 8 at zero. Thus, while gate 5 is high, all the other outputs are low or zero since at least one of the associated diodes is conducting. Sometimes two or more diodes will be conducting, but only one is necessary to prevent the gate from operating, and producing an output.

If you follow the truth table combinations, applying high and low inputs as indicated and noting the output, or lack of output, you will see that the truth table shows the proper combination for the desired output, and no other combination will produce the same results.

TWO-LEVEL AND-OR GATE

Application.

Combinations of AND-OR gates which form a two-level logic circuit can be used to apply the outputs of two or more logic circuits to the input of another logic circuit to produce logic addition, subtraction and other functional operations.

Characteristics.

May use positive or negative logic, or combined logic.

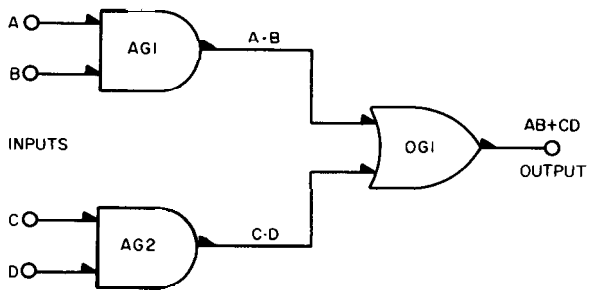
Has not less than four inputs for one output, and may have six or eight inputs with only one output, if desired.

The actual input levels may be different, however, the outputs are always at the same level.

Output never exceed the input (no amplification is obtained).

Circuit Analysis.

General. Two-level logic circuits have two basic input circuits and a single output circuit. The input circuits may have a number of input lines, each controlled by a diode, but there is only one output line. Thus it is common practice to make the input circuits AND gates, and the output circuit an OR gate. Although this logic may be changed to exactly the opposite by applying negative logic inputs. Thus, the AND gates become OR gates, and the OR gate becomes an AND gate without changing any circuitry. This allows complete flexibility in combining logic operations, and, therefore, two-level logic circuits are universally used throughout computers. The logic diagram for a combination of two positive AND gates, and a positive OR gate is shown in the following illustration.

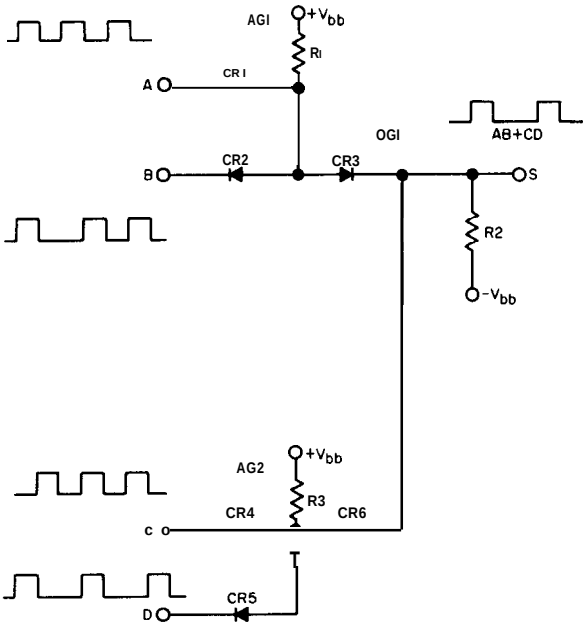


Two-Level Positive AND-OR Gate

Circuit Operation. The schematic for a typical two-level AND-OR gate is shown in the following

491-044 0 73 34

illustration. Although only two inputs are shown for each branch circuit for ease of discussion, a large number of inputs may be accommodated.



Two-Level AND-OR Gate Schematic

It is evident from the schematic that AND gate number 1(AG1) is identical to AG2. Two different inputs are applied to each AND gate. The output of the AND gates are applied through CR3 and CR6, and are summed across R2. A table of combinations shows that the following truth table is applicable, where O is ground or zero level, and 1 is a +5.

INPUTS				OUTPUT
A	B	C	D	S
0	0	0	0	0
0	1	0	1	0
1	0	1	0	0
1	1	1	1	1

Truth Table

Thus with no input applied, diodes CR1, CR2 and CR4, CR5 conduct since they are forward biased, and the voltage across RI and R3 is dropped to zero. OR diodes CR3 and CR6 are also conducting (anode is more positive than cathode) so that this output is also zero. When either A or B, or C or D is made a 1 (by applying plus 5 volts) the associated diode is reverse-biased and stops *conducting.* However, circuit operation remains unaffected since the other diode of the pair still conducts and holds the gate in the zero state. However, whenever both inputs are applied simultaneously to either AND gate, both diodes are reverse biased, conduction ceases, and the voltage at the bottom end of R1 or R3 is the same as the supply, if the reverse bias is equal to or greater than the supply. If the reverse bias is only a portion of the supply voltage, (as is the case) conduction above that level holds the output at the value of the reverse bias. Thus with a 10 volt supply and a 5-volt reverse bias, the output is +5 volts. This output of the AND gate when applied to the OR gate passes through either CR3 or CR6 and appears as the output sum (AB + CD). When +5 volts appears at the output the inactive OR diode is reverse-biased by that same amount, so that the other AND output has no effect. That is the exclusive OR function is represented, where either one or the other (AG1 or AG2) appears but not both. In this respect, the truth table appears erroneous. However, it is just the manner in which it is arranged. Thus this circuit is sometimes called a **onequarter adder, since** it only represents the sum of two digits. When another AND gate is added to indicate the carry where both OR gate inputs are present simultaneously, the circuit then is known as a half-adder (discussed separately later in this section of the Handbook).

HALF-ADDER CIRCUITS

Application.

Half-adders are used to form the sum of two incident binary digits. "They are used as the basic circuit for a full-adder (two half-adders make a full-adder). Thus full binary adding networks used in computers consist of a number of half-adders, and associated circuitry.

Characteristics.

May use either positive or negative logic, or combined logic.

Usually has four input lines with two output lines.
Consists of three AND gates and one OR gate.
Gain is less than 1 (no amplification is provided.)

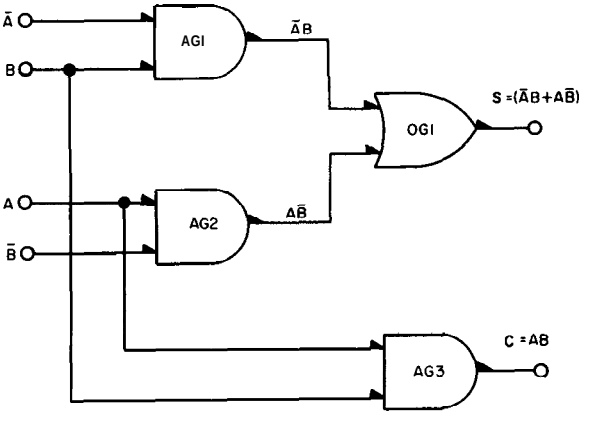
Circuit Analysis.

General. Since the half-adder performs binary (arithmetic) addition it is necessary that its output be identical to the results of the binary addition table as follows:

A + B	0 + 0	0 + 1	1 + 0	1 + 1
SUM	0	1	1	0
CARRY	0	0	0	1

We see from the table that two outputs are needed, since there is a carry of 1 when two 1's are added. It is evident that to add three binary numbers another carry output is needed. Hence to add more than two binary bits it is necessary to employ more than one half adder so that full-adders (consisting of two or more half-adders) are usually used in adder networks.

Circuit Operation. A typical half-adder is shown in the accompanying logic diagram.



Half-Adder Logic Diagram

Examining the diagram we see that three twodiode AND gates AG1, AG2, and AG3 are used, together with a single two-diode OR gate OG1. The logic equation at the output shows that the sum output (S) is high (H), and active whenever the two inputs A and B are unlike, and is inactive low (L) whenever the two inputs are alike. The output equation $S = \bar{A}B + A\bar{B}$ is read as "A or B, but not both"; this is the **axclusive OR** function. The carry output is active and high (H) whenever the two inputs A and B are equal to binary l's, and is inactive low (L) for all other conditions. The following table of combinations shows the proper output for any particular input combination.

INPUTS		OUTPUTS	
A	B	S	c
L	L	L	L
L	H	H	L
H	L	H	L
H	H	L	H

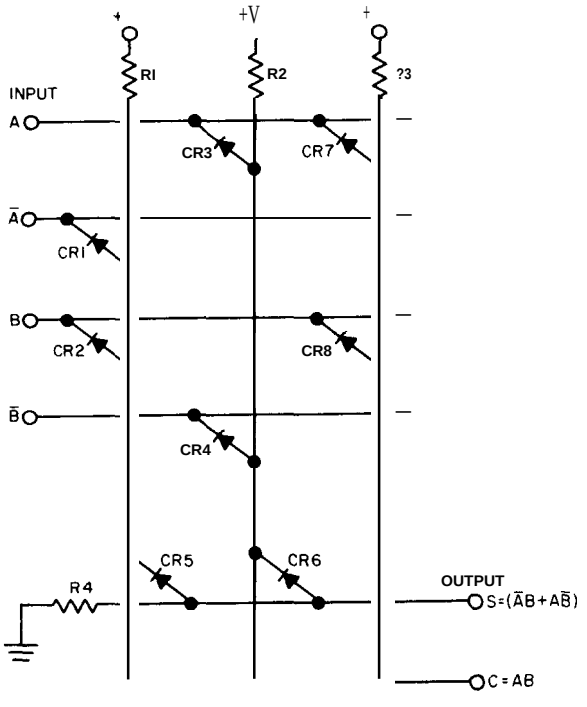
Table of Combinations For Half-Adder

When the table of combinations is converted into a truth table by substituting the O's and 1's, as shown in the following table, it is evident that it corresponds to the preceding binary addition table, and that the circuit is performing the desired function.

INPUTS		OUTPUTS	
A	B	SUM	CARRY
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

Half-Adder Truth Table

Circuit details are shown in the following matrix schematic (the half-adder may also be considered as a rectangular or square matrice).



Half Adder Matrix Diagram

Examination of the matrix diagram reveals that AND gate number 1 consists of diodes CRI and CR2 with current limiting resistor RI; AND gate number 2 consists of diodes CR3 and CR4, with current limiting resistor R2, and the carry gate is AND gate number 3 with diodes CR7 and CR8, and current limiting resistor R3. The OR gate consists of diodes CR5 and CR6, with current limiting resistor R4. Zero volts represents logic O (L), and +V volts represents logic 1 (H).

Assume that inputs A and B are logic l's, thus their input line is at a high level (H). Therefore, associated diodes, CR3, CR7 on line A, and CR2, CR8 on line B are reverse-biased and will stop conduction. Thus output C of AND gate number 3 (the carry gate) will rise to +V volts and also be at a high level, which is the output expressed by the formula C=AB. With inputs A and B high, their complement inputs $\overline{A}$ and $\overline{B}$ (NOT A and NOT B) are low, causing diodes CR1 and CR4 to conduct. Therefore, OR gate diodes CR5 and CR6 will not conduct, since the potential at the anode end of R1 and R2 will be zero, and with the diode cathodes connected to ground through R4 no potential exists across these diodes. Thus there is no output from the S output line, and it is a logic O.

In a similar manner, it is evident that for the sum output (S) to be high (H), inputs $\overline{A}B$ or $A\overline{B}$ but not both must be a logic l(H). For these conditions, either diode CR7 or diode CR8 is held inoperative by reverse bias from the logic 1 input, while the other diode conducts because of the lack of an input (both diodes must be reverse biased to produce an output). Therefore, carry output, C, remains inactive and low or a logic O. By following the table of combinations (or truth table) for each input condition, and by using the matrix diagram to determine which diodes are activated and which are not, you can verify operation of the circuit against each unique output listed in the table. Normally, when inputs A and B are alike, the sum output is always O(L), and when unlike it is always l(H). The carry output, C, is always O (low) except when both A and B inputs are high (l), in which case it is also high (H), and a logic 1.

FULL ADDER

Application.

The full-adder is used in digital computers to add two or more digital characters containing any combination of bits. The full adder may be a specially designed circuit or it may be formed from two or more half adders.

Characteristics.

May use either positive or negative logic, or combined logic.

Consists of four inhibit gates, three OR gates, and two AND gates.

Has three input lines and two output lines.

Circuit Analysis.

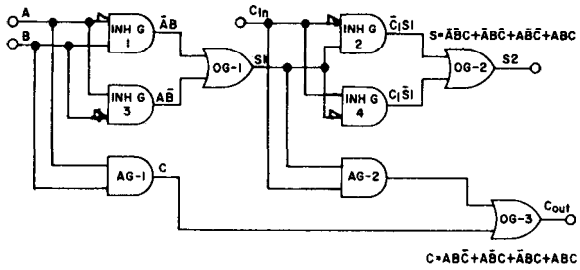
General. The full-adder performs the binary addition of two characters that can not be added by a single half adder. The conventional adder consists of two half adders and an OR gate. The first half-adder combines the augend and addend of the applied characters, and the second half-adder combines the resulting sum of the first half-adder and any carry pulses received from other full-adders. The sum output from the second adder is the sum output of the

full-adder. The separate OR gate receives carry pulses from each half-adder to produce a carry pulse for application to other full-adders.

Each full-adder is connected in a series, or a parallel, or a series-parallel arrangement, to produce the true sum of the applied digits or bits by the most desirable mode of operation. If the adder is connected in series it is necessary to use more than one full-adder, but if the adder is connected in parallel, a single full-adder plus additional elements are used to produce a true sum. The following figure is a typical example of binary addition showing the resultant binary sum that is produced from a binary augend and binary addend.

Addend 1101
Augend 1011
Sum 0110
Carry 1001

Circuit Operation. A typical full-adder is shown in the following logic diagram. The circuit consists of four inhibit gates, two AND gates and three OR gates. Each gate is identified by a number for ease of explanation. Since the full-adder provides for the application of a carry pulse as well as the addend and the



Full-Adder Logic Diagram

augend pulses, the logic equations for the sum and carry outputs of the full-adder (as shown in the logic diagram) become more involved than the sum and carry equations for the half-adder. The following table of combinations shows the proper output for any combination of inputs.

A	B	C_{in}	S	c_{out}
L	L	L	L	L
L	L	H	H	L
L	H	L	H	L
H	L	L	H	L
L	H	H	L	H
H	L	H	L	H
H	H	L	L	H
H	H	H	H	H

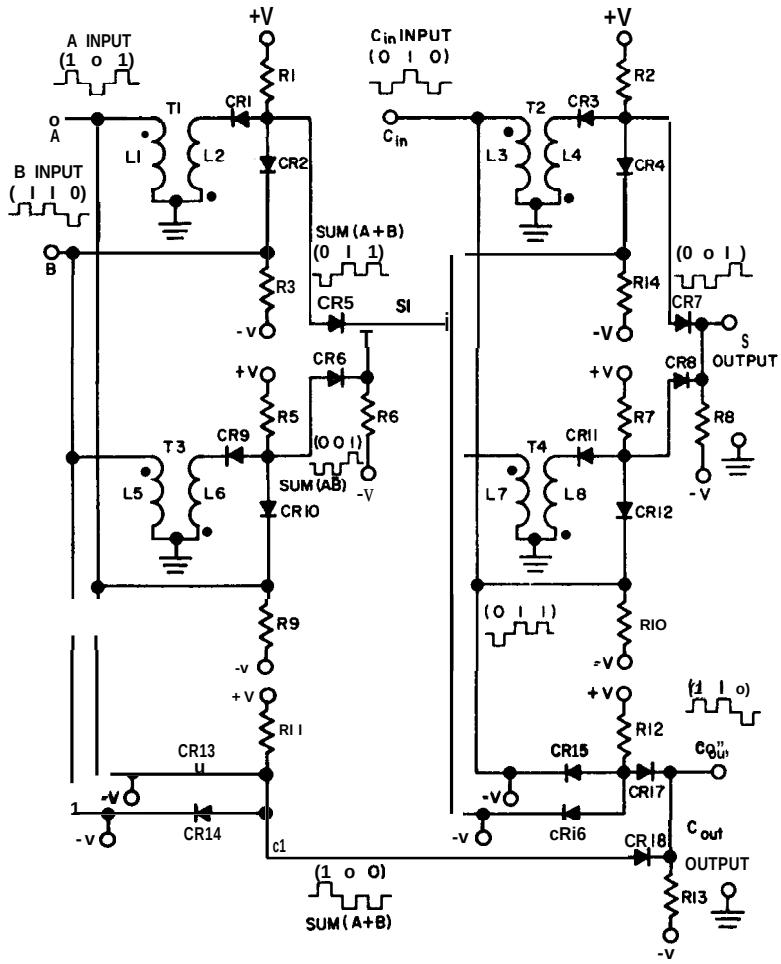
Table of Combinations

A truth table that corresponds to the table of combinations is shown in the following table.

A	B	C_{in}	S	c_{out}
o	0	0	0	0
0	0	1	1	0
0	1	0	1	0
1	0	0	1	0
0	1	1	0	1
1	1	0	0	1
1	1	1	1	1

Truth Table

The schematic representation of a diode full-adder is shown in the following illustration. The three inputs to the adder are labeled A, B, and C_{in}; the two outputs are labeled S and C_{out}. Diodes contained in the full-adder inhibit gates are: CRI, CR2, CR3, CR4, CR9, CR1O, CR11 and CR12. Resistors Rl, R2, R3, R4, R5, R7, R9 and RIO are inhibit gate load resistors, Transformers T1, T2, T3 and T4, consisting of coils L1 through L8, provide inversion of pulses applied to the inhibiting input of the inhibit gates. Diodes CR5, CR6, CR7, CR8, CR17 and CR18 make up the OR gates of the full-adder; resistors R6, R8, and R13 are associated OR gate load resistors. Diodes CR13, CR14, CR15, and CR16 make up the AND gates; resistors R11 and R12 are associated AND gate load resistors.



Full-Adder

The diode full-adder shown in the schematic, operates with positive logic; that is, positive pulses must be applied to the full-adder inputs to produce any circuit response. A positive pulse, then, represents a logic 1, and a negative pulse (or lack of a pulse) represents a logic O. Assume that a logic character of 101 is applied sequentially to the full-adder A input, while a logic character of 110 is applied sequentially to the full adder B input, and a logic character of 010 is applied sequentially to the full-adder C_{in} input. The first augend bit (first bit of the character applied to input A) is then a positive pulse; the first addend bit (first bit of the character applied to input B) is a negative pulse (or lack of a pulse) and the first carry input bit (first bit of the character applied to input C_{in}) is likewise a negative pulse (or lack of a pulse). The positive augend bit is applied to primary L1 of transformer T1 which induces a corresponding negative voltage in secondary L2 of T1. This negative pulse causes inhibit gate diode CR1 to conduct at a greater rate, causing greater current to flow through inhibit gate load resistor R1 and a larger voltage drop across R 1. The anode end of resistor R1 then becomes negative. The positive augend bit also appears at the cathode of inhibit gate diode CR1O. In this case, the positive input pulse cancels the effect of

the negative supply voltage applied through resistor R9 to the cathode of CR1O. Since a negative input is applied to input B and inverted by T3, diode CR9 is reverse biased and does not conduct. There is now no current flowing through inhibit gate load resistor R5, and likewise no voltage drop across resistor R5. The voltage at the anode end of R5 is the value of the positive supply voltage. The positive augend bit also appears at the cathode of AND gate diode CR13, canceling the negative supply voltage applied to the cathode, and preventing diode CR13 from conducting. AND gate diode CR14, however, remains conducting because of the forward bias supplied by the negative voltage applied to the cathode of CR14 and the positive voltage applied to the anode of CR14. Current flows through AND gate load resistor R11, producing a voltage drop across R11 which makes the anode end of R 11 negative. This negative voltage represents a logic O first half-adder carry output.

The negative voltage previously produced at the anode end of R1 appears at the anode of first half-adder sum output OR gate diode CR5. Since a diode w-ill not conduct if a negative voltage is applied to reverse bias the anode, CR5 does not conduct. The positive voltage produced at the anode end of inhibit gate load resistor R5, also appears at the anode of OR gate diode CR6. With a positive voltage appearing on the anode of CR6 from the inhibited B input, CR6 conducts, causing current flow through OR gate load resistor R6 and produces a voltage drop across the resistor. The voltage at the cathode end of R6 is positive. This is the sum output (S1) of the first half-adder.

The carry input pulse (C_{in} which is a logic O, is the augend input of the second half-adder. The sum output of the first half-adder, which is a logic 1, is the addend input of the second half-adder. This logic 1 pulse appears simultaneously at the cathode of inhibit gate diode CR4, at primary coil L7 of transformer T4, and at the cathode of AND gate diode CR15. The positive pulse appearing at the cathode of CR4 provides a reverse bias which prevents diode CR4 from conducting, and prevents voltage from being developed across load resistor R2. Hence, the anode end of resistor R2 rises to the positive supply voltage value. The positive pulse applied through primary coil L7 of transformer T4 induces a negative pulse into secondary coil L8. This negative pulse then appears at the cathode of inhibit gate diode CR11, causing CR11 to conduct more heavily, and increasing the flowing through load resistor R7. An increased voltage drop appears across resistor R7, making the anode end of R7 negative. The negative voltage appears at the anode of second half-adder sum output OR gate diode CR8. The positive voltage previously produced at the anode end of resistor R2 simultaneously appears at the anode of output OR gate diode CR7. Although diode CR8 does not conduct, diode CR7 does conduct, causing current to flow through the full-adder sum output OR gate load resistor R8 and develop a voltage drop across R8, which leaves the cathode end of R8 positive. This positive (logic 1) pulse is the sum output of the second half-adder (S) for the duration of the first bit.

The (logic 1) positive addend pulse appears at the cathode of second half-adder carry AND gate diode CR15, preventing diode CR15 from conducting. Second half-adder carry output AND gate diode CR16 conducts, however, because of the negative voltage at the cathode of CR16 and the positive voltage applied to the anode of CR16 through the AND gate load resistor R12. As a result, current flows through load resistor R12 and the voltage drops across resistor RI 2, leaving the anode end of resistor R12 at zero voltage. This zero voltage appears at the anode of carry output AND gate diode CR17. Due to the lack of previous carry, the zero voltage produced at the anode end of resistor R1 1, appears at the anode of carry output AND gate diode CR18. Neither diode CR17 nor diode CR18 conduct because of the negative voltage (or lack of positive voltage) at their anodes. No current flows through load resistor R13 and no voltage drop appears across R13. The voltage at the cathode end of RI 3 is the applied negative voltage value; the carry output of the full-adder is then a logic O for the duration of the first logic bit.

The second augend bit (A input) is a logic O; the second addend bit (B input) is a logic 1, and the second carry input bit (C_{in} input) is a logic 1. The logic 1 bit or positive pulse applied to the B input appears at the cathode of inhibit gate diode CR2 and coil L5 of transformer T3. At the cathode of CR2, the positive pulse prevents CR2 from conducting, preventing current from flowing through load resistor R1, and preventing any voltage dropping across resistor R1. The anode end of resistor R1 is then at the same potential as the positive supply voltage applied

to resistor R1. At primary coil L5, the positive voltage pulse causes a negative pulse to be induced into secondary coil L6, of transformer T3. The negative pulse appears at the cathode of inhibit gate diode CR9, causing CR9 to conduct more heavily and in increased current flows through load resistor R5. The voltage drop across R5 is increased making the anode end of resistor R5 negative.

The logic 1 bit or positive pulse applied to the B input also appears at the cathode of first half-adder carry AND gate diode CR14, preventing diode CR14 from conducting. First half-adder carry output AND gate diode, CR13, still conducts, however, since a negative voltage is applied to the cathode of CR13 and a positive voltage is applied through the AND gate load resistor, RI 1, to the anode of CR13. The conducting of CR13 causes current to flow through load resistor RI 1 and the voltage to drop across RI 1. The anode end ofR11 remains at a zero or effectively negative potential. This negative potential represents a logic O carry output of the first half-adder.

The logic O (zero or negative voltage) pulse produced at the anode end of resistor R5 appears at the anode of first half-adder sum output OR gate diode CR6, and the logic 1 (positive pulse) produced at the anode end of resistor R1 appears at the anode of first half-adder sum output OR gate diode CR5. Diode CR6 does not conduct because of the negative voltage appearing at the anode of CR6; however, due to the positive potential on the anode of diode CR5 and the negative potential on its cathode, OR gate diode CR5 conducts. Current then flows through the OR gate load resistor, R6, producing a voltage drop across it. The cathode end of resistor R6 then swings positive. This positive potentird swing represents a logic 1 sum output of the first half-adder.

The logic 1 (positive) pulse applied to the C_{in} input is the augend of the second half-adder; the logic 1 (positive) pulse applied from the cathode end of R6, (the sum output of the first half-adder) is the addend of the second half-adder. Because of both inputs being positive, a positive pulse appears at each of the following points: primary coil L3 of transformer T2, the cathode of inhibit gate diode CR4, primary coil L7 of transformer T4, the cathode of inhibit gate diode CR12, the cathode of the second half-adder carry output AND gate diode, CR15, and the cathode of the second half-adder carry output AND gate diode CR16.

In both second half-adder inhibit gates, current is prevented from flowing through the non-inhibiting diodes of the inhibit gate (CR4 and CR12) by the positive voltage appearing at their cathodes. The positive voltage pulse appearing at the primary coils (L3 and L7) of transformers T2 and T4, however, causes negative voltage pulses to be induced into the secondary coils (IM and L8) of these transformers, placing a negative voltage on the cathodes of inhibit gate diodes CR3 and CR11. As a result, diodes CR3 and CR11 conduct, creating current flow through the diodes and their load resistors, R2 and R7. The current flow through the load resistors causes a voltage drop across them, leaving the anode ends of both load resistors at zero, producing a negative swing. This negative swing at the anode end of resistor R2 appears at the anode of second half-adder sum output OR gate diode CR7, and the negative swing produced at the anode end of resistor R7 appears at the anode of second half-adder sum output OR gate diode CR8. With either zero or a negative voltage appearing at the anodes of both diodes they are reverse biased, and neither diode conducts. As a result, no current flows through either diode or through the second half-adder sum output OR gate load resistor, R8, and no voltage drop appears across resistor R8. The voltage at the cathode end of resistor R8 is the negative supply voltage value. This negative voltage represents a logic O sum output of the second half-adder and the total sum of the full adder during the duration of the second bit.

The positive (logic 1) pulse appearing at the cathodes of each of the second half-adder carry output AND gate diodes CR15 and CR16, reverse biases the diodes. Hence, no current flows through either diode, or the AND gate load resistor R12, and no voltage drop appears across resistor R12. The voltage at the anode end of resistor R12 is the vahre of the positive supply voltage. This voltage appears at the anode of full-adder carry output OR gate diode CR17. The logic O (negative) pulse produced at the anode end of tirst half-adder carry output load resistor R11 appears at the anode of the other full adder carry output OR gate diode, CR18. The logic O pulse at the anode of CR18 has no effect, but the logic 1 (positive) pulse at the anode of CR17 causes current to flow through diode CR17 and load resistor R13, developing a positive voltage drop across resistor R13. The resulting positive voltage at the cathode end

of resistor RI 3 represents a logic 1 full-adder carry output for the second bit time period.

The third augend bit (A input) is a logic 1; the third addend bit (B input) is a logic 1, and the third carry input bit (C_{ti} input) is a logic O. Because both augend and addend inputs are positive, a positive pulse appears at each of the following points: primary coil L1 of transformer Tl, the cathode of inhibit gate diode CR2, primary coil L5 of transformer T3, the cathode of inhibit gate diode CR1O, the cathode of first half-adder carry output AND gate diode CR13, and the cathode of first half-adder carry output AND gate diode CR14.

In both first half-adder inhibit gates, current is prevented from flowing through the non-inhibiting diodes of the inhibit gate (CR2 and CR1O) by the positive pulse appearing at their cathodes. The positive voltage pulse appearing at the primary coils (Ll and L5) of transformers T1 and T3, however, causes negative voltage pulses to be induced into the secondary coils (L2 and L6) of these transformers, placing a negative voltage on the cathodes of inhibit gate diodes CR1 and CR9 and they conduct. Thus current flows through the diodes and associated load resistors, RI and R5. The current flow through the load resistors produces a voltage drop across them, leaving the anode end of both load resistors zero or effectively negative. The effective negative pulse voltage at the anode end of resistor R1 appears at the anode of first half-adder sum output OR gate diode CR5, and the effective negative puke voltage at the anode end of resistor R5 appears at the anode of first half-adder sum output OR gate diode CR6. With the effective negative pulse voltage at the anodes of both diodes they are reverse biased, and neither diode conducts. Therefore, no current flows through either diode, or through first half-adder sum output OR gate load resistor R6, and no voltage drop appears across resistor R6. The voltage at the cathode end of load resistor R6 is the negative supply voltage value. This negative voltage represents a logic O sum output of the first half-adder.

The third positive bit (logic 1) pulse appearing at the cathodes of each of the first half-adder carry output AND gate diodes CR13 and CR14, reverse biases the diodes. This prevents current flow through either diode, or AND gate load resistor RI 1, and no voltage drop appears across resistor RI 1. The voltage at the anode end of resistor R1 1 is the value of the positive supply voltage. This positive voltage represents a logic 1 first half-adder carry output.

The third logic O (negative or zero) pulse applied to the C_{in} input is the augend of the second half-adder; the logic O (negative or zero) pulse applied from the cathode end of R6 (the sum output of the first half-adder) is the addend of the second half-adder. Since both addend and augend bits applied to the second half adder are a logic O, there is no circuit action in the second hrdf-adder. The second half-adder produces a logic O sum output, which is the output for the full adder during the time that the third sequence of bits is applied. For the same reason, there is a logic O carry output for the second half-adder during the time that the third sequence of bits is applied.

The logic 1 (positive) pulse output of the first half-adder carry output appears at the anode of full-adder carry output OR gate diode CR18, while the logic O (positive) pulse output of the second half-adder carry output appears at the anode of full-adder carry output OR gate diode CR17. Diode CR17 does not conduct because there is no positive voltage on the anode. (Diodes CR15 and CRI 6 conduct and drop the voltage across R12 to zero). The positive carry pulse voltage applied to the anode of diode CR18 causes CR18 to conduct, producing a current through the diode and load resistor R13. This voltage drop appears across resistor R13, making the cathode end of resistor R13 swing positive. This positive voltage swing represents a logic 1 full-adder carry output at the time that the third sequence of bits is applied.

When it is necessary to obtain the true sum from a single full-adder stage, a delay line is placed after the C_{out} output. The delay line moves each digit of the carry output one significant place to the left to establish the correct time relationship for the sum of the S output and the C_{out} output.

PART 16-3. TRANSISTOR LOGIC

TRANSISTOR LOGIC (GENERAL)

Like the diode, the transistor may be employed in logic circuits. While some of the basic circuits such as the AND and the OR circuit perform the same operation as in diode logic, numerous advantages are obtained, and in addition, circuits not possible with diodes can be utilized, such as NAND, NOR, and similar not operations. The additional element in the transistor provides the ability to provide an inherent inversion similar to that normally obtained in the electron tube. Of much greater importance, however, are the improvement in operating speed possible with the transistor, plus the possibility of obtaining a gain through the circuit. For stages that require a heavy current output for operating relays and other electronic devices the transistor emitter-follower connection provides power output with reduced gain. Because of the high input and output impedances possible with the transistor, the shunting effect of parallel inputs or outputs is not as great a problem as it is with diodes. Thus an entire new field of logic circuits and application was open by the use of transistors. In turn, other new circuitry was developed by combining diode and transistor logic (DTL), or by using direct coupling (DCTL). Basic circuits using transistor logic, DTL, DCTL, and RTL (resistor-transistor logic), will be discussed in this Section of the Handbook.

OR GATE

Application.

The transistor "OR" gate is used in applications where an output gate is desired with the presence of a pulse at only one (or more) of its inputs.

Characteristics.

May use positive, negative, or combined logic.

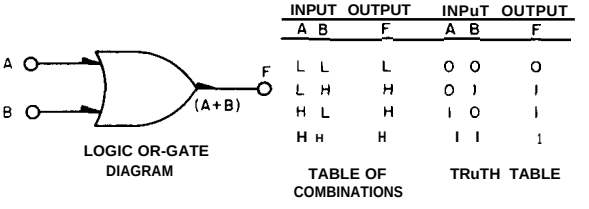
Provides additional gain.

May be either single transistor or multiple transistor type (multiple type provides a transistor for each input).

Circuit Analysis.

General. There are many types of transistor OR gates. When the common-emitter configuration is used, the circuit usually becomes a NOR circuit because of the polarity inversion. The common-collector configuration has the same polarity at input and output, but falls within the class of Emitter-Follower circuits which are separately discussed. Thus the common-base connected OR circuit is the only remaining circuit which does not fall within another circuit classification and has the same polarity output as input. Consequently, the following discussion mainly concerns the common-base circuit, though other representative OR circuits may be briefly shown for completeness. It should be realized that in logic operations identical logic circuits have many forms which vary with design. For example, where one designer may use a single transistor OR gate to perform logic addition, another designer may use three or four transistors to accomplish the same purpose. This is why the logic designer usually uses the block diagram type of logic diagram representation rather than the schematic, since the function performed denotes the type of circuit, while the parts and actual circuit connections or arrangement are of no consequence as long as the desired logic operation is performed.

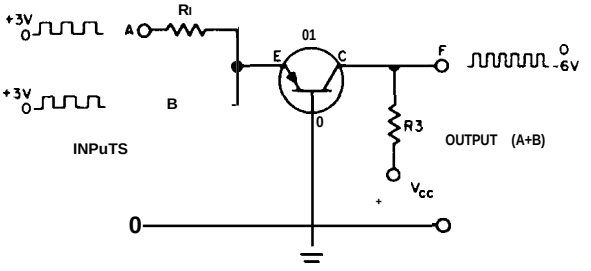
The symbolic logic representation of a positive transistor OR circuit is shown in the following illustration, together with a table of combinations. When the values of O and 1 are substituted in the table of combinations for L and H, respectively it is recognized as a standard OR truth table. Thus it is clear that in logic notation and representation both the diode and the transistor OR circuits are identical (see discussion of Diode OR-Cate in this section of the Handbook).



Logic OR-Gate Diagram | Table of Combinations | Truth Table

The fdled-in triangle indicates high level operation or positive logic. With a positive signal representing 1, a positive output is obtained.

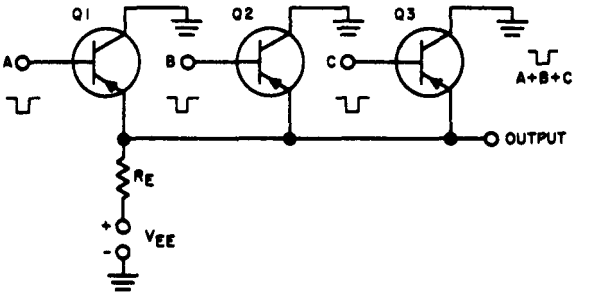
Circuit Operation. The schematic diagram of a typical two-input, positive, single-transistor OR-gate is shown in the foUowing illustration.



Two-Input, Common-Base, Positive OR Gate

In the circuit shown, the emitter is left floating and reverse bias is applied to the collector. Therefore, with no signal applied either RI or R2, simulating a O, transistor Q1 rests in the cutoff condition, Collector current cannot flow (because of reverse collector bias) and the output voltage is the same as the collector supply voltage (–6 volts as shown on the waveform). When a +3-volt signal is applied either R1 or R2 simulating a 1, forward bias is applied to the emitter, and collector current flows through R3 producing a positive-going output. In this case it is assumed that the input voltage is sufficient to drop the collector potential to O, and a 6-volt positive output is obtained. When the input signal is removed, the transistor returns to its quiescent state, with no collector current flowing and the O level at -6 volts. There is, of course, a reverse current flow (I_{cbo}) due to thermal effects inherent in transistor operation. However, this reverse current is so small (usually less than a few microampere) that it may be neglected. Since there is no signal inversion in the common base circuit, the output signrd is an amplified replica of the input signal (except for distortion produced during turn-off). This circuit will not operate as a negative OR gate by reversing the polarity of the input signal since it is already at cutoff. The circuit is only slightly affected when both OR signals are applied simultaneously (the case of the inclusive OR). In this instance, the application of both input signals merely increases the minority carriers released in the transistor and it takes Q1 longer to recover from the operating pulse, thus producing slightly longer output pulse than when individually triggered. Input resistors RI and R2 are large valued and are used to isolate the two inputs, since they are both connected to the same emitter.

Circuit Variations. A typical 3-transistor OR gate is shown for comparison in the accompanying illustration.



Three-Stage OR Gate

A study of the schematic reveals that the circuit arrangement is that of the emitter-follower, and that the three outputs are parallel comected using common load and bias resistor R_E. In the O or inactive state a positive voltage is applied to the base of Q1, Q2, and Q3 and they rest in a cutoff state. When a 1 signal, consisting of a negative voltage is applied to any transistor, the base is forward biased and emitter current flows. The emitter current flow through R_E develops a negative output signrd, and the emitter resistor also determines maximum current flow in the triggered transistor. Once the input signal is removed, the stage again resumes its cutoff condition. An output trigger results when any of the inputs are energized or when all of the inputs are energized, simultaneously, representing inclusive OR function. Since a negative input produces a negative output, negative logic is employed.

AND GATE

Application.

The transistor "AND" gate is used in applications where an output gate is desired only when pukes are applied to rdl inputs at the same time.

Characteristics.

May use either positive, negative, or combined logic.

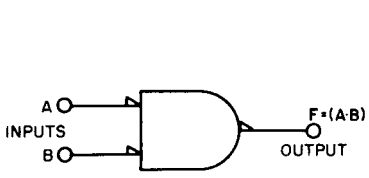
Provides gain and higher speed than the diode "AND" gate.

Can consist of a single stage with multiple inputs, or a number of similar stages with separate inputs.

Circuit Analysis.

General. The AND gate, like the OR gate previously discussed in this section of the Handbook, can consist of a single stage with multiple inputs, or a number of similar stages with separate inputs. The AND logic function requires that an output be produced only when all the inputs are applied simultaneously. No output is obtained for any other combination of inputs.

Circuit Operation. The logic diagram for a typical AND circuit using the common-base configuration is shown in the accompanying diagram, together with a truth table.



INPUT		OUTPUT
A	B	F

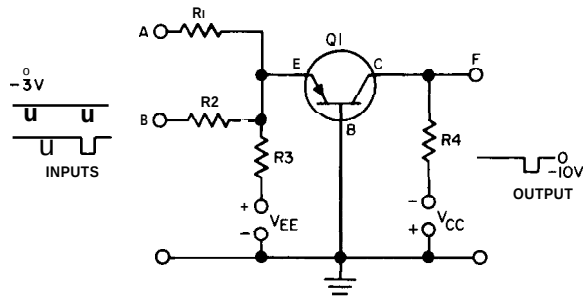
0	1	0
1	0	0
1	1	1

Transistor AND-Gate Logic Diagram Truth Table

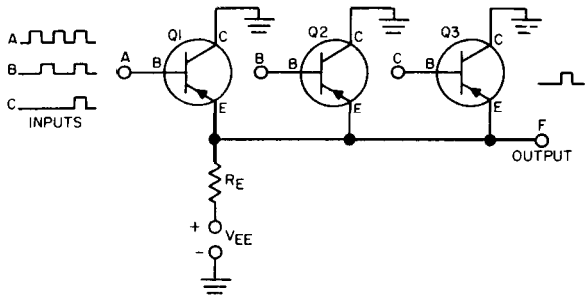
The open triangles indicate that negative logic is used, and the symbol for the transistor AND gate is the same as that for the diode AND gate. The truth table is recognized as a standard AND table, where an output only occurs when both inputs are applied simultaneously. The schematic for this negative AND-gate is shown in the accompanying figure.



Negative Transistor AND-Gate Schematic, Common-Base Circuit

As shown in the schematic, transistor QI is forward biased by the positive voltage applied to the emitter. Thus with a reverse collector bias applied through R4, and a forward bias applied through R3, the transistor conducts heavily in the quiescent or inactive state, and the collector voltage is dropped to zero across load resistor R4. Thus, there is no output and a logic zero is represented. When an input signal such as a negative pulse or step-voltage is applied to either input A or B, but not to both, the forward bias is reduced. This slight reduction in bias changes the collector current very little so that the input still remains effectively at the zero output level. When the negative input is applied to both inputs simultaneously, twice the current produced by a single input flows through base resistor R3 and drops the forward base-bias to below the cutoff point. Collector current now ceases flowing through R4 and since the voltage drop across R4 is now zero, full reverse collector voltage appears at the collector, producing a negative output voltage. When the input signal ceases, collector current flow through R4 resumes, and again drops the collector voltage to zero. Thus, the output voltage rises and falls as both inputs rise and fall together.

Circuit Variations. A typical schematic for a three-input AND-gate, using separate transistors for each input is shown in the accompanying illustration.



Three-Stage AND Gate

Examination of the schematic reveals that the emitter-follower connection is used, with the transistor outputs connected in parallel across a common load and bias (emitter) resistor. Since the emitters are connected to a positive bias voltage, forward bias causes each of the transistors to conduct. With no input applied, emitter current flow through resistor R_E (because of forward biased emitter) drops the output voltage to zero. Thus, the emitter voltage is effectively reduced to zero level. When a "1" signal of say +5 volts is applied to either Q1, Q2, or Q3 the transistor is reverse biased and ceases conduction, meanwhile, the other two transistors continue to conduct and keep the output at zero level. When all three inputs are applied simultaneously, current flow through them is reduced and the emitter voltage rises toward the bias supply, creating a positive output voltage. When the positive output voltage rises to +5 volts, the emitter voltage is again at zero bias level and stays at this point until the input pulse ceases, whereupon once again heavy forward conduction causes the emitter voltage to be reduced to zero. Thus any positive input signal level less than the total emitter bias voltage, will effectively pass through the transistor(s) and appear as the output voltage (the actual output amplitude is a fractional amount less than the full amplitude of the input signal because of ohmic drop in the transistor, however, this drop is so low as to be considered negligible).

NOT GATE

Application.

The transistor NOT gate is used in computer and high speed switching circuits to provide signal inversion and high gain.

Characteristics.

Either positive, negative, or combined logic may be used.

Gain is possible.

Fixed-bias is usually employed.

Output signal is inverted in phase and polarity from input signal.

On a logic basis, the output is the complement of the input.

Circuit Analysis.

General. When the common-emitter configuration is used, the output polarity is always inverted by inherent transistor action similar to the electron tube grounded cathode circuit. In logic operation it is sometimes desired to produce a signal which is identical but opposite that of the input signal. This is the logical NOT operation, and the circuit is also known as an inverter, which produces the complement of the input signal. This discussion will be limited to the use of a single stage operating as an inverter or NOT circuit. Other circuit variations will be discussed with the other circuits in which they are employed. The voltage gain obtained through this circuit also makes it useful as a level restorer.

Circuit Operation. The logic representation of a typical NOT (inverter) circuit is shown in the accompanying illustration.

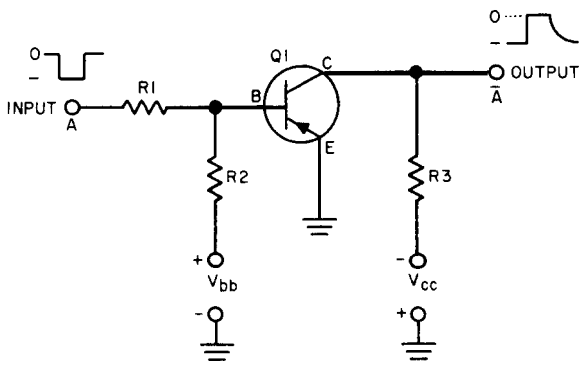
I NVERTER TRUTH TABLE

Logic Inversion Diagram and Symbol

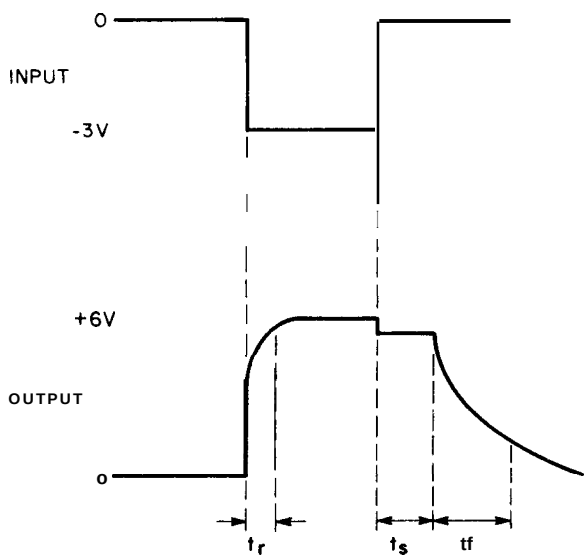
Inverter Truth Table

The open triangle on the input side and the closed triangle on the output side indicate that with a negative input, an inverted or positive output is produced. The actual schematic of a typical inverter is shown in the following figure.



Transistor NOT Gate

In the quiescent condition (the "O" state) with a positive base bias applied, transistor Q1 is at cut-off and no current flows (reverse collector current flow, Iceo, is considered negligible). Since no voltage drop to oppose the supply and the collector and output voltage fall to almost the value of the negative supply, representing a logic zero output. When a negative (1) input signal is applied, the base bias is changed from a reverse to a forward bias and causes emitter current to flow. Collector current flow through R3 drops the negative supply voltage to approximately zero so that a positive going output is developed. With sufficient forward base bias (drive) to cause saturation, the output rests at the zero voltage level until the input signal is terminated. When the input signal stops, the collector voltage does not change immediately because of the minority carriers inserted into the base during saturation (in the PNP transistor these are holes). Therefore, collector current flow continues for the duration of the storage delay time until the minority carriers are drained out, whereupon the collector voltage becomes negative-going and falls to approximately the same value as the supply voltage. The relationships between input pulse and rise and fall times (tr and tf) on the output pulse and storage delay time (ts) are shown in the following waveforms. The output waveform is slightly exaggerated to clearly show the delayed and deformed pulse which is produced. Since the circuit function is merely that of on or off, the pulse distortion is of no consequence except for the slight delay in operating time which ensues. Resistors R1 and R2 function as a base bias divider, with R1 also acting as a base current isolating resistor, so that the base cannot be shorted by connecting the input to ground when producing a logic zero input. Rise time, tr, is also known as turn-on time and is defined as the period from the start of the square wave until it reaches 90 percent of steady state amplitude. The turn-on delay is caused by the finite time it takes the carriers produced by emitter action to travel to the collector. The fall time, tf, is also known as the turn-off time, and is the time which elapses from the start of the falling off period until it falls to within 10 percent of the final signal level. Storage relay time, ts, is defined as the time from the ending of the input pulse to the start of the trailing edge of the output pulse.



Input and Output Waveform Relationships

Fixed bias and large driving pulses are usually used to produce a sharp turn-on time, and other forms of logic such as DTL and RCTL are used to decrease the

turn-off times. These circuit variations will be discussed in more detaiI with the appropriate logic and in the circuits in which they occur. Since the transistor design also determines the turn-on and turn-off characteristics, a special group of transistors of various types classified as "switching transistors" are employed to obtain greater speed and cleaner switching operation.

TRUTH TABLE

NOR Logic Diagrams **Truth Table**

NOR GATE

Application.

The transistor NOR gate is used in computers and switching devices to supply an inverted OR (that is a complemented OR) output.

Characteristics.

May use positive, negative, or combined logic.

Usually uses fixed bias.

Provides an inverted or complemented output.

Has a high impedance and a low output impedance.

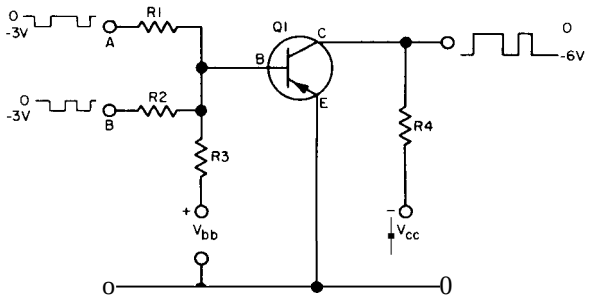
Circuit Analysis.

General. The NOR gate provides a standard OR output but in inverted or complemented form. Thus a NOT OR output is supplied from a single stage. Since the transistor common-emitter configuration produces an inverted output signal, it is only necessary to change the common-base OR circuit to a common-emitter arrangement to produce a NOR circuit.

Circuit Operation. The logic diagram for a typical NOR circuit and its associated truth table is shown in the following illustration.

The open triangles in the logic diagrams denote that negative logic is used. Thus the 1 -state requires a negative input signal for activation. Since the output is inverted in the NOR circuit, this is indicated by the small circle (in the upper diagram) adjacent to the triangular output level indicator. This indicates that with a negative input a positive output is obtained. The same condition could also be indicated by omitting the small circle and using a filled-in triangle at the output as shown in the lower (alternate) diagram. In this case the input and output levels are indicated as being different or inverted, and since the input is indicated as negative in the activated state by the open triangles, the logic is also negative. It should be noticed that the circle when used to express inversion must be located at the symbol. The small circles at the input and output terminals represent terminal connections and have no logic significance.

The schematic for a typical single stage transistor NOR circuit is shown in the accompanying illustration. Note that the PNP commonanitter configuration is used.



PNP Transistor NOR Gate

A positive (reverse) fixed bias is applied to the base to keep the transistor cut off in the inactive state. With logic "O" (in this case O volts) applied at inputs A and B, and reverse bias applied to the base and collector, no conduction occurs; therefore, the collector and output voltage is approximately the same as the collector supply voltage (in this case -6 volts), This output voltage represents a logic "1" at the output, verifying the first condition in the truth table.

When a negative input (logic "1") is applied to A or B, or to both A and B, it forward biases the base and causes collector current flow. The voltage drop caused by collector current flow through R4 reduces the collector voltage (and the output to zero). Thus a high input signal produces an inverted or low (positive) output signal. Resistors RI and R2 function as isolation resistors to prevent loading on the separate inputs A and B. Since the input resistors are connected in series with R3 to ground, they form a voltage divider which places the larger voltage across R3 and the base of Q1. Both R3 and either R1 or R2 also protect against shorting of the base bias or input circuit respectively, when a zero level input is applied. The high resistance of the input resistors requires that a relatively high voltage be used to cause base current **to flow.** Hence, operation of this type is known as voltage mode operation. (In DCTL logic the resistors and bias are omitted and only a fraction of a volt input is necessary to drive the base into conduction, and this is called the current mode of operation.)

When both inputs are simultaneously applied, the larger negative input assumes control. When Q1 is driven into collector saturation by the activating signal, excess carriers are inserted into the base and the turn off time is extended by the storage time needed to drain the transistor of these excess holes. Because the full operating range of the transistor from cutoff to saturation is available, relatively high and power output can be obtained from this common+ mitter arrangement.

NAND GATE

Application.

The transistor NAND gate is used in computers and switching devices to supply an inverted AND (a complemented AND) output.

Characteristics.

May use positive, negative, or combined logic.

Usually uses fixed bias.

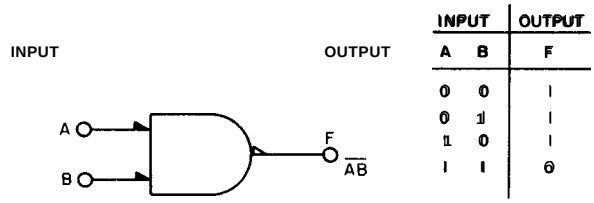
Provides an inverted or complemented output.

Has a high input impedance, and a low output impedance.

Circuit Analysis.

General. The NAND gate provides a standard AND output but in inverted or complemented form. Thus a NOT AND output is supplied from a single stage. Since the transistor common-emitter configuration produces an inverted output signal, it is only necessary to change the common-base AND circuit to a common-emitter arrangement to produce a NAND circuit. This circuit is also sometimes referred to as a coincidence circuit or an all circuit in other publications.

Circuit Operation. The logic diagram for a typical NAND circuit, with its associated truth table is shown in the following illustration.

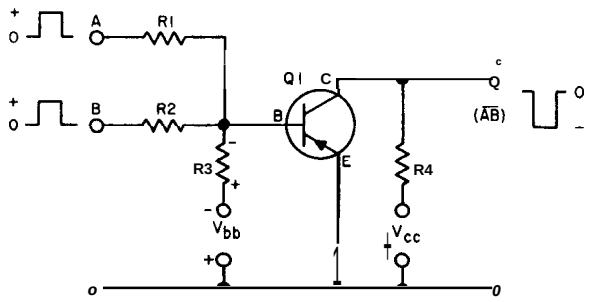


INPUT		OUTPUT
A	B	F
0	0	1
0	1	1
1	0	1
1	1	0

NAND LOGIC Diagram Truth Table

The closed triangles in the logic diagram indicate that positive logic is employed. That is a positive input signal represents an active 1. The inversion of output produced by the NAND circuit is indicated by using an open triangle at the output, as shown in the logic diagram.

The schematic of a two-input, single-stage transistor NAND gate is shown in the following illustration. Note that the common-emitter configuration is used.



PNP Transistor NAND Gate

A negative, fixed base bias is applied to transistor Q1 to provide forward bias, and make the transistor conduct heavily in the so-called inactive state. With no input signal applied, and with forward base bias the transistor operates in the saturation region. Heavy collector current flow through R4 produces a voltage drop which reduces the negative collector voltage to zero. Since reverse collector bias is applied, a positive output is produced (absence of the input signal in this case represents a zero input). Thus the first combination in the truth table is verified. When a positive (one) input signal is applied to either input A or B, but not both, the voltage developed across RI or R2 by base current flow is insufficient to stop conduction, and a zero or positive output still occurs. However, when the input signal is applied simultaneously to both A and B terminals, base current flow through R3 is twice that produced by single input signal, and, since it is in a direction which produces a polarity opposite to the forward base it cancels the bias, reducing it to zero. With no forward bias applied to the base and a reverse bias applied to the collector, transistor Q1 ceases conduction. With no collector current flow through R4, no voltage drop is produced, and the collector voltages falls to approximately the negative supply vahre. Thus a negative output is produced indicating a zero. Input resistor R1 and R2 act as isolating resistors for the separate AND inputs, and together with base resistor R3, preventing shorting of either the base or the bias when zero (grounded) input is applied. Since Q1 normally operates in the saturation region, excess carriers are inserted into the base, and the turnoff time is extended by the storage time needed to drain the transistor of these excess holes. Because the full operating range of the transistor from saturation to cutoff is available, relatively high gain and power output can be obtained from this common+vnitter arrangement.

INHIBIT GATE

Application.

The inhibit gate is used in digital computers to produce an output pulse when a signal is applied to one input, but not the other.

Characteristics.

The inhibit gate uses a transistor NOT circuit to control a diode AND gate.

The circuit produces no amplification.

Uses PNP transistor.

Uses negative logic.

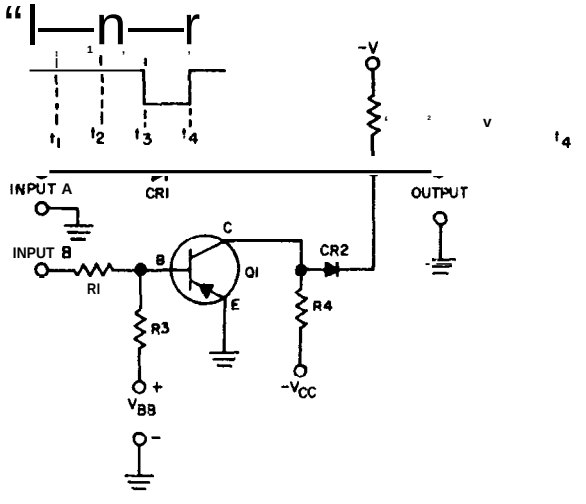
Circuit Analysis.

General. An inhibit gate produces an output pulse if a signal is applied to only one of two possible inputs. If a signal is applied to the inhibit input, no

491-044 0 - 73 . 85

output occurs. No output is produced since the inhibit input signal is inverted by the transistor, and cancels the effect of any signal supplied to the other AND gate input.

Circuit Operation. The schematic of a typical inhibit gate is shown in the accompanying illustration.



inhibit Gate

Diodes CR1 **and CR2** form a negative diode AND gate controlled by transistor NOT gate Q1. Resistors R1 and R3 form a base bias voltage divider. Resistor R4 is the collector load resistor for transistor Q1. Resistor R2 is the AND gate voltage dropping resistor from which the output is taken.

The following truth table indicates the desired output for the different input combinations. A "1" indicates the presence of a pulse and "0" indicates the lack of a pulse.

INPUT A	INPUT B	OUTPUT F
0	0	0
1	0	1
1	1	0
0	1	0

Truth Table

In the quiescent or inactive state, with no inputs applied, diode CRI is forward-biased, and current flow through load resistor R2 drops the source voltage to zero. Thus, the output voltage is zero. At this time, transistor Q1 is reverse-biased by a positive bias voltage from a separate supply applied to the base of QI through R3. Hence, no current flows through Q 1 or collector load resistor R4 (reverse leakage current I_{CEO} is considered negligible). Consequently, QI has no effect on the output of AND gate diode CR2, since it is reverse-biased by the negative collector supply voltage applied to the anode.

When a negative input signal pulse is applied to input A (time t_1), reverse bias is applied to the anode of CR1 and prevents any current tlow from source –V. Since no IR drop exists across R2, became of lack of current flow, the output end of R2 is at the full potential of the negative supply voltage. The output voltage remains negative until the negative input pulse ends at time t_2. From time t_2 to t_3 no input is applied to A and the source voltage is dropped to zero across R2, producing no output. At time t_3, a negative (inhibit) pulse is applied to input B, forward biases transistor Q], and emitter to collector current flows. Collector current flow through collector resistor R4 reduces the voltage at the collector of QI, and produces a positive swing. The positive voltage swing developed across R4 is applied to the anode of CR2 to forward-bias the diode. At time t3, another negative input pulse is also applied to input A. The positive pulse developed by the signal applied to input B, forward biases CR2, and causes the source voltage to drop across R2, producing an effective zero output voltage. Thus, there is no output voltage developed between times t_3 and t_4. The only effective output that is developed, is the negative output which occurs between times t_1 and t_2, during the time that only a negative input pulse is applied to input A, and no input is applied to B.

DUAL TYPE (AND-OR) GATE

Application.

The dual type AND-OR gate is used in digital circuits to produce two outputs simultaneously; one

output is produced only when all input pulses are applied, and the other output is produced when any or all of the input pulses are applied.

Characteristics.

Three inputs and two outputs are provided.

The circuit uses six PNP transistors.

Three transistors function as an OR gate.

Three transistors function as an AND gate.

Produces positive logic output for negative logic input.

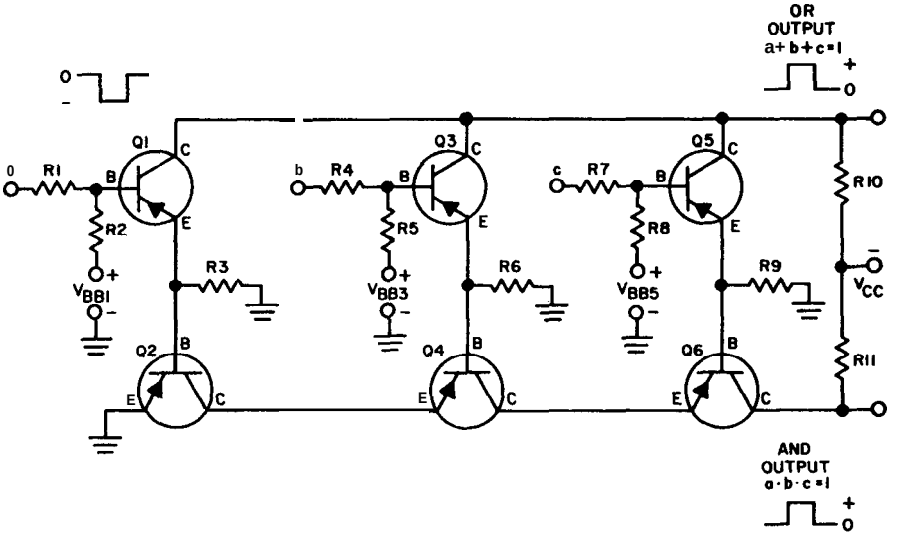
Circuit Analysis.

General. In some cases it is desirable to obtain an AND gate output and an OR gate output simultaneously from inputs common to both gates. The dual gate makes this possible. Two or more inputs to the circuit, then produce two outputs, one being the AND output and one being the OR output. Just as in the single logic OR gate, any combination of applied signals produces a high output (logic 1). By the same reasoning, all input signal pulses must be applied before a high output (a logic 1 output) can be obtained from the AND gate of the dual circuit. If all input signals are applied, a high output is obtained from both the AND and the OR gate output terminals, The following truth table shows the input and output signal relationships for a three terminal input.

INPUT A	INPUT B	INPUT c	OUTPUT AND	OUTPUT OR
0	0	0	0	0
1	0	0	0	1
0	1	0	0	1
0	0	1	0	1
1	1	0	0	1
1	0	1	0	1
0	1	1	0	1
1	1	1	1	1

Truth Table

Circuit Operation. The schematic of a dual type AND-OR gate is shown in the accompanying illustration. Transistors Q1, Q3, and Q5 form the OR gate of the circuit.



Dual Type And-Or Gate

Transistors Q2, Q4, and Q6 form the AND gate of the circuits. Resistors RI, R4, and R7 are input and bias resistors to the bases of the OR gate transistors. Resistors R2, R5, and R8 are base bias resistors for Ql, Q3, and Q5, respectively. Resistor R1O is the collector load resistor for the OR gate transistors, Q1, Q3, and Q5. Resistor Rll is the collector load resistor for the AND gate transistors, Q2, Q4, and Q6. Resistors R3, R6, and R9 are emitter stabilizing resistors for OR gate transistors Q1, Q3, and Q5. Voltage sources V_{BB1}, V_{BB3}, and V_{BB5} provide the base bias for the OR gate transistors. Resistors R3, R6 and R9 are also bias return resistors for the AND gate. The emitters of the OR gate are direct coupled to the bases of the AND gate.

The circuit is arranged to develop positive output pulses when negative input pulses are applied. When no input pulses are applied the biasing networks of Q1, Q3, and Q5 provide a reverse bias which prevents these transistors from conducting. Since no current flows through these transistors, no current flows through collector load resistor R9. The output and collector potentials of these transistors are then at the negative collector supply voltage values. This represents a logic O output.

When no current flows through the OR gate transistors, the base bias of transistors Q2, Q4, and Q6 is provided by leakage current I_{CBO} flowing through R3, R6 and R9. Since these emitter stabilizing resistors for Q1, Q3 and Q5 are small in value and the leakage current is negligible, the bases of Q2, Q4 and Q6 are effectively at zero and these transistors are prevented from conducting. Since no current flows through these AND gate transistors, no current flows through the AND gate collector load resistor, R1 1, and the output of the AND gate is at the negative supply voltage value, or a logic O.

When a single negative pulse is applied to any of the inputs (a, b or c) the transistor base to which the input pulse is applied is forward biased and conducts. The increasing emitter to collector current of the transistor causes an increasing collector current to flow through resistor R1O. The current flow through collector resistor R1 O produces a voltage drop across the collector resistor and makes the collector and output end of R1O more positive. This positive output voltage swing constitutes a logic 1.

The emitter current flow of the single OR gate transistor, drives the base of the coupled AND gate transistor in a forward biased direction. This has no effect on the output of the AND gate, however, since, all three series connected AND gate transistors must conduct simultaneously for a complete current path to exist for any one of the transistors. If no current flows through the AND gate, no current flows through the AND gate load resistor RI 1. The output voltages of the AND gate is then the negative collector supply voltage value. This negative voltage is a logic O.

When negative pulses are applied to any two of the three inputs, for example to inputs a and b, the reverse bias of transistors Q1 and Q3 is cancelled. Transistors Q1 and Q3 are forward biased and conduct. The emitter to collector current of Q1 and Q3 increases and causes current to flow through collector resistor R1O and produces a voltage drop across resistor R1O. Thus, the output of the OR circuit is a positive pulse (a logic 1).

The current flowing through transistors Q1 and Q3, and R3 and R6, causes the base of Q2 and Q4 to be driven negative. The negative voltage forward biases transistors Q2 and Q4. Normally, Q2 and Q4 would conduct if they had a complete current path to the collector supply source. However, since transistor Q6 is not conducting, the series current path for transistors Q2 and Q4 is not complete and they cannot conduct. The voltages at the output of the AND circuit is again the value of the collector supply voltage. This voltage is a logic O.

When negative signal pulses are applied to each of the three inputs, the reverse base bias of each OR gate transistor is cancelled by the negative input pulse causing all of these transistors to be forward biased and conduct. Emitter to collector current flow through these transistors causes current to flow through collector load resistor R1O, producing a voltage drop across R1O and a positive pulse output for the OR circuit. This positive pulse is a logic 1. Negative emitter voltage produced by the conduction of Q1, Q3, and Q5 forward biases the bases of Q2, Q4, and Q6, series AND gate transistors Q2, Q4, and Q6 not conduct, since they are forward biased and the series current path is completed. The conduction of Q2, Q4, and Q6 allows current to flow through R11 and produce a voltage drop across it. Hence, the voltage at the collector end of R1 1 becomes positive, and the output is a positive pulse (a logic 1). A dual output now exists.

FLIP-FLOP CIRCUIT

Application.

The transistor flip-flop is used in electronic computers to supply an output and its complement simultaneously, as an off-on trigger, and for storage purposes. It forms the basic circuit used in most registers.

Characteristics.

May use positive, negative, or combined logic.

Usually employs self-bias.

Provides two outputs (one is the inverse of the other).

Requires a turn-off or reset trigger to change state.

Has two stable states, sometimes called off and on (or O and 1).

INPUTS		OUTPUTS	
A	B	BxX	Y
0	1	0	1
1	0	1	0

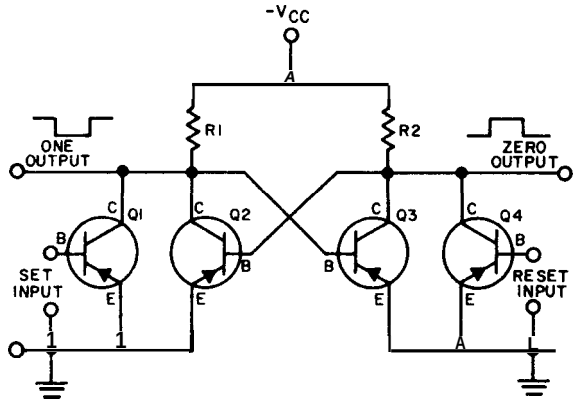
Truth Table

Circuit Analysis.

General. The basic transistor flip-flop is sometimes considered as two transistor inverters placed back-to-back. However, by far the simplest arrangement, the dc flip-flop uses a minimum of parts and corresponds closely to the mechanical form of "relay flip-flop" described earlier in this section of the Handbook. Actually, the flip-flop is considered to be a multivibrator, and the various types of transistor multivibrators are fully discussed in the Multivibrator Section of this Handbook (including the binary M.V.). The flip-flop circuit is included here for the sake of completeness of the logic section since most computers contain many flip-flops. Consequently, logic considerations will be stressed, and the overall operation may not be as detailed as might be found in the Multivibrator Section circuit discussions. However, sufficient detail will be given to satisfy the logic student. The symbolic logic diagram and truth table are shown in the following figure.

Like the other logic symbols, the flip-flop logic symbol is functional and is the same regardless of internal circuit. Thus any number of types of multivibrator may be indicated by the same logic symbol. Input and output level indicators are not shown since, in most instances, they may be determined from the levels shown on the outputs of driving or following circuits. The designation of clear (reset) or (C) and set (S) inputs are not required to be shown. However, the C input is always placed on the left of the diagram with the O output terminal, and the S input is placed on the right of the diagram with the 1 output in accordance with American and Military Standard usage (other arrangements may be found in other texts). The truth table shows inputs A and B with outputs X and Y. In most instances, these are the same terminals, and the table merely indicates that when one transistor is in the zero state the other transistor of the flip-flop is in the 1 state, and vice versa.

Circuit Operation. The schematic of a typical DCTL flip-flop IS shown in the following illustration;



Direct-Coupled Transistor Logic Flip-Flop

Resistor R1 is the collector load resistor for inverter transistor Q2; resistor R2 is the collector load resistor for inverter transistor Q3. Transistor Q1 is a set transistor, by which the ffip-flop is switched to the second steady state condition. Transistor Q4 is a reset transistor, by which flip-flop is returned to the originaf steady-state condition.

Both transistors conduct when power is first appfied, since the negative supply voltage of the collectors is fed to the opposing bases. Because of slight variations in parts and transistors, one transistor tends to conduct more heavily than the other. As this occurs, positive feedback from this collector to the other base produces a rapid switching action. Thus, one transistor is driven towards saturation and the other transistor is driven toward cutoff. A stable state is reached when one transistor is essentially at saturation. Assume that Q3 is the saturated transistor and Q2 is the cut off transistor. Collector resistance values are such that saturation current does not drop the source potential to zero, but leaves it slightly negative (about 0.1 volt). Hence a small negative forward bias is fed back to Q2, which conducts very lightly at afmost cutoff. The conduction is so slight that it can be assumed that Q2 is cut off. With Q2 at effective cut-off, the collector voltages rises toward the supply vafue sufficiently to keep the base of Q3 heavily forward biased. Normally, Q3 would be completely saturated. However, the low base to emitter resistance of heavily conducting transistor Q3 effectively clamps the coffector potentiaf of Q2 to only a few tenths of a volt negative (approxirnately 0.3 volt) instead of the fufl negative supply voltage. Hence, instead of being completely saturated (as initiaffy assumed for ease of discussion) Q3 remains heavily conducting, but is not slowed up by minority-carrier storage effects that would normafly occur if saturation had occurred. (This base of a saturated transistor cannot be quickly changed from forward to reverse bias until the excess charge of electrons has leaked off.) Thus, the output level of Q2 is held down to only a few tenths of a volt (0.2 volt) peak-to-peak swing. The transistors stay in this initial steady state condition until a switching pulse is applied to conducting transistor Q3.

When a negative pulse appears at the set input, it is applied to the base of Q1. The negative set-pulse forward biases Q1 into conduction; a large base current is initiated, and a large coffector current flows through resistor R1. The large current flowing through resistor R1 causes much of the colfector supply voltage to be dropped across R1, leaving the collectors of Q1 and Q2 near zero volts. Thus, Q1 and Q2 are nearly saturated. The slightly negative coffector voltage of Q2 now appears at the base of Q3, causing Q3 to be reverse biased. The reverse bias of Q3 causes Q3 to be driven nearly to cutoff; very little current flows through Q3 or resistor R2. There is then very little voltage dropped across resistor R2, and the voltage at the collector of Q3 rises toward the negative supply voltage vafue. This negative voltage supports the forward bias of Q2 and causes it to conduct heavily. The negative ffip-flop output at the co flector of Q2 which represented a logic one, is now reduced to a nearly zero voltage output at the collector of Q2 and now represents a logic zero. The effectively cut-off condition of Q3 produces a low negative voltage at the coflector, by the clamping action of the low base to emitter resistance of Q2 (as previously occurred for Q3), and Q3 now produces a logic one output. The ffip-flop remains in this second steady state until a triggering or gate pulse is appfied to the reset input.

When a negative pufse is applied at the reset input, it appears at the base of Q4. Q4 is forward biased by the negative pulse. Thus, Q4 conducts heavily, causing a large base current to flow and a large

collector current to flow through resistor R2, the collector load resistor of Q3 and Q4. The current through resistor R2 produces a voltage drop which makes the collectors of Q1 and Q2 only slightly negative. The small negative voltage at the collector of Q3 appears at the base of Q2, and reduces the forward bias of Q2. As a result, little collector current flows through resistor Rl, and very little voltage is dropped across R1. The collector of Q2 then rises toward the negative supply voltage. This negative voltage appears at the base of Q3 to increase the forward bias of Q3 and switch operation back to the original state (Q3 conducting heavily and Q2 effectively cut off). The relatively large negative voltage output at the collector of Q2 represents a logic one, and the small negative voltage output at the collector of Q3 represents a logic zero. The flip-flop remains in this steady state until a triggering or gating pulse is again applied to the set input.

RESISTOR-TRANSISTOR LOGIC FLIP-FLOP

Application.

The resistor-transistor logic flip-flop is used in digital computer circuits to produce alternate logic 1 and logic O rectangular pulses when triggered.

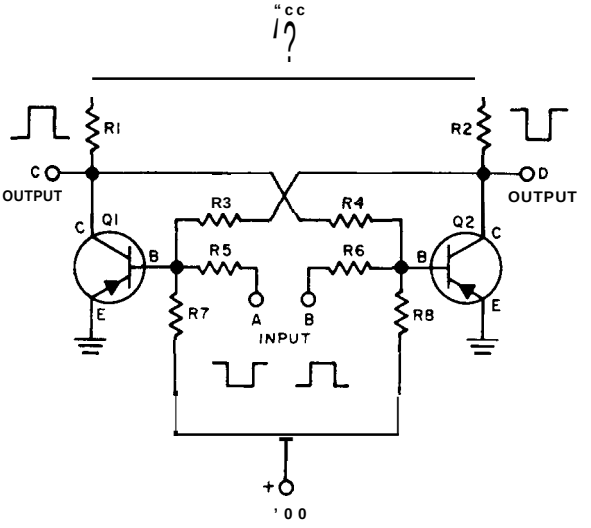
Characteristics.

Requires an external trigger pulse.
Operating speed is relatively slow.
Consists of two cross-coupled inverter stages.

Circuit Analysis.

General. The resistor-transistor flip-flop employs two cross-coupled transistor inverters to form a triggered multivibrator circuit. The collector output of each transistor is coupled to the base of the other transistor; thus, the collector voltage of one inverter supplies a feedback voltage to drive the other inverter. The circuit produces two simultaneous rectangular pulse outputs (logic 1 and logic O), one output is 180 degrees out of phase with the other (of opposite polarity). The change in logic state from one output to the other is dependent upon the application of an external trigger pulse.

Circuit Operation. The schematic of a typical resistor-transistor logic flip-flop is shown in the following illustration. Resistors RI and R2 are collector load resistors. Feedback resistor R4 couples the collector of transistor Q] to the base of transistor **Q2; and** feedback resistor R3 couples the collector of transistor Q2 to the base of Q1. Resistors R7 and R8 are base bias resistors, through which the fixed bias supply voltage, + V_{BB} is applied to the bases of Q1 and Q2, respectively. Resistors R5 and R6 are input resistors across which the A and B driving pulses are applied to trigger the bases of Q1 and Q2, respectively. The outputs of the flip-flops are obtained from terminals C and D.



Resistor-Transistor Logic Flip-Flop

Assume that Q1 is initially conducting heavily (at saturation), and transistor Q2 is cutoff. The large collector current of Q1 flowing through collector load resistor RI, develops a large voltage drop (positive swing) across R6, which drops the collector voltage of Q1 to zero. Since Q2 is cut off, no collector current flows, and no voltage is dropped across collector load resistor R2. The collector of Q2 then rises to the negative collector supply voltage value. The negative collector voltage swing of Q2 coupled to the base of Q1 through R3, produces a negative driving pulse which increases the forward bias of Q1 making QI conduct heavily. Similarly, the zero collector voltage of Q1 coupled to the base of Q2, provides a positive-going reverse bias for Q2, which effectively increases the reverse bias voltage

supplied from the + V_{BB} fixed bias supply, and Q2 is held at cutoff.

If a negative pulse simultaneously appears at input A it is dropped across resistor R5, and is applied to the base of Q1. The forward bias of Q1 is increased, but, since Q1 is already conducting at maximum (at saturation), the increased forward bias of Q1 has no effect. On the other hand, if a negative pulse appears at input B, the pulse voltage is dropped across resistor R6 and is applied to forward bias the base of Q2. The forward bias of Q2 produces a collector current flow through resistor R2. The collector current flow through resistor R2 causes the collector supply voltage to be dropped across R2, producing a positive swing at the collector of Q2. This positive-swinging voltage coupled to the base of Q1 through R3, reduces the forward bias on Q1, and the fixed positive bias voltage $+V_{BB}$ assumes control and cuts off Q1. With Q1 cut off, no current flows through resistor R1, and no voltage is dropped across it. As a result the collector of Q1 rises to the negative collector supply voltage value. This negative voltage swing, coupled to the base of Q2 through R4, drives Q2 into saturation. A steady state now exists, with the collector of Q1 (output C) at the negative supply source voltage value (logic 1), and collector of Q2 (output D) at zero volts (logic O). This steady state condition remains constant until a negative driving pulse is applied to input A.

When a negative driving pulse is applied to input A, it appears at the base of Ql, after being dropped across resistor R5. The fixed reverse bias of Q1 is overcome, and Q1 is forward biased, causing collector current to flow through resistor R1. The heavy current through resistor R1 causes all of the collector voltage to be dropped across R1, leaving the collector of Q1 at zero volts. The loss of negative drive voltage on the collector of Q1 is applied through R4 to the base of Q2, reducing the forward bias of Q2 to zero. The reverse bias $+V_{BB}$ supplied through resistor R8 then resumes control and biases Q2 into cutoff. When Q2 is at cutoff no collector current flows through resistor R2 and no voltage is dropped across it, causing the collector of Q2 to be at the negative supply voltage value. A second steady state now exists, with the collector of Q1 (output C) at zero volts (logic O) and the collector of Q2 (output D) at the negative supply voltage value (logic 1). This is the same state that existed prior to any actuating pulses being applied. The flip-flop remains in this state until another negative driving pulse is applied to input B.

INVERTER

Application.

The transistor inverter is used in digital computers to provide an inverted pulse which is the reciprocal of the applied pulse, and is opposite in polarity to the input pulse.

Characteristics.

Can be made to produce a positive pulse output from an applied negative pulse, or produce a negative pulse output from an applied positive pulse.

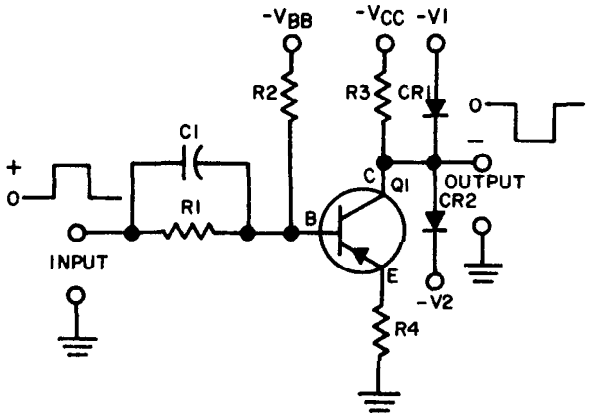
Inversion is provided by the circuit transistor.

The diodes of the diode-transistor inverter increase the operating speed of the circuit.

Circuit Analysis.

General. The transistor inverter is used in logic circuits to produce a voltage output which is 180° out-of-phase with the input to the inverter. Since a voltage applied to the base of a PNP type transistor produces the reciprocal of the applied voltage at the collector, a transistor will provide the required inversion. By clamping the collector of the transistor at a voltage greater than the saturation voltage with one diode, the transistor is prevented from going into saturation. By also clamping the collector of the transistor at another lower voltage level, the voltage that the collector reaches between applied pulses becomes well defiied. The use of the diode increases the operating speed of the circuit, since the operating range is effectively reduced.

Circuit Operation. The schematic of a typical transistor inverter is shown in the accompanying illustration. The input is applied to the base of inverting transistor Q1, through resistor R1. Forward bias is applied to the base of the transistor through base bias resistor R2. Capacitor Cl provides overdrive current during the rise time and fall time of the applied pulse. This reduces switching time and increases the operating speed of the circuit. Resistor R3 is the collector load resistor for Q1. Diodes CR1 and CR2 are collector voltage clamping diodes. Resistor R4 is the emitter stabilization resistor for the circuit.



Transistor Inverter

A positive voltage pulse is applied to the base of transistor Q1 through input resistor R1. The positive pulse decreases the forward bias supplied by $-V_{BB}$ through resistor R2. Since the forward bias of Q1 is reduced, the collector current and voltage across load resistor R3 is reduced, causing the collector potential to reduce also, The anode of diode CR1 is at a negative potential, preventing CR1 from conducting until the cathode of CR1 becomes more negative than the anode potential. Once the cathode of CR1, which is at the collector potential of Q1, becomes more negative than the anode potential, CR I conducts. Then, regardless of any further decrease in the conduction of Q1, the cathode potential of CR1 and the collector potential of Q1 remains constant at a negative potential slightly less than V1.

When the applied positive pulse ends, the voltage at the base of transistor Q1 falls to the fixed negative base bias potential of $-V_{BB}$. The forward bias of Q1 increases, causing the collector current of Q1 to increase, and the voltage drop across R3 to increase. The collector voltage of Q1 therefore rises in a positive direction. Once the collector voltage of Q1 goes positive and exceeds V2 (the slightly negative voltage at the cathode of CR2) diode CR2 conducts, keeping the collector voltage of Q1 constant during any further tendency of the collector current of QI to increase.

As a result, then, of an applied positive pulse, a negative pulse is developed at the output of the inverter. Furthermore, by making the proper choice of clamper voltages V1 and V2, the reciprocated output voltage is clamped over a fixed range. This enables the inverted pulse voltage to be kept to the same magnitude as the applied voltage pulse, in addition to increasing the operating speed of the circuit.

EMITTER-FOLLOWER CIRCUITS

Application.

The transistor emitter-follower circuit is usually used in computers and switching circuits to provide a high output current to drive other transistor circuits. This circuit is also used for impedance matching, driving coaxial lines, and for isolating input and output stages.

Characteristics.

May use either positive, negative, or combined logic.

May use either fixed or self bias, depending on the circuit arrangement.

Because of the low output impedance, a high current gain is obtained, but the voltage gain is always less than 1 (output smaller than input).

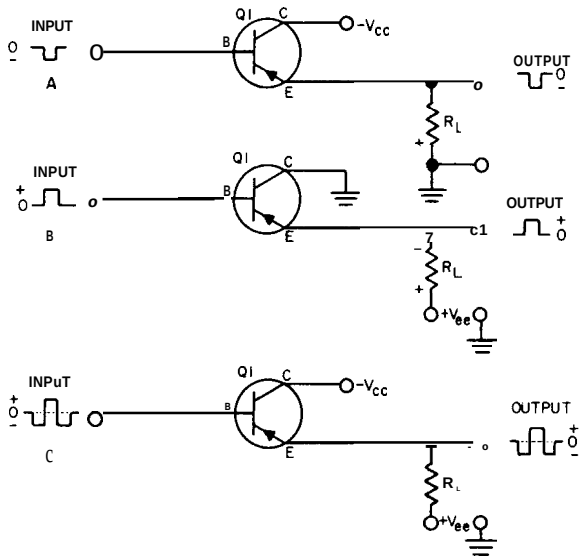
Circuit Analysis.

General. The emitter-follower or common-collector transistor configuration is usually (but not always) operated in the active region. Bias is normally such that the stage operates as a class A amplifier, as opposed to operating in the entirely saturated or cutoff region. Thus the emitter-follower will usually respond to either a positive or a negative input signal. Since the output is in-phase with the input a negative input will produce a negative output, and a positive input will produce a positive output. Operation is similar to the cathode-follower type of electron tube circuit. In the electron tube cathode-follower, there is a large difference in voltage between the grid input level and the cathode output level. However, in the emitter-follower, there is only a slight difference in dc input and output levels (usually less than 0.5 volt). Therefore, the emitter-follower makes a very useful

dc current-amplifier, capable of large current amplification without shifting the level between the two stages to any noticeable extent.

Circuit Operation. There is no special symbolic representation for an emitter-follower circuit. The logic diagram uses functional symbols only, regardless of circuit configuration. Thus an OR gate (or and AND gate) may be formed of either common-base, common-emitter, or emitter follower (common-collector) arrangements, and they would be drawn identically in the logic diagram, although the schematic representation would be different. Operation of the common-collector circuit is described for sinusoidal input in the introduction to the Amplifier Section of this Handbook. Operation of the emitter-follower in response to pulse input is discussed in the following paragraphs, and then typical OR and AND circuits are analyzed.

In the following figure, three emitter-follower types of operation are illustrated. Part .4 shows a negative bias applied to the collector and no bias applied to the base, the emitter is returned to ground through load resistor RL.

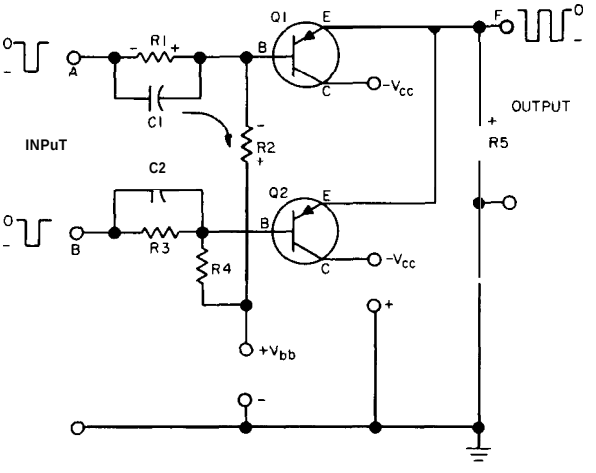


Emitter-Follower Circuits

With a reverse collector bias and no forward base bias the transistor rests in an essentially cutoff condition with no collector current flow. With no input there is not output. A positive input signal would only bias the base further in a reverse direction and no output would occur. However, with a negative input signal the base is quickly driven into conduction by the forward bias, and both emitter and collector currents flow. Electron flow is from the emitter through RI and back to the collector, and a negative output voltage is developed across load resistor RL. Thus the output voltage follows the input voltage. When the input signal is terminated the transistor stops conducting and the output pulse is completed as shown by the waveforms in the illustration. In Part B of the figure the opposite condition is shown, the collector is connected to ground and the base is again left open, but the emitter is forward-biased by a positive voltage to ground. With no base bias, and forward emitter bias, heavy emitter current flows and produces a voltage drop across RL which opposes the forward bias and drops the output to approximately zero. Application of a negative input signal cannot increase the emitter current any appreciable amount so the output remains at zero. However, when a positive input pulse is applied, the base is biased more positive than the emitter (reverse bias), and collector and emitter current flow ceases. As a result, the output voltage rises to the value of the positive emitter bias, since no voltage drop is produced across RL to reduce the output. In Part C of the figure, both forward emitter bias and negative (reverse) collector bias are applied, and the transistor is biased at the center of its active region (Class A operation). With no signal applied, the quiescent vrdue of collector current represents zero level. When a negative input is applied, the forward bias is increased, a larger collector current flows, and a negative voltage drop - appears across RL and at the output. In a similar manner, when a positive input signal is applied, collector current flow is reduced by the increasing reverse bias, and the emitter voltage rises towards the bias value, producing a positive output. Thus the emitter output follows the input signal, and operates entirely in the active region (this is the same operation as occurs in regular amplifier operation).

A typical emitter-follower OR-Gate is shown schematically in the following illustration. The inputs are separate and the outputs are connected in parallel. In the quiescent condition, with no signal

applied, both Q 1 and Q2 are nonconducting since collector current is prevented from flowing by reverse

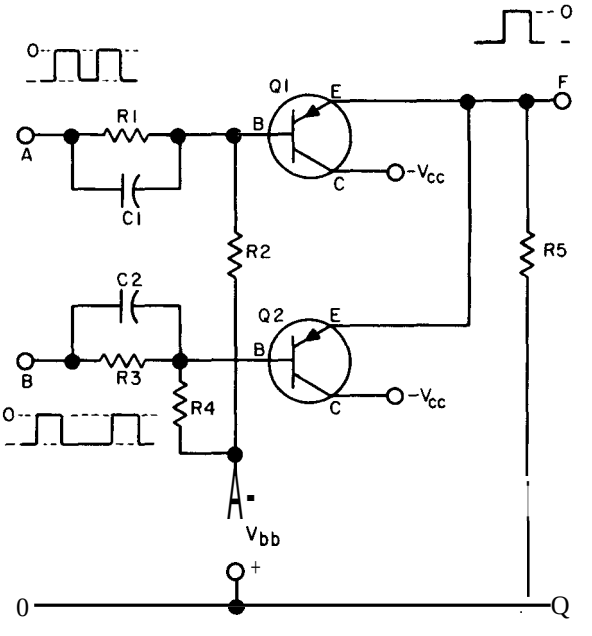


Emitter-Follower OR Gate

base bias applied through R2 and R4 from a fixed bias source. When the A input is activated by a negative one signal, Q1 is forward biased and emitter current flow through R5 develops a negative going output voltage across R5. The output voltage is slightly less than the input voltage by the base+ mitter voltage. Capacitor Cl helps speed up action by applying the leading and trailing edges of the pulse trigger instantiy to the base, bypassing R1 so that only the low frequency components representing the flat-top portion of the pulse are attenuated by RI. In addition, R1 and R2 form a dual voltage divider. When input A is at ground potentiai representing a zero input, the base is isolated from the input by R1 preventing it from being shunted to ground, and maintaining the desired high input impedance. When Q1 is conducting the base-collector resistance is low, but is prevented from shunting the bias source by R2. Thus the bias remains unaffected by any input signal shunting effect. As a result of base current flow through R1 a negative input voltage is developed, and the bias and signal voltages add algebraically, to produce a forward (negative) bias. When the input signal is removed, the fixed positive bias again resumes control, biasing the base in a reverse direction and stopping conduction.

When an input signal is applied to input B, identical operation occurs. Capacitor C2 now passes the leading (and later the trailing) edges to Q2, while resistors R3 and R4 form a similar input voltage divider and bias divider as explained for RI and R2 previously. When Q2 conducts, the output voltage is developed across emitter load resistor R5. A negative input produces a negative output. When the input signal is removed the transistor again returns to its normal cutoff condition and output ceases. When an output is developed by either Q1 or Q2, this negative voltage is applied as a reverse emitter bias to the non-conducting transistor so that it is prevented from being triggered. Should an input be appLied to both A and B simultaneously, the signal with the larger negative amplitude will prevail and cause only that circuit to operate.

By reversing the input polarity and bias an emitter-follower AND gate is obtained, as shown in the following schematic.



Emitter-Follower AND Gate

By comparing the emitter follower OR-Gate schematic shown previously with the emitter-follower AND-gate shown above, it is seen that the circuits are

identical. By changing the base bias to a forward bias, Q1 and Q2 conduct in the absence of an input signal, and emitter current flow through R5 develops a negative voltage drop which holds the output to a steady negative level and produces a zero. When a signal is applied to either A or B but not to both inputs simultaneously, the input to which no signal is applied continues conduction and holds the output at zero. However, when an input is simultaneously applied to both A and B, both transistors are cut off and Q1 and Q2 stop conduction. The output rises in a positive direction to zero and produces an equivalent positive (one) output. When the input pulse ceases, both transistors resume conduction, and the output falls to the normal steady negative output level representing a zero.

Although the emitter-follower output voltage is always smaller in amplitude by the amount of base+ mitter bias, a current and power gain are achieved. Current amplification is obtained by using a small amount of base current (usually in the microampere range) to control the large emitter current flow (usually in the milliampere range). Average current gains on the order of 25, or more, are obtained. Since the power output is the voltage times the current, it is easily seen why a power gain is obtained even though voltage amplification is not produced. Although the common-base and common-emitter connections also can provide a power gain, the emitter-follower arrangement is unique in that it provides a low impedance and high current output. Therefore, it is usually employed as a driver stage capable of operating two or three other transistor stages without dropping to a very low level, or for operating relays, or lamps, which require high current at low voltage.

LAMP DRIVERS AND RELAY PULLERS

Application.

Lamp drivers and relay puller circuits are used in computers and switching circuits to supply the power and voltage necessary to drive indicator lamps and operate relays indirectly by triggering a transistor.

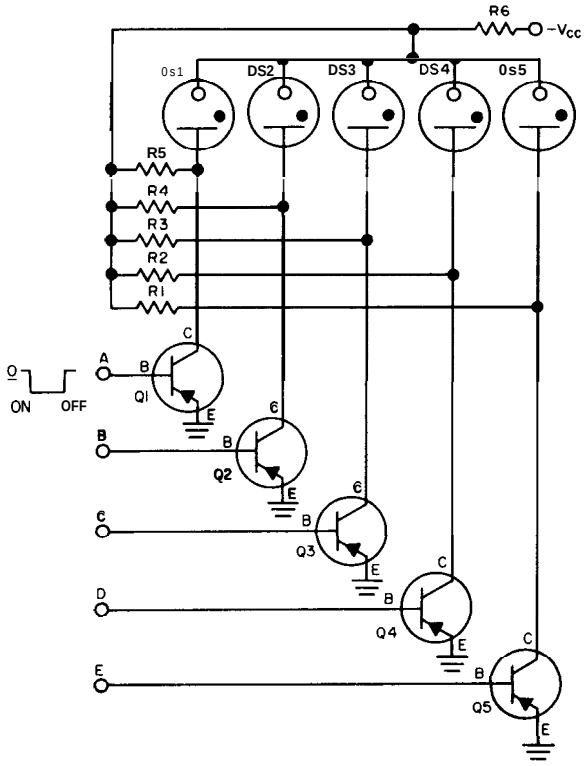
Characteristics.

Provides large voltage or power output, as needed.
Is controlled by a small voltage or current.
May be self-biased or fixed biased.
Usually provides a high input impedance and a moderate or low output impedance.

Circuit Analysis.

General. There are a number of circuits used to control the indicator lamps and relays used in computers and switching circuits. It is rather difficult to specify a basic circuit since there are so many variations. Therefore, a circuit capable of controlling high voltage and low current devices, and another one capable of controlling low-voltage, high-current devices are selected as typical circuits for discussion. The single transistor type of circuit usually requires that the trigger hold the stage in the “off” or the “on” state, whereas the two transistor circuit requires only an “off-on” trigger be applied to change its state. Since the advent of thyratron semiconductor devices, using pnpn four layer diodes or similar controlled rectifier devices, it is possible to have a single stage trigger itself in a “holding” condition until the shut-off trigger arrives. While it is also possible to use diodes for control elements, the transistor finds universal use since it may easily be “turned on” or turned off” without elaborate circuitry.

Circuit Operation. The schematic for a typical high-voltage circuit capable of operating neon indicator lamps is shown in the following schematic. The source of collector voltage is also used to supply the neon indicators. Each of the lamps is

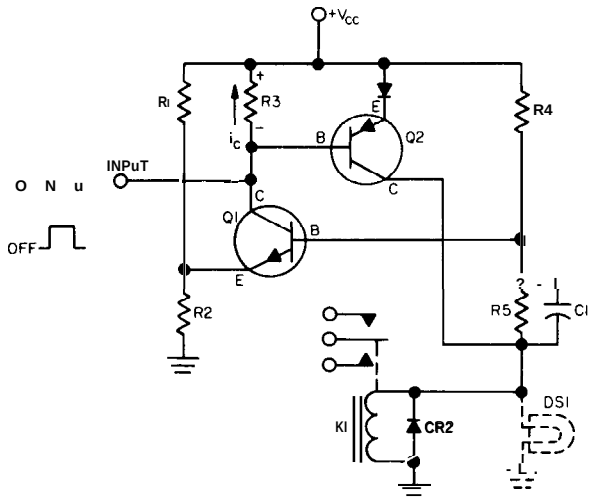


High-Voltage Neon Lamp Driver

resistors R6 and R5 keep the collector voltage within transistor ratings, while heavy conduction to ground through Q1 offers a low resistance path for indicator lamp DS1. As long as the voltage across the lamp is high enough to ionize the lamp (55 to 65V for neon), it is illuminated. Once illuminated, the lamp continues to glow until the voltage across it drops below 15 volts, or transistor Q1 stops conducting. When the forward bias is removed from the base of Q1 by turning off the trigger pulse, conduction through Q1 ceases, lamp DS1 is disconnected from ground, and is extinguished.

Each of the lamps maybe illuminated by applying a negative trigger. Note that this circuit is designed for sequential operation of the lamps, and once conduction is produced in any lamp, the voltage across all lamps will drop to a low value (just above 15 volts) because of the shunting effect of the lamp being triggered. For parallel operation, R6 is eliminated and a separate resistor is connected in series with each indicator lamp, thus allowing the full source voltage to ionize each lamp when triggered.

A typical schematic of a relay puller or lamp driver circuit for low-voltage, high-current applications is shown in the following illustration. Two transistors and a diode are employed in a bi-stable arrangement where the relay or lamp is turned on by a negative trigger and then held in that position until turned off by a positive trigger. Transistor Q1 is used controlled by a separate transistor, and resistors R1 through R5 are collector voltage dropping resistors. Resistor R6 is a current limiter, and is also used to drop the lamp voltage during operation to avoid overload on the transistors. Normally, when no input is applied, the transistors rest in a cut-off state. No collector or emitter current flows (except that due to reverse current flow) and the neon indicator lamps remain out because they are only connected to one side of the line. The "cut-off' condition is obtained by leaving the transistor base floating, and applying reverse collector bias. Because there is no forward-bias, and the collector is reverse-biased no emitter current may flow. In the active state, a negative input signal is applied which produces a forward bias on the base of the activated transistor. Assume for the sake of discussion that Q1 is activated and that emitter current flows. Current flow through



Relay Puller-Lamp Driver Circuit

to control Q2. Resistors RI and R2 are **emitter bias** resistors, while R4 and R5 are base bias resistors for Q1. Bias values are such that in the "off" condition Q1 is held at cutoff, so no current flows through collector resistor R3. Thus the base of Q2 is held positive, which produces a reverse bias for the PNP transistor and prevents emitter current from flowing and actuating the relay or lamp. When a negative trigger is applied, the base of Q2 is driven negative and this forward bias causes emitter flow through Q2 thereby operating relay K1 or illuminating indicator lamp DS1, whichever is used. In the quiescent condition, complementary NPN transistor QI is held in the nonconducting state because the base bias voltage produced across voltage divider R4 and R5 is smaller than the emitter bias produced by divider R1 and R2, thus the base is effectively reverse biased and Q1 does not conduct. Since relay Kl, or lamp DS1, are connected in series with the base voltage' divider consisting of R4 and R5, whenever **Q2** conducts the voltage across this load raises the bias on Q1 base by a like amount and thus supplies a forward bias. With the forward bias controlling Ql, it now conducts and produces a collector current flow through R3. Electron flow is in the direction which produces a negative drop across R3, which holds the base of Q2 in a forward biased condition, and keeps collector current flowing when the input trigger ceases. Operation is initiated by a negative trigger, causing Q1 to conduct, and, in turn, QI holds Q2 in the conducting state; this action continues until a positive trigger is applied to the input to turn it "off".

When a positive "off" trigger is applied to the base of transistor Q2, it momentarily produces a reverse bias, and causes Q2 to stop conduction. Immediately, the voltage developed across the relay or lamp by Q2 collector current flow drops to zero, and the base of transistor Q1 drops to a lower voltage (that produced across R5) than the emitter, to produce an effective negative or reverse base bias for the NPN unit. Thus conduction through Q1 is stopped, and both transistors rest in the cutoff state. Diode CR1 ensures that current may only flow in the proper direction and prevents initiation of a reverse current flow during switching operations. Diode CR2 operates as a discharge diode across the windings of relay Kl, so that any transients caused by the inductive kick in the coil when it is turned off cannot harm the transistor. Capacitor C 1 bypasses R5 so that any load change is reflected immediately as a bias change on the base of Q1, and produces quicker turn-on and turn-off operation.

PARALLEL ADDER

Application.

The parallel adder is used in computers to produce the sum of two binary characters, each containing several bits, by the simultaneous application and addition of all bits.

Characteristics.

A single full-adder is used for each bit of the applied characters, except for the least significant digit.

A half-adder is used for each least significant applied bit.

Can use either positive or negative logic.

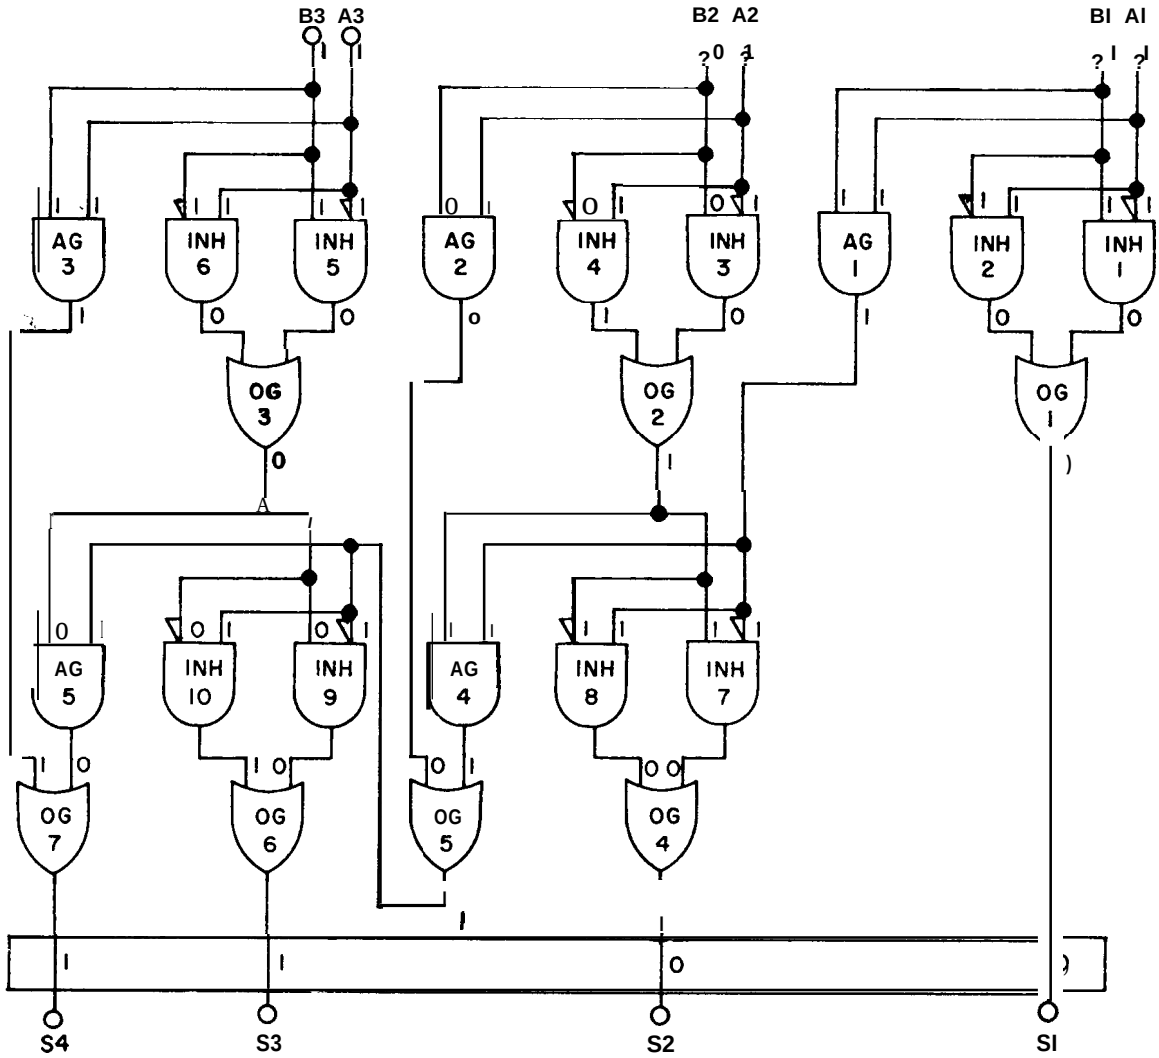
For every two inputs there is a single output.

Circuit Analysis.

General. A parallel adder is formed by individual full-adders (each full-adder being the combination of two half-adders) and a single half-adder. The single half-adder is the initial stage of the parallel-adder, the carry output of which is applied to the carry input of the full adder that follows it. The carry output of this full adder is applied to the carry input of the next full adder that follows it. This type of connection is used between the first half-adder stage and each subsequent full adder stage. The last full-adder stage, however, uses the carry output as the last bit in the resulting sum character of the parallel adder. The remaining sum character bits are the logic pulses produced at the sum outputs of each stage. The pulses produced by the consecutive stages (from right to left) represent progressively significant bits of the resulting sum character. In this way, the parallel adder performs the addition of two applied binary characters simultaneously.

Circuit Operation. The logic diagram of a typical two stage parallel adder is shown in the following illustration. A logic diagram is used rather than a schematic diagram, since the amount of circuitry needed to form a parallel adder becomes extensive and would tend to obscure understanding the basic operation of the adder. For a detailed description of

the circuit action that occurs in each individual gate refer to the circuit explanations of the OR Gate, the AND Gate, and the Inhibit Gate, previously described in this section of the handbook.



Parallel Adder

The logic diagram of a typical parallel adder shown on the accompanying illustration is composed of five AND gate, numbered sequentially (1 through 5) from right to left, seven OR gates, numbered sequentially (1 through 7) from right to left, and ten Inhibit gates, numbered sequentially (1 through 10) from right to left. The logic gates are arranged in three adder stages, each stage represents in right to left order, applied input and output pulse bits in the input and output characters. The stages have subscripts assigned to the inputs and outputs of each stage according to the significance of the place in the input and output characters. Gates are considered parts of a full-adder stage if they react to inputs to

that stage, and aid in producing the output of that stage. That is, all gates that react to first stage augend and addend (Al and B1, respectively) inputs and aid in producing the sum output (S1) of the first stage are considered as part of the first adder stage. Each stage with the exception of the first adder stage, consists of two half-adders. The first half-adder reacts to the applied augend and addend bits, and the second half-adder reacts to the sum output of the first half-adder of that stage and the carry output of the preceding stage.

If an augend character (a set-of-digits to which another set-of-digits is to be added) of 111 and an addend character (a set-of-digits to be added to another set-of-digits) of 101 are applied to the inputs of the parallel adder, logic 1 pulses appear at the following inputs: both inputs of inhibit gate number 1, both inputs of inhibit gate number 2, both inputs of AND gate number 1, the inhibiting input of inhibit gate number 3, the non-inhibiting input of inhibit gate number 4, the augend input of AND gate number 2, both inputs of inhibit gate number 5, both inputs of inhibit gate number 6 and both inputs of AND gate number 3. The two logic 1 inputs to both inhibit gates numbers 1 and 2 develop a logic O output from both gates. These two logic O outputs are applied to the two inputs of OR gate number 1, which, in turn, produces a logic O output. This logic O is the first place bit (least significant) digit of the sum output character (S1).

The logic 1 pulse appearing at the inhibiting input of inhibit gate number 3, causes a logic O to be developed at the output. The logic 1 pulse appearing at the non-inhibiting input of inhibit gate number 4, causes a logic 1 pulse to be developed at the output of inhibit gate number 4. The logic O output of inhibit gate number 3, and the logic 1 pulse output of inhibit gate number 4, appear at the two inputs of OR gate number 2. A logic 1 pulse is developed at the output of OR gate number 2. At the same time, the two logic 1 pulses appearing at the inputs of AND gate number 1 produce a logic 1 pulse output, which becomes the augend input of the second half-adder of the second state. The logic 1 pulse developed at the output of OR gate number 2 becomes the addend input of the second half-adder of the second state. The logic 1 augend pulse to the second half-adder of the second stage, and the logic 1 addend pulse to the second half-adder of the second stage, appear at the inputs of inhibit gates number 7 and 8, and at the inputs of AND gate number 4. The two inhibit gates (7 and 8) develop logic O outputs, which are applied to OR gate number 4; OR gate number 4, also develops a logic O output. This logic O is the second place digit of the sum output character (S2).

The original second stage (first half-adder) augend and addend bits of logic 1 and logic O, consecutively, appear at AND gate number 2, which develops a logic O output to be applied to OR gate number 5. The second stage, second half-adder logic 1 addend and augend pulses appearing at AND gate number 4 produce a logic 1 pulse output from AND gate number 4. This logic 1 pulse output is also applied to OR gate number 5. OR gate number 5 then produces a logic 1 pulse to be used as the augend to the second half-adder of the third stage.

The third stage augend and addend bits of logic 1 appearing at the inputs of inhibit gates 5 and 6, result in a logic O output pulse from each inhibit gate. The third stage augend and addend bits of logic 1 appearing at the inputs of AND gate number 3, produce a logic 1 pulse at the output of this gate. The logic O outputs of inhibit gates 5 and 6 appear at the two inputs of OR gate number 3, which also produces a logic O output. The logic O output of OR gate number 3 is the addend to the second half-adder of the third stage. The logic 1 pulse produced by OR gate number 5 of the second stage adder is the augend to the second half-adder of the third stage, and appears at the inhibiting input of inhibit gate number 9, at the non-inhibiting input of inhibit gate number 10, and at the augend input to AND gate number 5. The logic O addend pulse to the second half-adder of the third stage, appears at the non-inhibiting input of inhibit gate number 9, the inhibit input of inhibit gate number 10, and the addend input to AND gate number 5. As a result, inhibit gate number 10 produces a logic 1 output, while inhibit gate number 9 and AND gate number 5 produce a logic O output. The logic 1 output of inhibit gate number 10, and the logic O output of inhibit gate number 9 are the inputs to OR gate number 6, which, because of the applied logic 1 pulse, produces a logic 1 output. This logic 1 pulse is the third pulse digit of the sum output character (S3).

The logic 1 pulse output of AND gate number 3 of the first half-adder of the third stage, and the logic O output of AND gate number 5 of the second

half-adder of the third stage, are applied to OR gate number 7. OR gate number 7 produces a logic 1 output which becomes the fourth place digit of the sum output character (S4). The resulting parallel adder sum output is then 1100, as shown in the rectangular block at the output area of the parallel adder logic diagram. The following binary and equivalent decimal addition table show that this is the true sum.

Series Adder

SERIES ADDER

Application.

The series or serial adder, as it is more frequently referred to, is used in digital computer circuitry to perform the addition of two binary characters sequentially, or in the order of the application of each bit to the adder.

Characteristics.

The series adder is formed by the combination of two half adders.

One OR gate, one AND gate, and one Inhibit gate form each half-adder.

A delay line used between the half-adders to establish the proper time relationship between bits.

Circuit Analysis.

General. The series adder performs the addition of two binary characters in the time order in which the bits of each character are applied. This is in contrast to the parallel adder which accomplishes the addition of all the bits of each character simultaneously. The logic diagram of the series or serial adder is shown in the accompanying illustration.

The two binary characters are applied to the first half-adder OR gate and the AND gate. If the first digit of both characters is a logic 1, the OR gate and the AND gate both produce a logic 1 output. The output of the OR gate is applied to the non-inhibiting input of the first Inhibit gate. The output of the AND gate is applied to the inhibiting input of the first Inhibit gate. Since an input is applied to both input lines of the Inhibit gate, no output is produced by the Inhibit gate. The output of the first hrdf-adder AND gate, however, is also applied through a diode to a delay line, where the pulse is retarded for the time period of one pulse before being applied to the next half-adder. Since there is no input to the second half-adder, there is no output (zero logic output) from the second half-adder. By the time the pulse applied to the delay line appears at the second half-adder, another binary digit from each character is being applied to the input of the series adder. If the second bit of each character is again a logic 1, the first half-adder AND and OR gates both produce logic 1 outputs. These outputs are again applied to the Inhibit gate inputs, where they are again prevented from developing an output. The second output of the first half-adder AND gate is also applied through a diode to the delay line where it is also retarded for

491-044 0 -13 86

the **time period** of one pulse. The first bit applied to the delay line is now delayed one pulse and is applied to the second half-adder OR gate and AND gate. As a result of this bit, the OR gate produces an output, but the AND gate does not. Since there is no pulse applied to the Inhibit input of the second half-adder Inhibit gate, from the second half-adder AND gate, the pulse applied to the non-inhibiting input of the Inhibit gate, from the second half-adder OR gate, is reproduced at the output of the series adder, as a logic 1.

When the second pulse applied to the delay line appears at the second half-adder, the third bit of each character is simultaneously applied at the input. If the third bit applied to the first half-adder A input is a logic 1, and the first half-adder B input is a logic O, the first half-adder OR gate produces an output pulse, but the first half-adder AND gate does not produce an output pulse. Since the only pulse applied to the first half-adder Inhibit gate is applied to the non-inhibiting input, an output pulse is produced. This pulse is applied to the second half-adder OR and AND gates, along with the second delayed pulse from the delay line. The second half-adder OR gate and AND gate produce output pulses which are applied to the second half-adder Inhibit gate. The presence of both pulses at the Inhibit gate prevents any output from occurring. The output of the second half-adder AND gate, however, is also returned to the beginning of the delay line where it is delayed for the time of one pulse. Since the other inputs have ceased, the delayed pulse is the only one applied to the second half-adder OR gate and AND gate, and there is only an output from the OR gate. This pulse is applied to the second half-adder non-inhibiting input of the Inhibit gate, and is reproduced at the output. The output now has one more digit than either of the applied input characters. The following truth tables show the binary augend, addend, and sum of the series adder. To the right of the binary character are the decimal equivalents. From the decimal equivalents of the augend, addend, and sum, it can be seen that the sum produced by the series adder is a true sum.

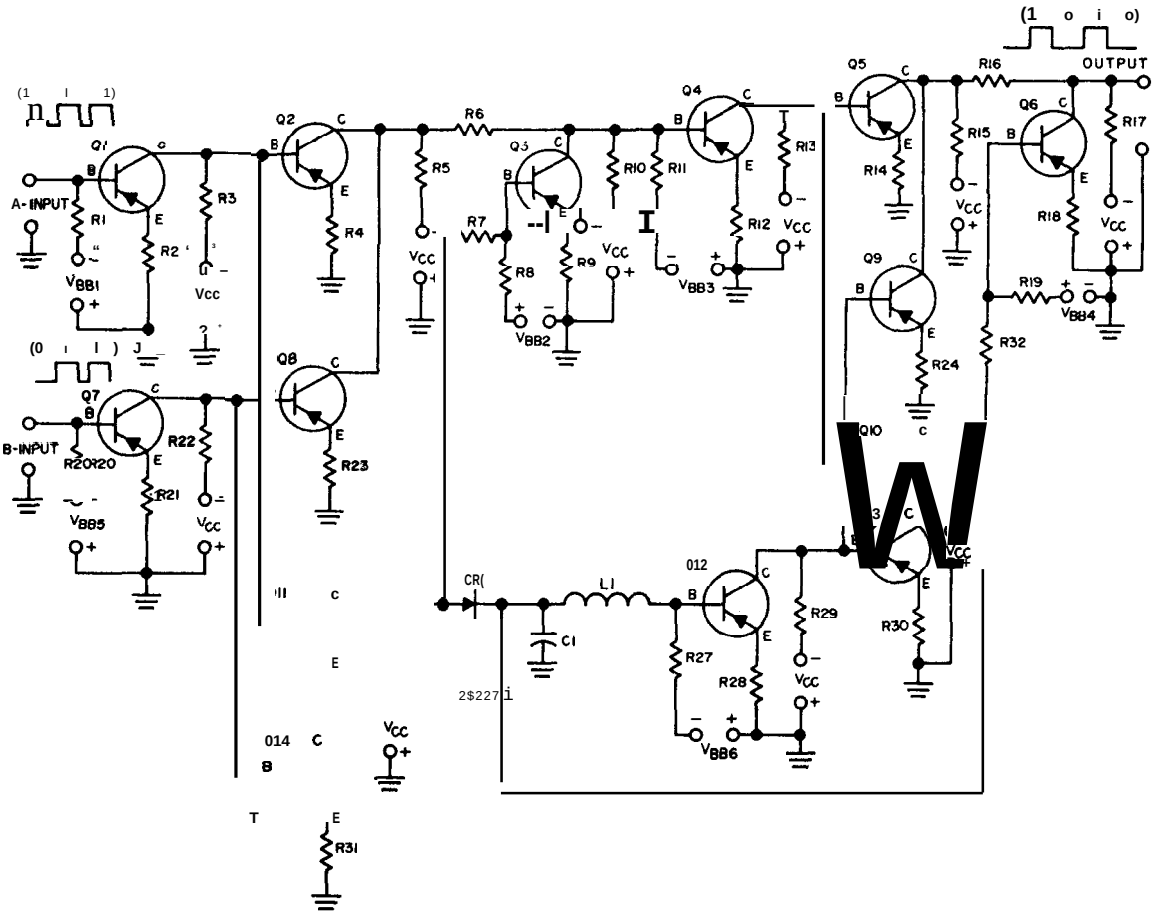
Addend	011	3
Sum	1010	10

Truth Table

Circuit Operation. The schematic of a full series adder, corresponding to the symbols of a given logic diagram is shown in the following illustration.



Series Adder

Transistors Ql, Q7, Q4, and Q12 are inverting transistors, and Q2, Q8, Q5, and Q9 are OR gate transistors. Transistors Q11, Q14, Q1O, and Q13 are AND gate transistors, while Q3 and Q6 are Inhibit gate transistors. Resistors R1, R8, RI 1, R20, R19, and R27 are base biasing resistors, and V_{BB1} V_{BB2}, V_{BB3} ' V_{BB4}, V_{BB5}, and V_{BB6} are base bias' voltage sources. Resistors R2, R4, R9, R12, R14, R18, R21, R23, R24, R28, R30, and R31 are emitter stabilization resistors. The collector load resistors are R3, R5, R1O, R13, R15, R17, R22, R25, R26, and R29. Resistors R6, R7, R16, and R32 are interstage coupling resistors, which also serve as a protection against the possible short to ground caused by a failure in the preceding stage. Diodes CR1 and CR2 control the direction of current flow from the AND gates to the delay line, and prevent the current of one AND gate from flowing into the output of the other AND gate. Capacitor Cl and inductor L1 form a delay line. Voltage source V_{cc} is the collector supply for all transistors in this circuit.

Assume that the first bits applied to the A input and B input are logic 1's, or positive pulses. These pulses cause the forward bias of Q1 and Q7 to decrease the emitter to collector current of Q1 and Q7, and thus, decrease collector current flow through

resistors R3 and R22. The voltage at the collectors of Q1 and Q7 then approaches the negative collector supply voltage. The negative-going voltage at the collector of Q1 is directly coupled to the bases of Q2 and Q11, and the negative-going voltage at the collector of Q7 is directly coupled to the bases of Q8 and Q14. The negative going voltage at each of the four transistor bases causes these transistors (Q2, Q8, Q11, and Q14) to be further forward biased and they increase conduction. When these transistors conduct, collector current flows through resistors R5 and R26. This collector current flow produces a voltage drop across both collector load resistors, and produces a positive swing on the collectors of Q2 and Q3 (the output of the first OR gate) for the time period of the applied pulse, and the collector of Q11 (the output of the first AND gate) also swings positive for the time of the applied pulse. The positive output of the first OR gate is applied through coupling resistor R6 to the collector of Q3. The positive output of the first AND gate is applied through coupling resistor R7 to the base of Q3, where it decreases the forward bias of Q3 so that it does not conduct. With no emitter current flow in Q3, no collector current flows through collector load resistor R1O, leaving the collector of Q3 at the negative collector supply voltage value. This effect, however, is canceled by the positive pulse applied through R6 from the OR gate output. Thus, there is no voltage output at the collector of Q3, and no input to the base of inverting transistor C4

Besides being applied to the Inhibit gate, the positive output of the first AND gate (the collector of Q11) is also applied through diode CR1 to the delay line consisting of Cl and L1. The capacitance of Cl retards the voltage for the time of one pulse; it takes this time for the capacitor to become charged. Simultaneously, the inductance of L1 causes the current to lag for the time period of one pulse. Since the pulse applied to the delay line is retarded for one pulse period, it cannot affect the subsequent circuitry during the time period of the first applied bit. Since there is also no output from the Inhibit gate during this time period, the additional circuitry is not affected, and the output of the adder remains in the same state as if no input pulses had been applied (a logic o **output).**

Assume now that the second bits applied to the A input and B input are also logic 1's, or positive pulses. These pulses produce an effect identical to the two previously applied positive pulses. There is a difference in the circuit action during the time period of the second set of bits, however, since the first pulse retarded by the delay line now makes its appearance at the second half-adder inverting transistor, Q12. This positive pulse decreases the forward bias of Q12, decreasing the collector current flow through collector load resistor R29 and the voltage drop across it. The voltage at the collector of Q12 rises toward the collector supply voltage. This voltage, negative for the time of the pulse from the delay line, is applied to the bases of Q13, of the second AND gate, and Q9, of the second OR gate. There are no other pulses applied to either of the two gates; and, since the AND gate requires the presence of a pulse at each of its inputs for a complete current path for either of the two AND gate transistors to exist, no output is produced by the AND gate. The delay pulse applied to the base of OR gate transistor, Q9, however, caused an output. The negative delay pulse increases the forward bias of Q9, and causes collector current to flow through collector load resistor R15, producing a voltage drop across RI 5. The collector end of R15 swints positive by the amount of voltage dropped across R15. This voltage is coupled through resistor RI 6 to the collector of Q6. Since there is not output, or a logic O output, from the second AND gate there is no positive pulse applied to the base of inhibiting transistor Q6. The positive pulse applied through coupling resistor R16 to the collector of Q6 then becomes the output, which is a logic 1. Since it was mentioned that the action of the series adder was the same for the application of the second set of bits as it was for the first set, the delay line again retains a pulse to be used with the application of subsequent bits.

Assume that the third and final bit applied to the A input is a logic 1, or positive pulse. The third bit applied to the B input, however, is a logic O, or lack of a pulse. The positive pulse applied to the A input again reduces the forward bias of Q1 reducing the emitter current of Q1 and collector current through collector load resistor R3. Hence, the collector rises toward the potential of the negative collector supply voltage. This negative voltage is coupled to the bases of Q2 (of the first OR gate) and Q1 1 (of the first AND gate). The AND gate requires a negative pulse to also exist on the base of Q14, so that both Q11 and Q14 will be forward biased and so that a complete

current path can exist for each of the AND gate transistors and resistor R26. However, since no positive pulse is applied to Q7, the fixed forward bias of Q7 remains at a level that permits emitter current and collector current flow through collector resistor R22 to drop the collector supply voltage across R22, making the collector voltage of Q7 zero. Since there is no negative voltage applied to the bases of OR gate transistor Q8 and AND gate transistor Q14, they remain reverse biased. Since there is only a negative voltage available at the base of QI 1 and not at the base of Q14, the first AND gate cannot produce an output. The voltage at the collector of Q1 1 is then the negative supply voltage value, which is the same as a zero output, since this negative voltage reverse biases diode CR1 and has no appreciable effect on the normal forward bias applied to Q3.

The negative pulse from the collector of QI applied to the base of OR gate transistor Q2 causes the forward bias of Q2 to increase, resulting in an increased collector current through collector load resistor R5, and an increased voltage drop across R5. This voltage drop leaves the collector of Q2 positive. This positive pulse voltage is coupled through resistor R6 to the collector of inhibiting transistor Q3. This voltage is applied directly to the base of inverting transistor Q4, where it reduces the forward bias of Q4, the emitter current of Q4, the collector current through collector load resistor R13, and the voltage drop across R13. Hence, the collector end of R13 rises to the negative collector supply voltage value. At the same time, the second positive pulse remaining in the delay line now appears at the output of the delay line, and is applied to the base of inverting transistor Q12. The delayed positive pulse reduces the forward bias of Q12, the emitter current of Q12, the collector current flowing through collector load resistor R29, and the voltage drop across R29. The voltage at the collector of Q12 then rises to the negative supply voltage value.

The negative pulses produced by inverting transistors Q4 and Q12 are applied directly to the bases of transistors Q5 and Q9 (the second OR gate) and the base of Q1O and Q13 (the second AND gate). The forward bias of each of these transistors is increased, thereby increasing the emitter currents, the collector currents through the AND gate collector load resistor and the OR gate collector load resistor, and the voltage drop across these collector load resistors. The voltage at the collector ends of both AND gate collector load resistor R25, and OR gate collector load resistor R15 is then positive, thus, making the outputs of both the second AND gate and the second OR gate positive. The positive AND gate pulse is applied through coupling resistor R32 to the base of the Inhibit gate transistor Q6. At the same time, the positive AND gate pulse is applied through diode CR2 to the delay line consisting of Cl and LI, where the pulse is retarded for the time period of one pulse. The positive pulse appearing at the base of Inhibit gate transistor Q6 reduces the forward bias, the emitter current, and the collector current through Q6 collector load resistor R17. Thus, the voltage drop across R17 is reduced, leaving the collector of Q6 at the negative collector supply voltage value. This negative voltage is canceled, however, by the positive output voltage of Q5 applied through coupling resistor R16 to the collector of Q6. The collector voltage, Inhibit gate output, and, finally, the series adder output is then zero volts (or a logic O).

There are no more bits applied to the input; however, the positive pulse applied from the second AND gate (during the time period of the third applied bit) to the delay line emerges from the delay line one pulse later. The delayed positive pulse appears at the base of Q12, where it decreases the forward bias of Q12, the emitter current, the collector current through collector load resistor R29, and the voltage drop across R29. The voltage at the collector end of R29 then rises to the negative supply voltage value. This negative voltage is coupled to the bases of AND gate transistor Q13 and OR gate transistor Q9. The negative voltage has no effect on AND gate transistor Q13, since, Q13 cannot conduct regardless of the voltage applied to base, unless the other AND gate transistor, Q1O, is conducting to provide a complete current path for Q13; and, in this case, Q1O is not conducting because no negative pulse is applied to its base. On the other hand, Q9 can conduct with the proper bias voltage, since Q9 has a complete current path from collector supply source to ground. When the negative pulse is applied to the base of Q9, then, the forward bias of Q9 is increased, emitter current is increased, collector current through collector load resistor RI 5 is increased, and the voltage drop across R15 is increased. The collector side of R15 thus becomes positive. This positive voltage swing, which is the output of the OR gate, is coupled through

resistor RI 6 to the collector of the Inhibit gate transistor, Q6, where it appears as the output of the series adder as a logic 1. Hence, when a three bit character of 111 (three positive pulses) is applied to the A input, and a three bit character of 011 (one lack of pulse and two positive pulses) is applied to B input, a four bit character of 1010 (a positive pulse, a lack of a pulse, a positive pulse, and a lack of pulse) is obtained at the output.

SERIES-PARALLEL ADDER

Application.

The series-parallel adder is used to add decimal numbers consisting of many bits when expressed in binary from, thus affording the benefit of increased speed through parallel addition, and using a smaller number of circuits by combining it with series addition.

Characteristics.

The series-parallel adder consists of six full binary adders, two half-adders, and an OR gate.

The binary equivalent of each decimal digit is handled and grouped in parallel.

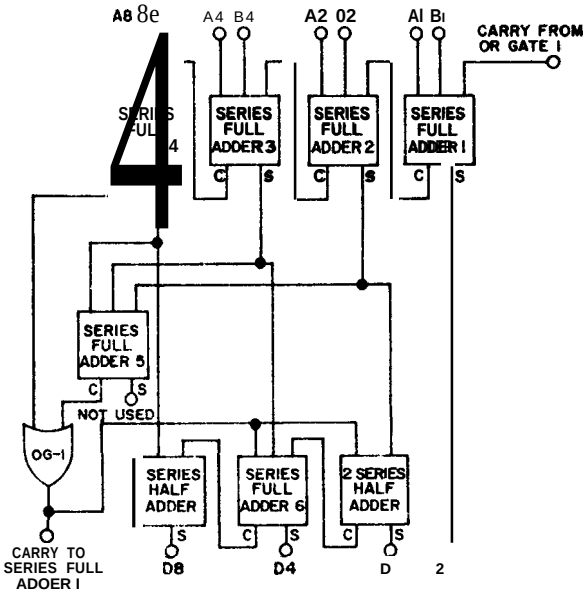
The decimal place is handled sequentially.

Circuit Analysis.

General. The series-parallel adder is a parallel arrangement of full serial adders and half serial adders. By using this arrangement fewer circuits are required than for a completely parallel arrangement, but by using a parallel grouping the benefits of greater speed are available. The binary equivalent of one decimal digit (1 through 9) of the addend and one decimal digit of the augend are applied to four addend and four augend lines. This is the parallel phase of operation for the adder. The binary equivalent of the next (more) significant place decimal digit of the addend and augend is applied one pulse time-period later to the four addend and four augend lines. This is the serial phase of operation. When the sum of the digits of the addend and augend are combined to produce a decimal equivalent sum that is greater than "9", the pulses that correspond to a second place digit are returned to the input through another carry line.

Circuit Operation. Rather than illustrate all of the circuits and circuit components involved in the composition of the series-parallel adder schematically, a block diagram approach is shown in the following illustration. This simple type of presentation is used to prevent confusion, avoid complexity and avoid duplication of effort, since the complete explanation of a series adder and a parallel adder is given separately earlier in this section of this handbook.

In the illustration, the A inputs represent the inputs to which the augend bits are applied. The B inputs represent the inputs to which the addend bits are applied. The inputs are arranged from right to left as 1 - 2 - 4 - 8, representing the decimal number equivalent of a pulse applied to that input. There is a corresponding series full-adder for each pair of numbered inputs. The adders are numbered in increasing order from right to left, as follows:



Series-Parallel Adder

full-adder No. 1 for inputs A-1 and B-1, full-adder No. 2 for inputs A-2 and B-2, full-adder No. 3 for inputs A4 and B4, full-adder No. 4 for inputs A-8 and B-8. Full-adders 1, 2, 3 and 4 are connected in parallel, having carry lines between each adder and

the following adder. The sum output of each of these full-adders, with the exception of full-adder No. 1, has its sum output applied to series full-adder No. 5. The sum output of full-adder No. 2 is also applied to half-adder No. 2; the sum output of full-adder No. 3 is also applied to full-adder No. 6, and the sum output of full-adder No. 4 is also applied to the input of half-adder No. 1. The sum outputs of half-adders No. 1 and No. 2, and full-adder No. 6 along with the sum output of full-adder No. 1 are the final outputs of the series-parallel adder. The carry output of series full-adder No. 5 and the carry output of series full-adder No. 4 are applied to OR gate No. 1. The output of the OR gate is returned to the carry inputs of full-adders No. 1 and No. 6 and half-adder No. 2. A carry line exists between half-adder No. 2 and full-adder No. 6, and a carry line exists between full-adder No. 6 and half-adder No. 1.

For ease of explanation, the binary equivalent of the decimal number "463" is used as the augend, and a decimal number "852" is used as the addend to be applied to the series-parallel adder. Since there are three digits or three places to each decimal character, there are three sequential pulse applications. In this case, the binary equivalent of the first-decimal augend digit, which is 0011, and the binary equivalent of the first decimal addend digit, which is 0010, are applied during the time period of the first sequence. The binary equivalent of the second decimal augend digit, which is 0110, and the binary equivalent of the second decimal addend digit, which is 0101, are applied during the time period of the second sequence. The binary equivalent of the third and final decimal augend digit, which is 0100, and the binary equivalent of the third and final decimal addend digit, which is 1000, are applied during the time period of the third sequence.

During the time period of the first sequence, then a logic 1 pulse is applied to the A inputs of full-adders No. 1 and No. 2, and a logic 1 pulse is applied to the B input of full-adder No. 2. As a result, full-adder No. 1 produces a logic 1 sum output with a logic O carry output pulse, and full-adder No. 2 produces a logic 1 carry pulse output with a logic O sum output. The logic 1 sum output of full-adder No. 1 appears at output D1 of the series-parallel adder as a logic 1. The logic 1 carry output of full-adder No. 2 is applied to the input of full-adder No. 3, which, in turn, produces a logic 1 sum output and logic O carry output. The logic 1 sum output of full-adder No. 3 is applied to the inputs of fulI-adder No. 5 and full-adder No. 6, each of which produce a logic 1 sum output and logic O carry output. The logic 1 sum output of full-adder No. 5 is not used, but the logic 1 output of full-adder No. 6 appears at output D4. The binary logic sum output of the series-parallel adder for the first time sequence is then 0101, which is equivalent to the decimal number 5.

During the time period of the second sequence, a logic 1 pulse is applied to the A inputs of full-adders No. 2 and No. 3, and a logic 1 pulse is applied to the B inputs of full-adders No. 1 and No. 3. As a result, full-adder No. 1 produces a logic 1 sum output pulse with a logic O carry output pulse. Full adder No. 2 produces a logic 1 sum outpulse, with a logic O carry output pulse. Full-adder No. 3 produces a logic 1 carry output pulse with a logic O sum output pulse, and (from the carry output of full adder No. 3, which is applied to the input of full adder No. 4). Full-adder No. 4 produces a logic 1 sum output pulse with a logic O carry output pulse. The logic 1 sum output of full-adder No. 1 appears at output D1 of the series-parallel adder as a logic 1. The logic 1 sum output of fuU-adder No. 2 is applied to an input of half-adder No. 2 and to an input of full-adder No. 5. The logic 1 sum output of full-adder No. 4 is applied to an input of full-adder No. 5 and an input of half-adder No. 1. Since there are pulses applied to two inputs of full-adder No. 5, there is a logic 1 carry output pulse produced, which is applied to OR gate No. 1.

OR gate No. 1 produces a logic 1 output, which is applied to fuU-adder No. 6, half-adder No. 2, and (after being delayed for the time period of one pulse sequence) is returned to full-adder No. 1. Since there is a logic 1 pulse applied to half-adder No. 2 from full-adder No. 2, and a logic 1 pulse applied to half-adder No. 2 from OR gate No. 1, half-adder No. 2 develops a logic 1 carry pulse with a logic O sum output pulse. The logic 1 carry pulse from half-adder No. 2 is applied to the input of full-adder No. 6, to which a logic 1 pulse is also applied from OR gate 1. Full-adder No. 6 then develops a logic 1 carry pulse with a logic O sum output pulse. The logic 1 carry pulse from full-adder No. 6 is applied to an input of half-adder No. 1, to which a logic 1 pulse has been applied from full-adder No. 4. Half-adder No. 1 produces no carry pulse, since there is no carry line, and produces a logic O sum output pulse, since it has

two logic 1 pulses applied to its inputs. The binary logic sum output of the series-parallel adder for the second time sequence is then 0001, which is the equivalent of decimal number 1.

During the time period of the third sequence a logic 1 pulse is applied to the carry input of full-adder No. 1, a logic 1 pulse is applied to the A input of full-adder No. 3, and a logic 1 pulse is applied to the input of full-adder No. 4. Full-adder No. 1 produces a logic 1 sum output with a logic O carry output pulse; full-adder No. 3 produces a logic 1 sum output pulse, and full-adder No. 4 produces a logic 1 sum output. The logic 1 sum output of full-adder No. 1 appears at output D1 of the series-parallel adder as a logic 1. The logic 1 sum output of full-adder No. 3 is applied to an input of full-adder No. 6, and to an input of full-adder No. 5. The logic 1 sum output of full-adder No. 4 is applied to an input of full-adder No. 5 and an input of half-adder No. 1. Since there are pulses applied to two inputs of full-adder No. 5, there is a logic 1 carry output pulse produced which is applied to OR gate No. 1. OR gate No. 1 produces a logic 1 output, which is applied to full-adder No. 6, half-adder No. 2, and (after being delayed for the time period of one pulse sequence) is returned to full-adder No. 1. The pulse applied to the input of half-adder No. 2 appears at the output of half-adder No. 2, (output D2) as logic 1. Since there is a logic 1 pulse applied to full-adder No. 6 from full-adder No. 3, and a logic 1 pulse is applied to full-adder No. 6 from OR gate No. 1, full-adder No. 6 develops a logic 1 carry pulse with a logic O sum out-pulse. The logic 1 carry pulse from full-adder No. 6 is applied to the input of half-adder No. 1. Half-adder No. 1 produces no carry pulse, since there is no carry line, and produces a logic O sum output pulse, since it has two logic 1 pulses applied to its inputs. The binary logic output of the series parallel adder for the third time sequence is then 0011, which is equivalent to the decimal number 3.

The logic 1 pulse returned to the carry input of full-adder No. 1 appears when a fourth time sequence would normally occur. This logic 1 input to full-adder No. 1 appears at output D1 as a logic 1. Since there are no logic 1 A or B pulses applied during the fourth time sequence, the binary logic output of the series-parallel adder for the fourth time sequence is then 0001, which is equivalent to a decimal 1.

During the four time sequences the output of the series-parallel adder is shown in the accompanying diagram. This output is correct, since the decimal sum of 463 and 852 is equal to 1315.

	4th Time Sequence	3rd Time Sequence	2nd Time Sequence	1st Time Sequence
Binary output	0001	0011	0001	0101
Decimal Equivalent	1	3	1	5

Series-Parallel Binary and Decimal Outputs

HALF SUBTRACTOR

Application.

The half subtracter is used in digital computers to subtract two binary digits, or it may be combined with other half subtracter circuits to form full subtracters which subtract characters containing more than two binary digits.

Characteristics.

Two inhibit gates are used.

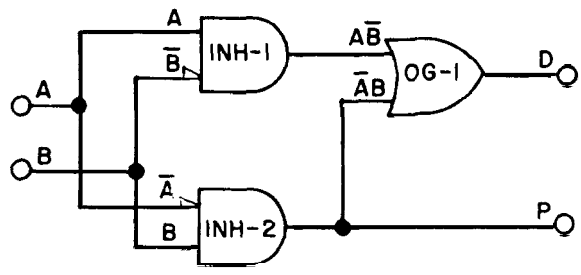
One OR gate is used.

Two inputs produce two outputs, a difference and a borrow output.

Uses negative logic, but can be arranged for positive logic.

Circuit Analysis.

General. The half subtracter will produce the difference between two binary characters, each containing two-binary digits or bits. This is accomplished by applying the binary characters to each of two inhibit gates with opposite inhibit inputs. The outputs of the two inhibit gates are applied to an OR gate. The following logic diagram illustrates the relationship between the required gates, and the truth table shows the possible input and output combinations.



INPUT	INPUT	OUTPUT	BORROW
A	B	o	P
o	0	0	0
I	o	I	o
0	I	I	I
I	I	o	0

Half Subtracter

In the preceding diagram, the signal applied to A is always the minuend (the number from which another is subtracted) and the signal applied to B is always the subtrahend (the number being subtracted).

If two binary digits or bits are applied to each input, and the minuend is always larger than the subtrahend, the circuit will produce the difference between the character applied to input A and the character applied to input B. This difference may or may not be a true difference. If it is not a true difference, additional half subtracter stages are necessary.

When the first A input bit is a logic 1 and the first B input bit is a logic 1, neither inhibit gate produces an output pulse; thus, there is no negative pulse applied to either of the OR gate inputs. There is, then, neither a difference pulse nor a borrow pulse produced when pulses are applied to inputs A and B simultaneously. In other words, the output is a logic o.

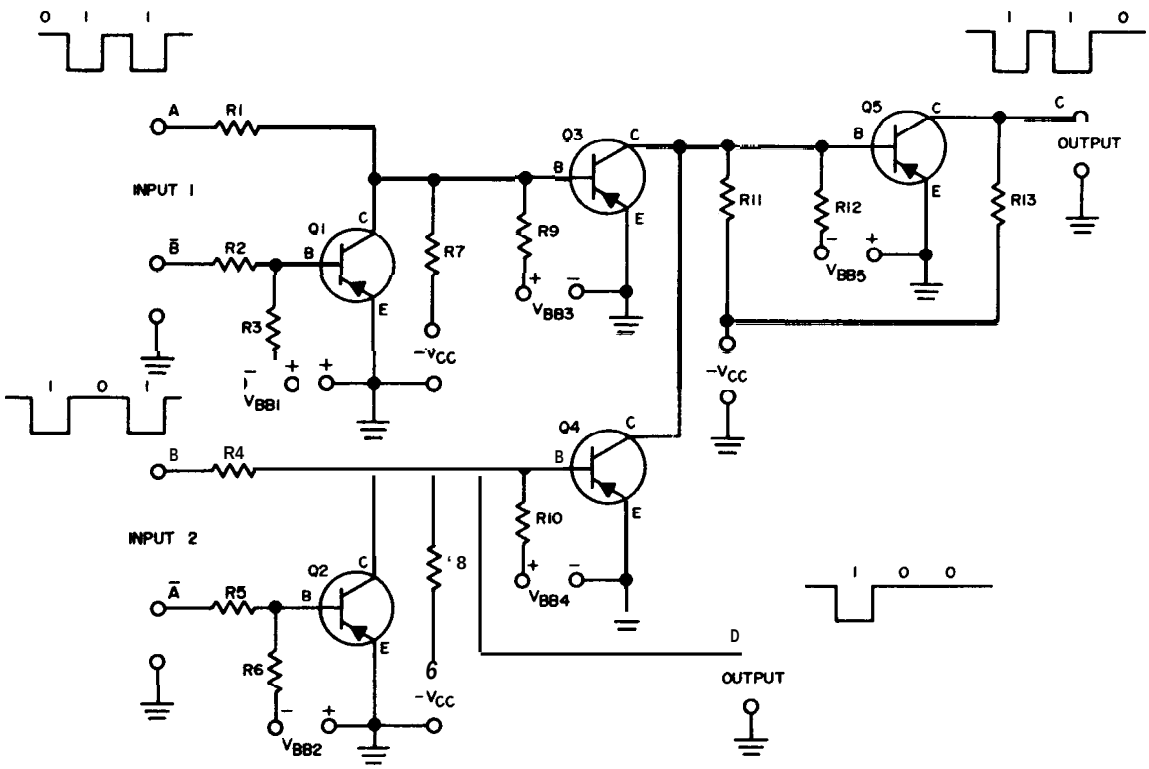
When the second A input bit is a logic 1 and the second B input bit is a logic O, the first inhibit gate produces an output, and the second inhibit gate produces no output. The OR gate is activated by the output of the first inhibit gate. The OR gate in turn,

produces a logic 1 output. Since the second inhibit gate does not produce an output, no borrow pulse is produced.

The following illustration shows the binary subtraction of the two characters and the equivalent decimal subtraction.

	Binary	Decimal
Minuend	11	3
Subtrahend	01	1
Remainder	10	2
Borrow	00	0

Circuit Operation. The schematic of a typical half-subtracter circuit is shown in the accompanying illustration.



Half Subtracter

Resistor RI is the input resistor for the A input to input 1; resistor R2 is the base input resistor for the corresponding B input; resistor R4 is the input resistor for the B input to input 2; resistor R5 is the base input and biasing resistor for the corresponding A input. Transistors Q1 and Q2 invert the applied pulses so that the pulses applied on the other inputs are inhibited. Transistors Q3 and Q4 comprise the OR gate. Resistors R3, R6, R9, and R1O are the corresponding base bias resistors for transistors Q1, Q2, Q3, and Q4. Voltage sources V_{BB1}, V_{BB2}, V_{BB3}, and V_{BB4}, are the fixed base bias voltage for transistors Q1, Q2, Q3, and Q4, respectively. Resistors R7 and R8 are collector load resistors for Q1 and Q2,

respectively. Resistor R1 1 is the collector load resistor for OR gates transistors Q3 and Q4. Transistor Q5 inverts the output of the OR gate, so that the output pulses of the subtracter are negative. Resistor R12 is the base bias resistor for Q5, and V_{BB5} is the base bias voltage source for Q5.

With no input pulses applied, the forward bias on the bases of Q1 and Q2 allow Q1 and Q2 to conduct. The conduction of Q1 and Q2 develops emitter to collector current, and current flows through collector resistors R7 and R8. Consequently, a voltage drop is produced across R7 and R8 sufficient to drop the collector potentials of Q1 and Q2 to zero. A negative pulse (logic 1) is applied to input A, causing the voltage at the collector of Q1 to become negative and, since the base of Q2 receives the negative pulse applied to the A input, the forward bias of Q2 is increased. In turn, Q2 conducts, and increases the collector current through collector load resistor R8. Thus, a voltage drop is developed across R8 which reduces the collector voltage of Q2, and produces a positive swing. At the same time that a negative pulse is applied to input A, a negative pulse is applied to input B. The negative B input pulse increases the forward bias of Q1 since it is directly applied to the base of Q1, causing the emitter to collector current of Q1 to increase, and the collector current through R7 to increase. Thus, the voltage drop across R7 is increased. This causes the collector of Q1 to swing positive, canceling the negative pulse applied at the A input. The negative pulse applied to input B also appears at the collector of Q2. This pulse, however, is canceled by the positive voltage swing developed on the collector of Q2, as a result of the negative pulse applied to input A.

Since the pulses applied to inputs A and B effectively cancel each other, no pulses are applied to the OR gate. Transistors Q3 and Q4 remain nonconducting since they are reverse biased. When no current flows through Q3 and Q4, no current can flow through resistor R11. The output of the OR gate is then the negative collector supply voltage value. This negative voltage applied to the base of Q5 forward biases Q5 and emitter current flows, producing a collector current flow through resistor R13. Thus, the collector voltage is dropped across R13, and the output at C is then a logic O. There is also no borrow pulse produced, since the inhibit gate responsible for providing the borrow pulse (Q2) also has no output.

When another negative pulse is applied to the A and $\overline{A}$ inputs, it causes the voltage at the collector of Q1 to become negative and causes Q2 to conduct because of the increased forward bias applied to the base of Q2. The emitter to collector current of Q2 is increased, the collector current through R8 is increased, dropping the voltage across R8, making the collector of Q2 swing positive. Since there are no negative pulses applied to the B inputs at this time, the negative A input, applied through resistor R1, appears on the base of Q3, and overcomes the reverse bias on the base of Q3, making Q3 conduct. The emitter to collector current of Q3 increases, which in turn, causes the collector current through resistor R1 1 to increase, and develop a voltage drop across R11. The positive-going collector voltage of Q3 is directly coupled to the base of Q5, and decreases the forward bias of Q5. The decreasing forward bias of Q5 decreases emitter to collector current of Q5, reduces collector current flow through resistor R13, and decreases the voltage drop across R13. The output voltage at C then rises to the negative collector supply voltage value, and effectively produces a logic 1.

The negative pulse applied to Q2 through input resistor R5, forward biases Q2, increases current flow through resistor R8, and makes it more positive. Since, there is no B pulse applied through R4 to oppose the output of Q2, the positive-going voltage on the collector of Q2 appears at the base of Q4, and also appears at borrow output D. The positive-going voltage applied to the base of Q4 biases it further into cutoff, and no output is produced by Q5. The positive-going voltage appearing at output D is a logic O. Hence no borrow pulse is produced by the application of the second negative pulse to input A.

In the case of the applied binary minuend and subtrahend, there is no borrow pulse produced. To describe the conditions where a borrow pulse is produced it is necessary to use an additional minuend bit and subtrahend bit. These two bits are not part of the original characters. Here, a minuend bit of a logic O is applied and a subtrahend bit of a logic 1 is applied, The minuend bit is applied to input 1-A and

input 2-A. Since this bit is a logic O, there is no actual pulse applied. At the same time a logic 1 is applied to input 1-B and input 2-B. This is a negative pulse. A negative pulse applied to the B input is coupled through resistor R2 to the base of Q1 where it increases the forward bias, and collector current through collector load resistor R7, producing a voltage drop across R7 which leaves the collector of Q1 positive. This positive voltage, directly coupled to the base of Q3, has no effect on the conduction of Q3, since Q3 is already biased off by the fixed positive bias voltage, this positive pulse only biases it further out of conduction. The negative pulse applied to the B input is coupled through resistor R4 to the borrow output D. The negative pulse applied to B input is also coupled through resistor R4 to the base of Q4, where it increases forward bias of Q4, causes emitter current to flow through Q4, collector current to flow through collector load resistor RI 1, and the collector voltage to drop across R11. The collector end of resistor R1 1 is now positive. This positive voltage is directly coupled to the base of Q5, where it decreases the forward bias of Q5, decreases the emitter current of Q5, decreases the collector current through collector load resistance R13, and decreases the voltage drop across R13. The collector and collector end of R13 thus rise to the negative potential of the collector supply voltage. This is a logic 1 output. For the application of a minuend bit of O and a subtrahend bit of 1, then, a difference bit of 1 is obtained and a borrow bit of 1 is obtained. The borrow bit has no function in the half subtracter; it must be applied to the circuitry of an additional half subtracter to obtain the proper binary answer involving bits that would produce a borrow pulse.

FULL SUBTRACTOR

Application.

The full subtracter is used in digital computers to subtract a number of binary digits from another group of binary digits. The full subtracter may consist of two or more half-subtracters, or may consist of other special circuit arrangements.

Characteristics.

Three inhibit gates are used.

Two OR gates are used.

One delay line is used.

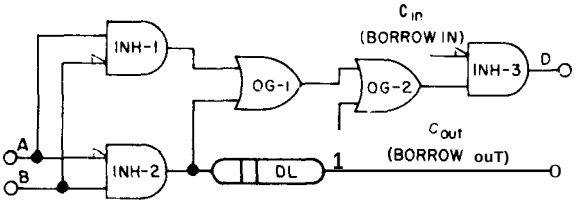
Three inputs produce two outputs.

Uses negative logic, but can be arranged for positive logic.

Circuit Analysis.

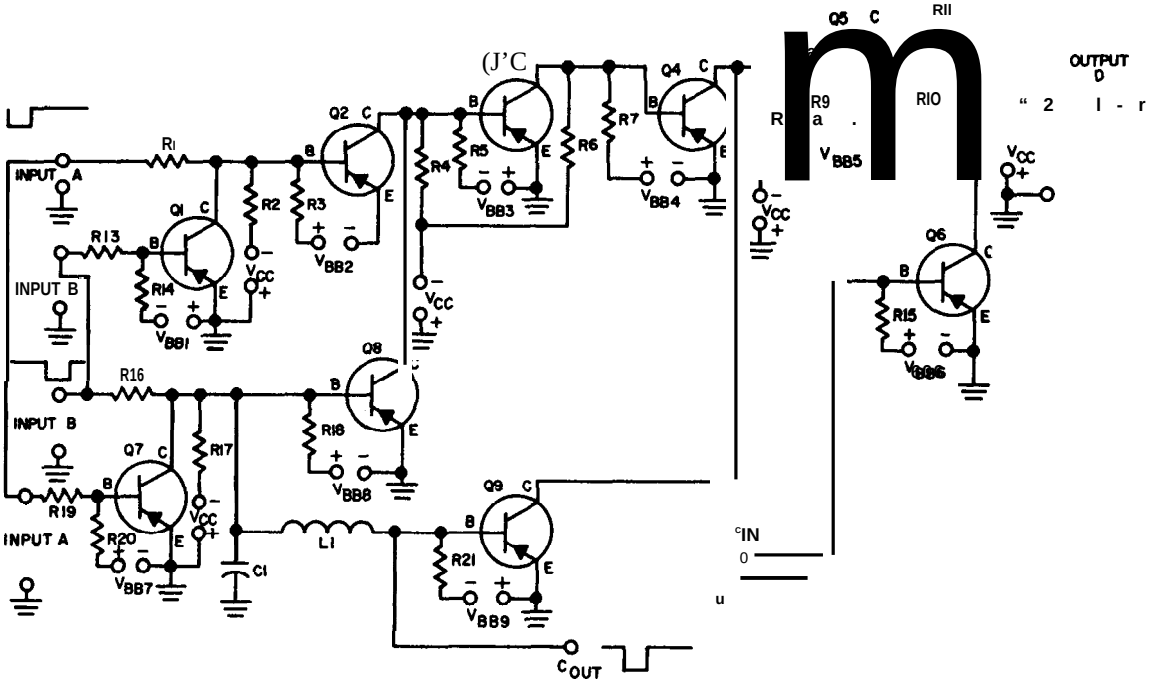
General. The full-subtracter must be used in a parallel or series configuration, usually consisting of other full-subtracters, to produce the time difference between applied characters. Each full subtracter, by itself, produces an incomplete difference of characters and borrow pulses. The full-subtracter performs subtraction by having the minuend (character being subtracted from) and the subtrahend (character which is subtracted from the minuend) applied to separate inhibit gates with opposite inhibit inputs. The outputs of the two inhibit gates are applied to an OR gate. One inhibit gate output is, however, applied to a delay line, where any applied pulse is retarded for the time period of one pulse. The output of the first OR gate and the output of the delay line are applied to a second OR gate, the output of which is applied to the non-inhibiting input of a third inhibit gate. Any borrow pulses from a preceding stage are applied to the inhibiting input of this inhibit gate. If a logic 1 pulse appears at the non-inhibiting input of the third inhibit gate, and there are no borrow pulses applied from preceding subtracters, a logic 1 difference results at the output of this full-subtracter. If, however, when a logic 1 pulse appears at the non-inhibiting input of the third inhibit gate, a logic 1 borrow pulse is applied from a preceding full-subtractor, a logic O difference results at the output. Any pulse that develops at the output of the delay line, besides appearing at the input of the second OR gate, appears at the borrow input of the following full-subtracter stage.

The following logic diagram illustrates a typical full-subtracter.



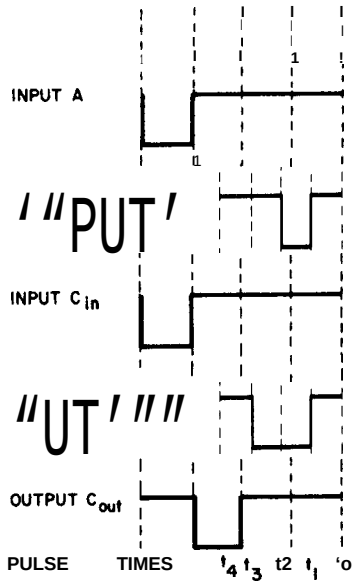
Full Subtracter

Circuit Oparation. The schematic of a typical full-subtracter is shown in the accompanying illustration. In the circuit QI, Q7, and Q6 are inhibit gate transistors; Q2, Q8, Q4 and Q9 are OR gate transistors; Q3 and Q5 are inverting transistors. Input resistors are R1, RI 3, R16, and R19. Biasing resistors are R3, R5, R7, R14, R15, R18, R20, and R21. *Voltage* sources V_{BB1}, V_{BB2}, V_{BB3}, V_{BB4}, V_{BB5}, V_{BB6}, V_{BB7}, V_{BB8}, and V_{BB9}, are bias voltage sources. Resistors R2, R4, R6, R8, R1O, R12, and R17 are collector load resistors. Capacitor Cl and inductor L1 form a delay line.



Full Subtracter

At time t_1 in the accompanying waveform chart, a negative pulse is applied to the B inputs, but no pulse is applied to the A inputs. One B-input pulse is coupled through resistor R13 to the base of inhibit transistor Q1. The negative input pulse forward biases Q1, causes collector current to flow through collector load resistor R2, and the voltage to drop across R2. As a result of the voltage drop across R2, the collector of Q1 swings positive. This positive pulse swing appears at the base of Q2, and, since a negative pulse is required at the base of Q2 for this transistor to be biased into conduction, Q2 remains in the nonconducting state. Thus, the positive pulse produced at the collector of Q1 has no effect on the output.



Waveform Chart

The other B input pulse, coupled through input resistor R16 to the base of OR gate transistor Q8, forward biases Q8. Hence, the emitter current of Q8 increases, and the voltage drop across collector resistor R4 increases. The positive voltage pulse swing developed at the collector of Q8 appears at the base of inverting transistor Q3, where it causes a reduction of forward bias. Therefore, the collector current of Q3 is reduced through collector load resistor R6, and the potential at the collector end of R6 rises toward the negative supply voltage value. This negative voltage appears at the base of OR gate transistor Q4, and forward biases Q4. As a result of the forward bias, the collector current through collector load resistor R8, and the voltage drop across resistor R8 increase. A positive-going voltage puke is now produced at the collector of Q4. This pulse appears at the base of inverting transistor Q5, and reduces the forward bias of Q5. Thus, the collector current through load resistor RIO is reduced, and the voltage drop across resistor R1O is also reduced. The potential at the collector end of R1O now rises toward the negative supply voltage value. This voltage coupled through resistor R11 is the output voltage, which is equivalent to a logic 1.

The input pulse applied to the base of Q8 through resistor R16 is also applied to the delay line composed of capacitor Cl and inductor L1. The delay line retards the applied pulse for the time period of one pulse, so that it emerges from the delay line at time t_2. This pulse is the borrow output pulse which is applied to another full subtracter.

At time t_2, no input pulse is applied, so that the pulse emerging from the delay line is the only pulse affecting circuit action. This negative pulse is a borrow output pulse (C_{out}) to be applied to the borrow input of a subsequent subtracter, but also appears at the base of Q9. The forward bias of Q9 is increased because of the applied delay pulse. The collector current through load resistor R8 and voltage drop across R8 increase. The potential at the collector of Q9 then swings positive, making the potential at the base of Q5 positive. As a result, the forward bias of Q5 is reduced, the collector current through resistor R1O is reduced, and the voltage drop across R1O is reduced. The collector of Q5 then rises toward the negative collector supply voltage value. This negative voltage swing is coupled through resistor R11 to the output, and is equivalent to a logic 1 output.

At time t_3, a negative pulse is applied to the A inputs, and a negative pulse is applied to the borrow input (C_{in}) of the full-subtracor. One of the A inputs is coupled through resistor R19 to the base of inhibit transistor Q7. This negative pulse establishes forward bias, causes collector current to flow through collector load resistor R17, and causes the voltage to drop across resistor R17. As a result, the collector of Q7 swings positive. This positive pulse swing appears at the base of Q8, and, since a negative pulse is required at the base of this transistor to bias it into conduction, Q8 remains in the non-conducting state. For this reason, the positive swinging pulse produced at the collector of Q7 does not affect the output.

The negative input pulse applied at A also appears at the base of Q2, forward biases Q2, increases collector current flow through load resistor R4, and increases the voltage drop across R4. The collector voltage of Q2 now swings positive. This positive voltage swing appears at the base of Q3, and decreases the forward bias of Q3. The emitter current of Q3, the collector current through collector load resistor R6, and the voltage drop across R6 are thereby reduced. The potential at the collector end of R6 then rises toward the negative collector supply voltage value.

This negative voltage appears at the base of Q4, causing the forward bias of Q4 to increase, **Because of this, the emitter** current increases, the collector current through collector load resistor R8, increase, and the voltage drop across R8 increases, making the collector voltage of Q4 positive. The voltage at the base of Q5 swings positive, reducing the forward bias of Q5, the emitter current of Q5, and the collector current through resistor R1O, thus, causing the voltage drop across resistor R1O to be reduced. The voltage at the collector of Q5 then rises toward the negative supply voltage value. This negative voltage would normally be coupled through resistor R1 1 to the output; however, the negative pulse applied to the full-subtracter borrow input appears at the base of Q6. The borrow pulse increases the forward bias of Q6 and the collector current through collector load resistor RI 2, producing a voltage drop across RI 2. As a result, the collector of Q6 swings positive canceling the negative pulse voltage applied from the collector of Q5, and no output is produced, resulting in a logic ***o.***

RETIMING AND RESHAPING CIRCUIT

Application.

The retiming and reshaping circuit is used in digital computers to develop, sharp, clean, square-wave pulses from deformed pulses which may have suffered distortion and timing displacement after circulating through delay lines, and numerous coupling circuits.

Characteristics.

Circuit consists of a combination of three separate basic circuits. An OR circuit, an AND circuit, and an amplifier.

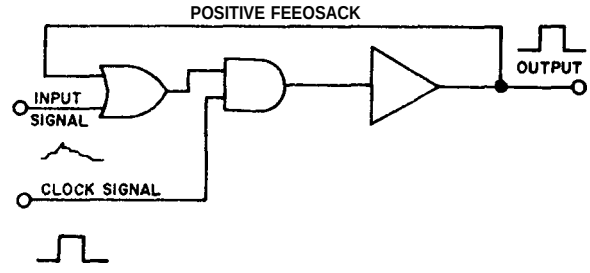
Uses four diodes and a transistor.

Uses positive feedback.

Employs a clock pulse for retiming.

Circuit Analysis

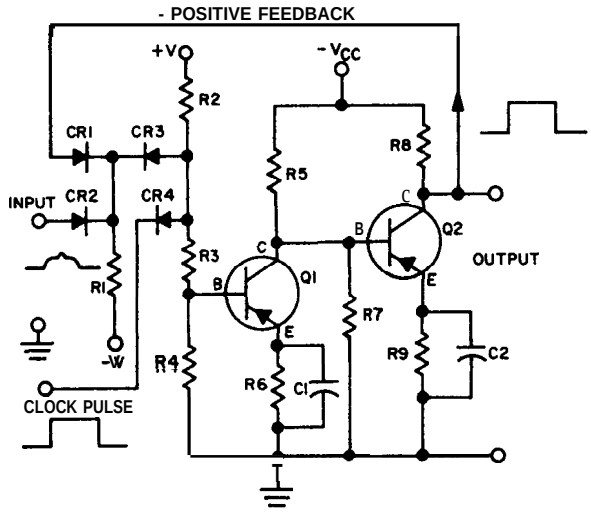
General. A general description of the retiming and reshaping circuit can be more easily understood by use of the following logic block diagram. As shown, the complete circuit consists of an OR circuit, an AND circuit, and a non-inverting amplifier stage.



Retiming and Reshaping Circuit Block Diagram

The input signal which is reshaped and retimed, is usually taken from a delay line. This input signal is applied to the OR circuit, and produces an OR output signal. The OR output signal is applied to the AND circuit together with a clock pulse of the proper frequency. The OR output signal normally arrives at the AND circuit input slightly before the clock input pulse. The AND circuit only produces an output when coincidence occurs between the OR output signal and the clock input signal. The output of the AND circuit is applied to a non-inverting amplifier, from which the output signal and a positive feedback voltage is obtained. The positive feedback voltage is applied to the OR input circuit, and causes any degeneration present in the other input pulse to be reduced so that the output of the OR circuit is a clean pulse.

Circuit Operation. The schematic of a typical retiming and reshaping circuit is shown in the following illustration. Diodes CR1 and CR2, together with resistor R1, form an OR circuit. Diodes CR3 and CR4, together with resistor R2, form an AND circuit. Resistor R3 couples the output of the AND circuit to the base of Q1, one of two transistors used in the non-inverting amplifier. Resistor R4 and R7 provide base bias for transistors Q1 and Q2. Resistors R6 and R9 are emitter stabilization resistors for Q1 and Q2, respectively. Capacitors Cl and C2 are emitter bypass capacitors. Resistors R5 and R8 are collector load resistors for Q1 and Q2.



Retiming And Reshaping Circuit

When no input is applied current flows from the negative supply source through R1 and through either or both diodes CR1 and CR2. The small current flow is just enough to drop the voltage at the junction of CR1, CR2, and R1 to zero volts, which is applied to the cathode of CR3. Since, when there is no input to CR3, current flows through CR3 and R2 due to the positive supply voltage applied to R2. The current flow is enough to drop the voltage at the junction of CR3, CR4, and R2 to zero volts, whether or not any pulses are applied to CR4. The voltage at the CR3, CR4, R2 junction is applied to the amplifier input; since this voltage is zero, there is no amplifier output.

When a positive pulse is applied to the anode of CR2, it increases current flow through resistor R1. During the period of increased current, the voltage developed at the junction of CR1, CR2, and R1 is positive and varies proportionally with the shape of the applied pulse.

The positive pulse developed at this junction is applied to the cathode of CR3, reverse biases the diode and prevents current from flowing through CR3. The output of the AND circuit is unaffected by this pulse, however, unless a positive pulse is also applied to CR4 at the same time. The pulses that are applied to CR4 are produced by a clock oscillator at a frequency which corresponds to the central timing frequency of the computer. If the input pulse at CR2 occurred at the proper frequency, it would occur at CR2 slightly before the clock pulse appears at CR4, so that by the time it also appears at CR3, it coincides with clock pulse applied to CR4. When they do coincide. the diodes are back-biased and current is prevented from flowing through R2, CR3, and CR4. The voltage at the junction of CR3, CR4, and R2 now rises to the positive supply voltage value (+ V), as long as both pulses coincide. The positive voltage at the CR3, CR4, and R2 junction, is coupled directly through resistor R3 to the base of Ql, and reduces the forward bias of Q1. As a result, the emitter to collector current of Q1 is reduced, current through collector resistor R5 is reduced, and the voltage at the collector of Q1 approaches the negative supply voltage. This negative-going voltage is directly applied to the base of Q2, and increases the forward bias of Q2. Hence, the emitter to collector current of Q2, increases and then increased collector current flows through R8. The increased current through R8 decreases the voltage on the collector of Q2, and develops a positive output swing. A portion of this output voltage is fed back to diode CR]. The feedback voltage reinforces the next input pulse if it is distorted. If the input pulse occurs at an improper frequency, only that portion of the pulse which occurs during the feedback pulse is reinforced. Timing is restored by the trailing edge of the clock pulse, which stops the AND gate output, and simultaneously ends the feedback pulse. In this way, the output pulse of the OR circuit, made up of CRl, CR2, and RI is assured of occurring at the proper frequency and being undistorted. This pulse then proceeds through the AND gate and the amplifier controlled by the clock pulse, as previously described during the application of the first input pulse. The resulting output of the retiming and reshaping circuit is a clean positive pulse occurring, at the proper frequency.

CURRENT STEERING GATE

Application.

The current steering gate is used in digital computers for gating serial counters, pulse steering networks, and for other gating applications.

Characteristics.

Two PNP type transistors are used.

The emitters of both transistors are coupled together.

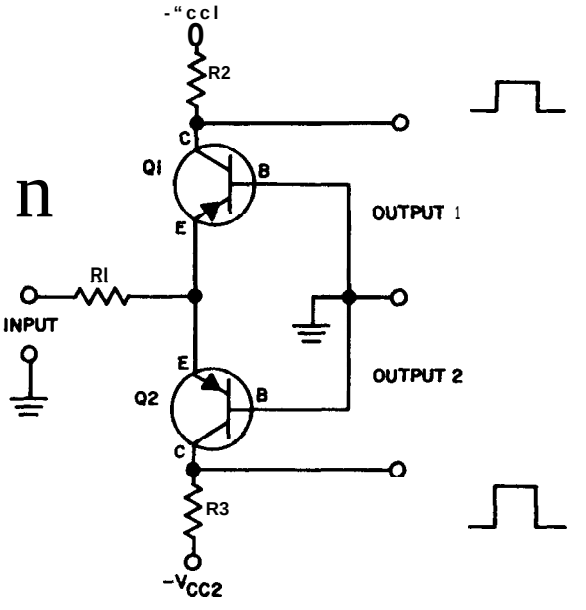
The bases of both transistors are grounded.

A single input may produce two outputs.

Circuit Analysis.

General. The current steering gate divides the current of the applied signal between two or more paths. The input signal is applied to the emitters of two or more transistors through a common emitter resistor. This allows for current division based on collector supply voltage of each transistor, and produces corresponding output voltages on the collectors of the transistors. The output can then be used to gate serial counters, steer pulses to required circuits, or provide other similar digital operations.

Circuit Operation. The schematic of a typical current steering gate is shown in the accompanying illustration. Resistor R1 is an emitter resistor common to both transistor Q1 and Q2. Resistors R2 and R3 are collector load resistors for Q1 and Q2, respectively. A positive square wave signal is applied at the input terminals, and is coupled to the emitters of Q1 and Q2 through emitter resistor R1. At this point, the current is divided between the two transistor paths in accordance with the two collector supply voltages and circuit resistances. If both collector supply voltage are equal and the circuit resistances are equal the division of current is rdso equal. In this case, it is assumed that the collector supply voltages are unequal. With the application of a positive square wave pulse, the forward bias of both transistors is increased. This causes the emitter to collector current of both transistors to increase, and the current through both collector load resistors to increase. The increase of current through the collector load resistors develops a large voltage drop across the two collector load resistors and thus, both outputs become more positive. The increase in the positive value of each output is not equal, since the collector supply voltages of each transistor are different.



Current Steering Gate

When the square wave input signal swings negative, the forward bias of the transistors is reduced. The emitter to collector currents are then reduced, and the currents through resistors R2 and R3 are reduced. The reduction of current flowing through the collector load resistors causes the collector and output voltages to approach the collector supply voltage values. These output voltages are different values, since the collector supply voltages are different values. Thus a single input signal may be used to supply two different control outputs of the same phase or polarity but of unequal amplitude.

DIODE - TRANSISTOR MATRIX SWITCH

Application.

The diode-transistor matrix switch is used in digital computer circuits to provide a single output, from any one of several available outputs, and to resolve any combination of more than one input.

Characteristics.

The switch consists of transistors, diodes, and resistors.

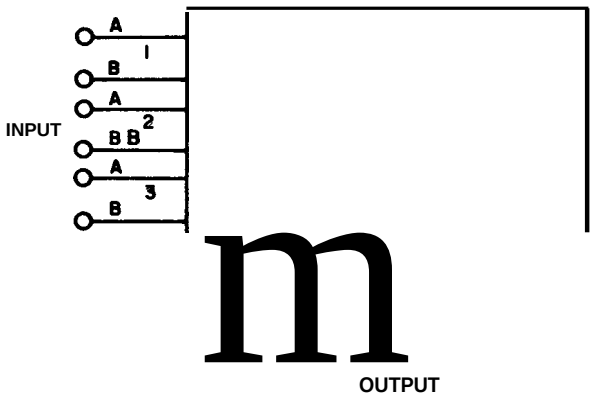
The diode provide switching action, and transistors, in emitter follower configuration, provide minimum reflection and maximum impedance match.

Positive and negative inputs are available from three sources.

Eight outputs are available.

Circuit Analysis.

General. The diode-transistor matrix switch resolves a specific set of input conditions by producing a logic 1 output at any one of eight outputs when the specific combination of input conditions exist. This concept can be seen from the following illustration.



Diode-Transistor Switching Matrix

In the illustration, the block represents the switching matrix, the lines to the left of the block represent input lines and the lines extending from the bottom of the block represent output lines. The input lines are divided into three pair of input groups, each pair (designated A and B) corresponds to two possible input states of either positive or negative signals. The eight outputs correspond to the eight possible output conditions which are shown in the following logic table, where logic 1 refers to positive pulses.

INPUT			OUTPUT							
0	2	3	1	2	3	4	5	6	7	8

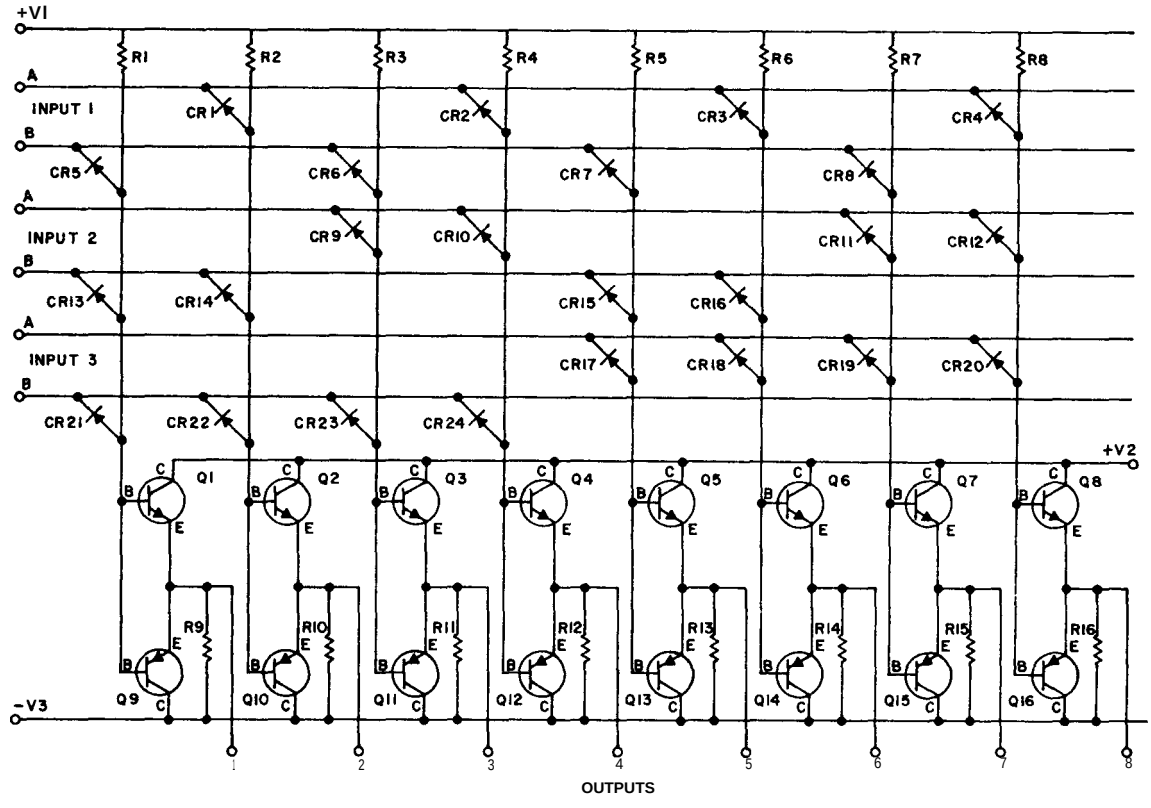
DIODE-TRANSISTOR SWITCHING MATRIX TABLE OF COMBINATIONS

Diode-Transistor Switching Matrix Table of Combinations

The fact that the block diagram there are two input lines for each group and in the logic table there is no separate line distinction for each input group, may appear contrasting. It is not, however, since in the logic table input numbers correspond to the A lines of each group.

Circuit Operation. The schematic of a typical diode-transistor matrix switch is shown in the accompanying Illustration. In the circuit resistors RI through R8 are load resistors for the diodes. The three diodes connected to each of the eight vertical lines are AND gates. CR5, CR13, and CR21 form the first AND gate; CR1, CR14, and CR22 form the



Diode-Transistor Matrix Switch

second AND gate; CR6, CR9, and CR23 form the third AND gate; CR2, CR1O, and CR24 form the fourth; CR7, CR15, and CR17 from the fifth AND gate; CR3, CR16, and CR18 form the sixth AND gate; CR8, CR11, and CR19, form the seventh AND gate, and CR4, CR12, and CR20 form the eighth AND gate. Transistors Q1 through Q16 form complementary emitter-follower circuits. Resistors R9 through R16 are emitter load resistors.

Assume that the first series of inputs are such that line A of input number 1 is a positive or logic 1 pulse, line B of input number 2 is a positive pulse, and line B of input number 3 is a positive pulse. The positive pulse applied to line A of input 1 prevents diodes CR1, CR2, CR3 and CR4 from conducting. The positive pulse applied to line B of input 2 prevents diodes CR13, CR14, CR] 5, and CR16 from conducting, and the positive pulse applied to line B of input 3 prevents diodes CR21, CR22, CR23, and CR24 from conducting. Diodes CR1, CR14, and CR22 are the only diodes connected to a common vertical line that are prevented from conducting. Diodes CR1, CR14, and CR22 remain reverse biased and no positive voltage applied from voltage +Vl is dropped across R2. The positive voltage from +Vl is, therefore, applied to the base of Q2 and Q1O. On the base of NPN transistor Q2 the positive voltage increases the forward bias and increases emitter current through emitter resistor R1O, leaving the emitter end of R1O positive. On the base of PNP transistor Q1O the positive voltage from supply +Vl decreases the forward bias and, since the transistor is already cutoff, no current flows through this transistor. As a result of the positive voltage appearing at the emitter end of R1O, then, a positive or logic 1 exists at output number 2.

On all of the other vertical lines, there is at least one conducting diode connected to each of these lines, because of the positive voltage that exists on

the anode of the diode and the lack of positive voltage that exists on the cathode. As a result, the positive voltage supply, Vl, is dropped across the series load resistor and the conducting diode, and the vertical line to which it is connected effectively swings negative. As this negative swinging voltage appears at the bases of the two transistors, neither transistor conducts, since the NPN transistor is effectively reverse-biased, and the PNP transistor is prevented from conducting because of the negative supply voltage, –V3, applied to reverse-bias the emitter. The –V3 supply voltage is not dropped across the emitter resistor and is, in effect, the output voltage. This equivalent to a logic O output.

Assume the second series of inputs are such that line B of input number 1 is a positive or logic 1 pulse, line A of input number 2 is a positive pulse, and line B of input number 3 is a positive pulse. The positive pulse applied to line B of input 1 prevents diodes CR5, CR6, CR7, and CR8 from conducting; the positive pulse applied to line A of input number 2 prevents diodes CR9, CR1O, CR11, and CR12 from conducting, and the positive pulse applied to line B of input number 3 prevents diodes CR21, CR22, CR23, and CR24 from conducting. In this case, diodes CR6, CR9, and CR23 are the only diodes connected to a common vertical line that are prevented from conducting. The load resistor in series with vertical line to which they are connected (R3) then, does not drop any of the positive voltage applied from voltage source +V. Hence, the positive voltage from +Vl appears at the base of Q3 and Q1 1. On the base of NPN transistor Q3 the positive voltage produces a forward bias, and produces emitter current flow through emitter resistor R11, making the emitter end of R1 1 swing positive. On the base of PNP transistor Q11 the positive voltage from +Vl decreases forward bias and, since the transistor is already cutoff causes no change in current through this transistor. As a result of the positive voltage swing appearing at the emitter end of R11, then, a positive or logic 1 exists at output number 3.

On all of the other vertical lines, there is at least one conducting diode connected to each of these lines, because of the positive voltage that exists on the anode. As a result, the positive supply voltage, V1, is dropped across the series load resistor by the conducting diode, and the vertical line to which it is connected becomes zero or effectively swings negative. As this negative voltage appears at the bases of the two emitter-follower transistors (one being a PNP transistor and the other being an NPN transistor) neither transistor conducts, since the NPN transistor is reversed biased and the PNP transistor cannot conduct because of the fixed negative reverse bias voltage, –V3, appearing at its emitter. The –V3 voltage is, in effect, the output voltage. This is equivalent to a logic *o* output.

Thus, a various inputs are applied, corresponding outputs are produced, representing either logic 1 or logic O, as described above, depending upon the input pulse combinations.

DIODE-TRANSISTOR FLIP-FLOP

Application.

The diode-transistor flip-flop produces logic 1 and logic O pulses to be used in digital computer circuits.

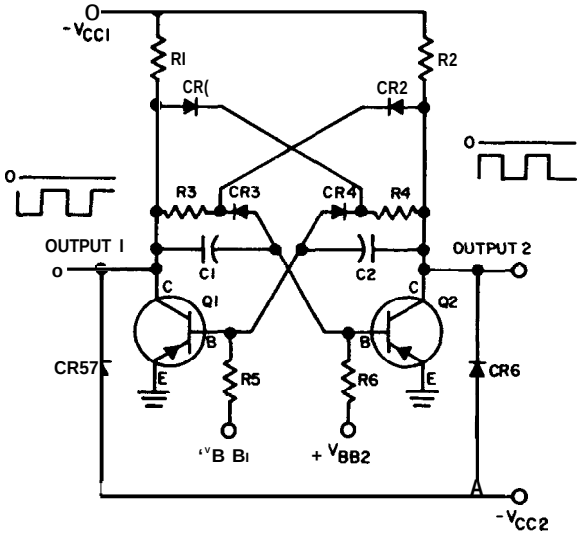
Characteristics.

Circuit is basically an astable multivibrator.
Uses two transistors and six diodes.
Uses diodes to provide faster operation.
Circuit provides two outputs of opposite polarity.

Circuit Operation.

General. The diode-transistor flip-flop, develops a logic 1 at one output and a logic O at the other output. One transistor conducts initially while the other is cut off. The greater conduction of one transistor holds the other transistor, at cut off until the pulse terminates. The second transistor is then driven into conduction, and the first transistor is cut off. Normally, this action continues until one transistor becomes saturated and the other transistor is cutoff; however, the diodes between the transistor prevents saturation of either transistor, and reduces the base recovery time, causing the conducting and non-conducting state of the transistors to occur more quickly.

Circuit Operation. The schematic of a typical diode-transistor flip-flop is shown in the accompanying illustration. In the circuit, resistors R1 and R2 are collector load resistors; resistors R3 and R4, along



Diode-Transistor Flip-Flop

with diodes CR3 and CR4, dc couple the collectors of transistors Q1 and Q2 to the bases of Q2 and Q1, respectively. Capacitors Cl and C2 ac couple the collector to the opposite base and provide a pulse switching action by which the flip-flop is automatically made to change state. Bias voltages $+V_{BB1}$ and $+V_{BB2}$ are applied to the bases of Q1 and Q2 through base bias resistors R5 and R6. Diodes CR5 and CR6 prevent either of the outputs from going highly negative by clamping them to the $-V_{CC2}$ potential.

Assume that transistor Q2 is initially in the conducting (logic 1) state and Q1 in the non-conducting (logic O) state, because of slight differences between the transistors and values of associated circuitry. Since Q2 is initially conducting, diode CR3 is conducting because of the high negative voltage on its cathode (the collector voltage of Ql) and the low negative voltage on its anode (Q2 base is near zero since the emitter to base drop is small). The negative supply voltage $-V_{cc}$ is applied across C1 to the base of Q2, providing a negative pulse to forward bias Q2. As the collector voltage drops across R2 it eventually reaches a low negative value which permits diode CR2 to conduct, and prevents Q2 from saturating. By using a silicon diode for CR3 and a germanium diode for CR2 the collector of Q2 is kept at a negative 0.2 volt value, and cannot saturate (go positive). During the steady state, capacitor Cl charges toward the negative collector supply voltage value, and gradually reduces the forward bias pulse on the base of Q2. By the time that capacitor Cl is almost fully charged, the forward bias of Q2 is reduced sufficiently to allow the fixed reverse bias V_{BB2} t. assume control and cut off Q2. When Q2 is cut off, collector current ceases to flow through resistor R2, and no voltage is dropped across resistor R2. The collector voltage of Q2 then rises toward the value of $-V_{cc}$, but is clamped to the value of $-V_{CC2}$ when the cathode of CR6 becomes more negative than the anode. As a result diode CR2 stops conducting. The negative pulse produced by the rising collector voltage of Q2 is coupled to the base of Q1 through coupling capacitor C2. The negative pulse voltage applied to the base of Q1 overcomes fixed bias $+V_{BB1}$ and forward biases Q1. Hence the base current and collector current increases. The large collector current flow through resistor RI produces a large voltage drop across R1, leaving the collector of Q1 at some small negative value. Q1 is prevented from going into saturation, however, when the collector voltage of Q1 falls sufficiently to allow diode CR1 to conduct and shunt some of the base drive current through diode CR4 to the collector of Q1. This constitutes the other steady state of the flip-flop, where Q1 is conducting heavily (logic 1 output at the collector of Ql), and Q2 is not conducting (logic O output at the collector of Q2).

During this steady state, capacitor Cl discharges through diode CR3 and resistor R3. At the same time, capacitor C2 is charging toward negative supply voltage $-V_{CC1}$ through resistor R5. As C2 charges, the forward bias of QI is gradually reduced. By the time capacitor C2 is almost fully charged, the forward bias of Q1 is reduced sufficiently to cause Q1 to be cut off. As a result, base current, collector current through resistor RI, and the voltage drop across RI cease. The potential of the collector of Q1 then rises toward the negative collector supply voltage value and is clamped to the value of V_{CC2} by CR5. The negative collector voltage appears across resistor R3, diode CR3, and the base of Q2, and the sharp collector negative pulse is coupled by capacitor Cl to the base of Q2. This large negative pulse voltage forward biases Q2 so that collector current flow through resistor R2 produces a voltage drop across R2. The collector voltage of Q2 falls to a very small negative value, which is sufficiently positive with respect to

$-vCcl$ to cause diode CR2 to conduct. As CR2 conducts, the base current of Q2 is shunted to the collector of Q2 through CR2, and prevents sufficient base drive to cause saturation. This is again the original steady state condition where Q2 is conducting heavily (logic 1 output at the collector of Q2), and Q1 is not conducting (logic O output at the collector of Ql).

During this steady state, capacitor C2 discharges through diode CR4 and resistor R4. At the same time, capacitor Cl charges to the negative supply voltage $-V_{ccl}$ through resistor R6. As capacitor C1 becomes charged, the cycle repeats resulting in a steady state where Q1 is again conducting heavily, and Q2 is not conducting. Note that when the switching action occurs it is regenerative, with the collector of one transistor feeding back a forward biasing pulsing to the other base. Thus a fast rising and sharp switching pulse is produced. By preventing the delay normally caused by saturation, and restricting the range of operation to lower levels, faster operation is obtained.

PART 16-4. COUNTERS

LOGIC COUNTERS (GENERAL)

Logic counters use appropriately connected logic flip-flops and logic gates which perform binary or decimal counting functions. The gates and flip-flops in the form of logic counters are used in digital computers to regulate digital operating sequences, and to facilitate interpretation and recording of binary or decimal information.

The counters can be classified according to their function, according to the manner in which they are connected, and according to the manner in which they store numbers. In the first category, counters are classified as up-(or forward) counters if they are made to increase in count for every applied pulse; as down-(or reverse) counters if they are made to decrease linearly in count for every applied pulse, and as combination up-down (reversible, or bilateral) counters if for every pulse applied to an input the count increases and for every pulse applied to another input the count decreases. In the second category, counters are classified as serial counters if the gates and flip-flops comprising the counter are connected in series; or as parallel counters if the gates and flip-flops comprising the counter are connected in parallel. In the third category, counters are classified as binary counters if the counter stores binary numbers, as a decimal counter if the counter stores decimal numbers, or as a binary-coded decimal digit counter if the counter stores decimal numbers in binary code.

The operational counter, ring counter, and decimal counter are described in the following paragraphs to describe typical counter operation. Various combinations of these basic circuits may be found in different computers.

OPERATIONAL COUNTER

Application.

Operational counters are used in digital computers to produce a desired output sequence regardless of the sequence of input pulses. They may be used to count only even numbers, every other number, or some specific combination thereof.

Characteristics.

A three-stage operational counter consists of three flip-flops, four AND gates and an OR gate.

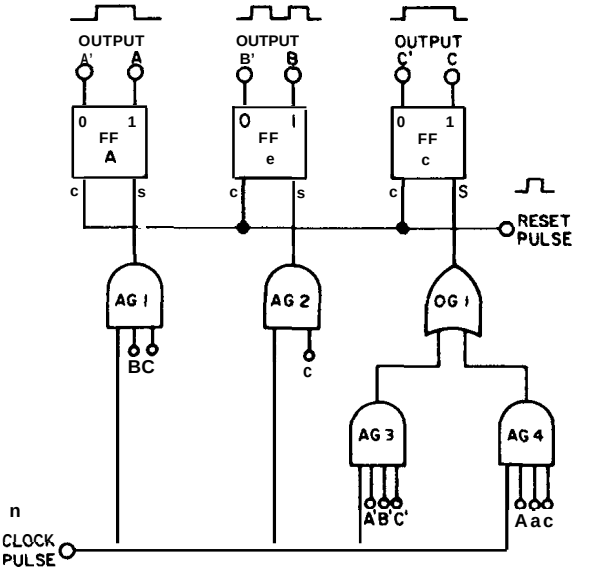
An external clock pulse is used to control the output.

An external reset pulse is used to set the flip-flops to their initial state.

Circuit Analysis.

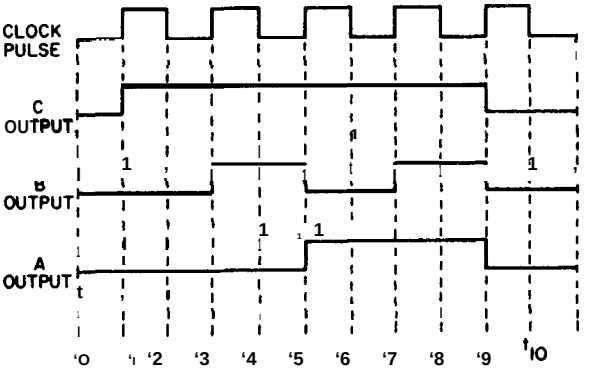
General. The operational counter uses logic flip-flops as bi-stable output elements, and both AND gates and OR gates to control the desired output sequence, depending upon the connection of these logic circuits in relation to each other, and in relation to the output flip-flops. The control gates and flip-flops may be arranged to produce a sequence to consecutively increasing even numbers with the aid of a clock pulse. The pulse width of the clock pulse determines how rapidly the counting sequence occurs, and the number of flip-flop elements determines the highest number that can be produced before the sequence begins again.

Circuit Operation. A block (logic) diagram of the operational counter is shown in the accompanying illustration.



Operational Counter

The counter uses three bi-stable elements, flip-flop A, flip-flop B, and flip-flop C, to produce either logic 1 or logic O outputs. Each flip-flop has a set input (S) actuated by pulses from the preceding AND or OR gate, and each flip-flop has a clear input (C) actuated by a reset pulse. The counter uses four AND gates, AG1, AG2, AG3, and AG4 to provide a gating (S) pulse to the corresponding flip-flop, when all inputs are applied to the proper AND gate. One OR gate, OG1, is used to trigger flip-flop C by either AG3 or AG4. None of the AND gates can be activated until a clock pulse is simultaneously applied. If the counter must be placed in its initial state at any time during the sequence, a reset pulse must also be applied. The outputs of the flip-flops are applied to the inputs of the AND gates together with the clock inputs.



Operational Counter Waveform Chart

The counter initially rests in a stable state where outputs A, B, and C are logic O, and outputs A', B', and C', are at a logic 1. This corresponds to time t. shown in the preceding operational counter waveform chart. The overall output at time t. is then 000, corresponding to the A, B, and C outputs.

At time t_1 a logic 1 clock pulse is applied. This logic 1 pulse complements the A', B', and C' logic 1 pulses at the inputs of AND gate No. 3. As a result, AND gate No. 3 develops a logic 1 output, which in turn provides a logic 1 input to OR gate No. 1. In turn, OR gate No. 1 produces a logic 1 output, which changes the state of flip-flop C; the C output is now a logic 1, and the C' output is now a logic O. Since the A, B, and C outputs of the flip-flops previously were at logic O, none of the inputs to AND gates Nos. 1,2, " and 4 (except the clock and C pulse) are at logic 1. The outputs of these AND gates, thus, are a logic O and do not produce any further change of state in the flip-flops. Flip-flops A and B provide a logic O at outputs A and B, and provide a logic 1 at outputs A' and B'. The overall output at time t_1 is then 001.

At time t_2, the clock pulse returns to logic O, and flip-flop C remains at 1, eliminating any possibility of supplying all logic 1 inputs to the AND gates. Hence, the output remains at 001.

The clock pulse again becomes a logic 1 at time t_3. This logic 1 pulse is complemented by the logic 1 C-output of flip-flop C at the input of AND gate No. 2. With all logic 1 pulses at the input of AND gate No. 2, AND gate No. 2 develops a logic 1 output, which is applied to the input of flip-flop B and causes flip-flop B to change state. The B output of flip-flop B is now a logic 1; the B' output of flip-flop B is now a logic O. Each of AND gate Nos. 1, 3, and 4, however, do not have all logic 1 inputs; therefore, the logic 1 clock pulse does not cause logic 1 pulses to be developed at the output of these AND gates. Consequently, flip-flop A remains in the initial state, and OR gate No. 1 is not activated to change the state of flip-flop C. Hence, the A output of flip-flop A is still a logic O, and the A' output of flip-flop A is still a logic 1; the C output of flip-flop C is still a logic 1, and the C' output of flip-flop C is still a logic O. The overall output of the counter at time t_3 then is011.

At time t_4 the clock pulse again returns to logic 0. As a result, none of the flip-flops change state, and the output remains at011.

When the clock pulse again becomes logic 1 at time t_5, AND gate Nos. 1 and 2 are provided with all logic 1 pulses. Since AND gate No. 1 has the logic 1 clock pulse applied together with a logic 1 pulse from the B output of flip-flop B and a logic 1 pulse from the C output of flip-flop C, AND gate No. 1 develops a logic 1 output, which causes flip-flop A to change state. The A output of flip-flop A now becomes logic 1, and the A' output of tlip-flop A now becomes logic O. Since AND gate No. 2 has the logic 1 clock pulse applied, and a logic 1 pulse from the C-output of flip-flop C, AND gate No. 2 then develops a logic 1 output, which is applied to flip-flop B, causing it to change state. The B-output of tlip-flop B now is a logic O, and the B' output of flip-flop B now is a logic 1. On the other hand, AND gates Nos. 3 and 4 do not

have all logic 1 pulses applied, and cannot develop logic 1 outputs. As a result, no inputs are applied to OR gate No. 1 and it cannot develop a logic 1 output to change the state of flip-flop C. The C-output of flip-flop C then remains at logic 1, and the C' output of flip-flop C remains at logic O. At t_5, then, the overall output of the counter is 101.

At time t_6 the clock pulse returns to a logic O, and there is no change in state of the flip-flops. The output therefore remains at 101.

At time t_7 a logic 1 clock pulse is again applied. AND gate No. 2 is provided with all logic 1 pulses, the logic 1 clock pulse, and a logic 1 pulse from output-C of flip-flop C. As a result AND gate No. 2 develops a logic 1 output, which causes flipflop B to change state. The B-output of flip-flop B now is a logic 1, and the B' output of flip-flop B now is a logic O. However, AND gate Nos. 1, 3, and 4 are not provided with all logic 1 inputs, since AND gates Nos. 1 and 4 require a logic 1 from the B output of flip-flop B, which is not at logic O, while AND gate No. 3 requires a logic 1 from the A' output of flip-flop A, which is now logic O, and a logic 1 from the C' output of flip-flop C, which is also a logic O. As a result, the logic O output of AND gate No. 1 prevents flip-flop A from changing state; the A output of flip-flop A remains a logic 1, and the A' output of flip-flop A remains logic O. As a result of the logic O output of AND gate Nos. 3 and 4, OR gate No. 1 is not provided with a single logic 1 input and, therefore, cannot develop a logic 1 output. Flip-flop C therefore remains in the same state, a logic 1 pulse from the A output of flip-flop A and a logic O from the A' output of flip-flop A. The overall output at time t_7 is then 111.

At time t_8 the clock pulse ends and the AND gates cannot be activated. The output thus remains at 111.

The application of a clock pulse at time t_9 provides activation of AND gate Nos. 1, 2, and 4, since, all other inputs to these AND gates are a logic 1. Each of the AND gates then produces a logic 1 output, which causes flip-flops A and B to change states, and causes OR gate No. 1 to develop a logic 1 output, which changes the state of flip-flop C. Flip-flop A develops a logic O at output A and a logic 1 pulse at output A'; flip-flop B develops a logic Oat output B and a logic 1 pulse at output B', and flip-flop C develops a logic O at output C and a logic 1 at output C'. The overall counter output at time t_9 is 000, the same as the overall output of the first sequence. This is the beginning of the next sequence of operation, which repeats in the same order described previously.

RING COUNTER

Application.

Ring counters are used in digital computers to produce a progressive binary logic output. Each consecutive stage triggers the next stage to produce a logic 1 output, and all other stages produce logic O outputs. This property of ring counters provides sequential time relationships for use with other circuitry.

Characteristics.

Counter consists of several flip-flop stages.

Delay lines separate adjoining flip-flops.

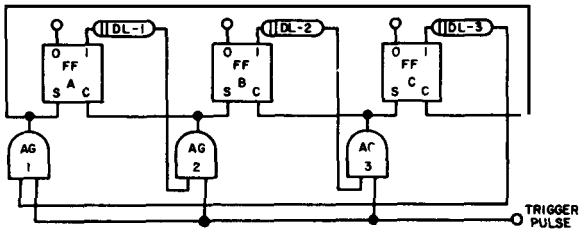
A common external pulse is applied to each flip-flop stage.

The output of the final stage is fed back to the input of the first flip-flop stage through a delay line.

Circuit Analysis.

General. A ring counter consists of a series of flip-flops, with each output connected to the input of the following flip-flop. The output of the last flip-flop is fed back to the input of the first stage flip-flop. Each flip-flop also receives a triggering pulse directly from an external triggering source. The triggering pulse, however, does not trigger each flip-flop, since the direct connection between stages restricts the action (change of state) of all but one flip-flop. The change of state of the one flip-flop when set into action by the triggering pulse establishes a logic 1 output; the same set-pulse causes the preceding flip-flop to be reset to logic O. After the last stage has been set to the logic 1 state, the subsequent trigger pulse will reset this stage to logic O and again set the first stage to logic 1, which starts the next counting sequence.

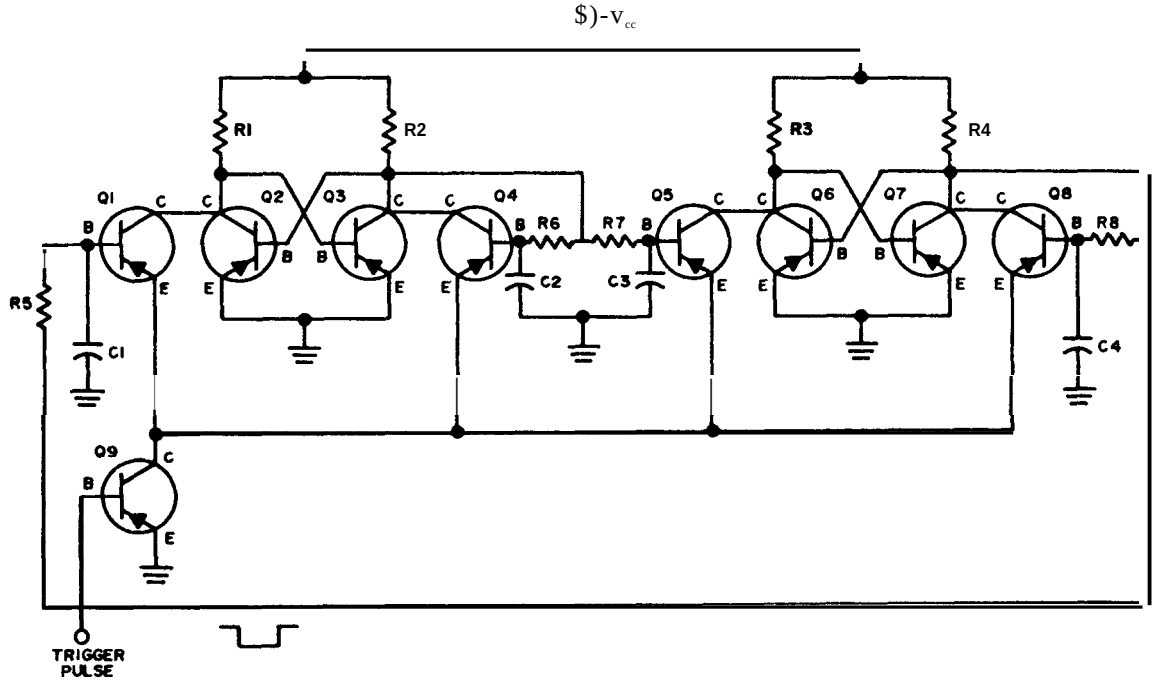
The logic diagram of a three stage ring counter is shown in the accompanying illustration. Three flip-flops, flip-flop A, flip-flop B, and flip-flop C, are bistable elements.



Three-Stage Ring Counter Scheinatic Program

Three AND gates, AND gate No. 1, AND gate No. 2, and AND gate No. 3 produce pulses which trigger the proper flip-flop to a logic 1 state, and reset the preceding flip-flop to a logic O state. Delay lines, DL-1, DL-2, and DL-3, retard the logic 1 output of the corresponding flip-flop from appearing at the input of the associated AND gate until a subsequent trigger pulse appears at the other AND gate input one bit later.

Circuit Operation. The schematic diagram of a two stage ring counter is shown in the accompanying illustration. Transistors Q2 and Q3, and Q6 and Q7 are flip-flop transistors. Transistors QI, Q4, Q5, and Q8 are AND gate transistors. Transistor Q9 is a trigger input transistor which complements each of the AND



Two-Stage Ring Counter Schematic Program

gate transistors to provide the AND function. Resisters R1, R2, R3, and R4 are collector load resistors. Resistors R5, R6, R7, and R8 provide base bias for the AND gate transistors and provide a time constant for the charging of capacitors Cl, C'2, C3, and C4. These capacitors provide a delay between the output of the flip-flops and the inputs to the next flip-flops and also provide a delay between the output of the flip-flops and the reset pulses.

Assume that a negative pulse appears at the base of Q1 at the same time a negative trigger pulse appears at the base of trigger input transistor Q9. Both Q1 and Q9 are forward biased by the negative voltage, and both transistors conduct. The collector current of

transistor Q1 flows through collector load resistor, RI, of Q1 and Q2, and produces a voltage drop across RI; thus, the collectors of Q1 and Q2 are left at O volts. The O voltage level at the collector of Q2 appears at the base of Q3, causing Q3 to be reverse-biased to cutoff. No collector current then flows through resistor R2, and no voltage is dropped across R2. The voltage at the collector of Q3 then rises to the negative collector supply voltage. This represents a logic 1 output of the first flip flop stage, while the second stage is in the logic O state. The negative supply voltage also appears at the collector of Q4, and at the junction of resistors R6 and R7. The negative collector supply voltage is immediately dropped across resistors R6 and R7 by the charging current to capacitors C2 and C3 so that the bases of Q4 and Q5 are at zero voltage level, biasing the transistors to cutoff. Capacitor C2 charges at a time constant rate equal to the value of resistor R6 times the capacitor value. As C2 charges, the voltage drop across it increases, and, at the same time the voltage drop across resistor R6 decreases gradually, and causes the forward bias on the base of Q4 to gradually increase. The RC combination acts as a delay line (DL1 in the logic diagram) for one trigger pulse. Capacitor C3 also charges to the negative supply voltage at a time constant rate equal to the resistance value of resistor R7 times the capacitance value of C3. The charging time constant of C3 is equal to the charging time constant of C2 (and is a part of delay line DL1). As C3 is charged, transistor Q5 is forward biased. When C2 and C3 are fully charged, forward biasing transistors Q4 and Q5, a negative trigger pulse occurs, forward biasing transistor Q9. The simultaneous forward biasing of transistors Q9 and Q4, and the simultaneous forward biasing of transistors Q9 and Q5 permits the three transistors, Q9, Q4, and Q5, to conduct, since there are two complete current paths: from the negative supply voltage source, 'V_{cc}, through collector load resistor R2, through transistor Q4, and through transistor Q9 to ground; and, from the negative supply voltage source, $-V_{cc}$, through collector load resistor R3, through transistor Q5, and through transistor Q9 to ground.

The current which flows through Resistor R2 produces a voltage drop across R2, causing the collector of Q3 and the base of Q'2 to be at zero volts. The zero volts on the base of Q2 reverse biases Q2, so that Q2 is cutoff. There is then no current flow through resistor RI and no voltage drop is developed across resistor R1. The collector of Q2 then rises to the negative supply voltage value; the base of Q3 is, thus, also at the negative supply voltage value. Hence, the base of Q3 is forward biased, causing Q3 to conduct. Even after the negative trigger pulse is removed and there is no further current path for transistor Q4, the voltage at the collector of Q3 is maintained at zero volts, since the collector current of Q3 develops a voltage drop across resistor R2. This state of the flip-flop represents a logic O output from this stage.

The current which flows through resistor R3, when the trigger pulse is applied, produces a voltage drop across R3, causing the collector of Q6 and the base of Q7 to be at zero volts. The zero volts at the base of Q7 reverse biases Q7 so that Q7 is cutoff. Because of this, no current flows through resistor R4 and no voltage is dropped across R4. The collector of Q7 then rises to the negative supply voltage value, placing the base of Q6 also at the negative supply voltage value. In this case, the base of Q6 is forward biased, so that Q6 will conduct and produce a current path through resistor R3, even after the negative trigger pulse is removed. The voltage at the collector of Q6 is thus maintained at zero volts. The zero volts at the collector of Q6 and the negative supply voltage at the collector of Q7 represent a logic 1 output of this second stage. With the application of the second trigger pulse, then, the first stage is brought to a logic O state from a logic 1 state, and the second stage is brought to a logic 1 state from a logic O state. (If additional stages were used, they would also be in the logic O state.)

During and after the application of the second triggering pulse, the negative collector supply voltage at the collector of Q7 is dropped across resistor R8 and resistor R5, so that the bases of Q8 and Q1 are at a zero potential, reverse biasing Q8 and Q1 to cutoff. Capacitors C4 and Cl then charge toward the negative supply voltage value through resistors R8 and R5. This R-C combination acts as delay line DL2 in the logic diagram, since no third stage is shown in the schematic. As capacitor C4 becomes charged the base of Q8 becomes forward biased, and as capacitor Cl becomes charged the base of Q1 becomes forward biased. With the application of the next negative trigger pulse, Q9 is forward biased. The simultaneous forward biasing of transistors Q9 and Q1, and the simultaneous forward biasing of Q9 and Q8 permits the three transistors (Q9, Q], and Q8) to conduct, since there are two complete current paths. One path

is from the negative collector supply voltage source, -Vcc , through collector load resistor R1, through transistor Q1, and through transistor Q9 to ground; and the other path is from the negative supply voltage source, $-V_{cc}$, through collector load resistor R4, through transistor Q8, and through transistor Q9 to ground.

The current flowing through resistor RI develops a voltage drop across R1, causing the collector of Q2 and the base of Q3 to be at zero volts. The zero volts bias at the base of Q3 reverse biases Q3 to cutoff. No current flows through resistor R2, and no voltage drop appears across resistor R2. The collector of Q3 rises to the negative supply voltage value, and the base of Q2 is also at the negative supply voltage value. Thus, the base of Q2 is forward biased, causing Q2 to conduct heavily. The voltage at the collector of Q2 is maintained at zero volts, since the collector current of Q2 develops a voltage drop across resistor R1, even after the trigger pulse is ended and there is no further current path for Q1. This flip-flop state represents a logic 1 output.

The current which flows through resistor R4, when the trigger pulse is applied, produces a voltage drop across R4, causing the collector of Q7 and the base of Q6 to be at zero volts. The zero volts bias at the base of Q6 reverse biases Q6 to cutoff. As a result, no current flows through collector resistor R3 and no voltage drop appears across R3. The collector of Q6 rises to the negative supply voltage value, placing the base of Q7 also at the negative supply voltage value. The base of Q7 is forward biased and conducts, producing a current path through resistor R4, even after the end of the negative trigger pulse. The voltage at the collector of Q7 is maintained at zero volts. The zero volt collector voltage of Q7, and the negative collector supply voltage at the collector of Q6 represents a logic O output of the second stage. With the application of the third trigger pulse, then, the first stage is brought to a logic 1 state from a logic O state, and the second stage is brought to a logic O state from a logic 1 state, and the cycle described above now repeats. (If three stages were used)as shown in the logic diagram), the third stage would have been driven to a logic 1 state, and stages 1 and 2 would be at logic O.)

DECIMAL COUNTER

Application.

The decimal or decade counter is used in digital circuitry to count the numbers 1 through 9 (the base 10 system) in binary form. The tenth pulse resets the counter to zero.

Characteristics.

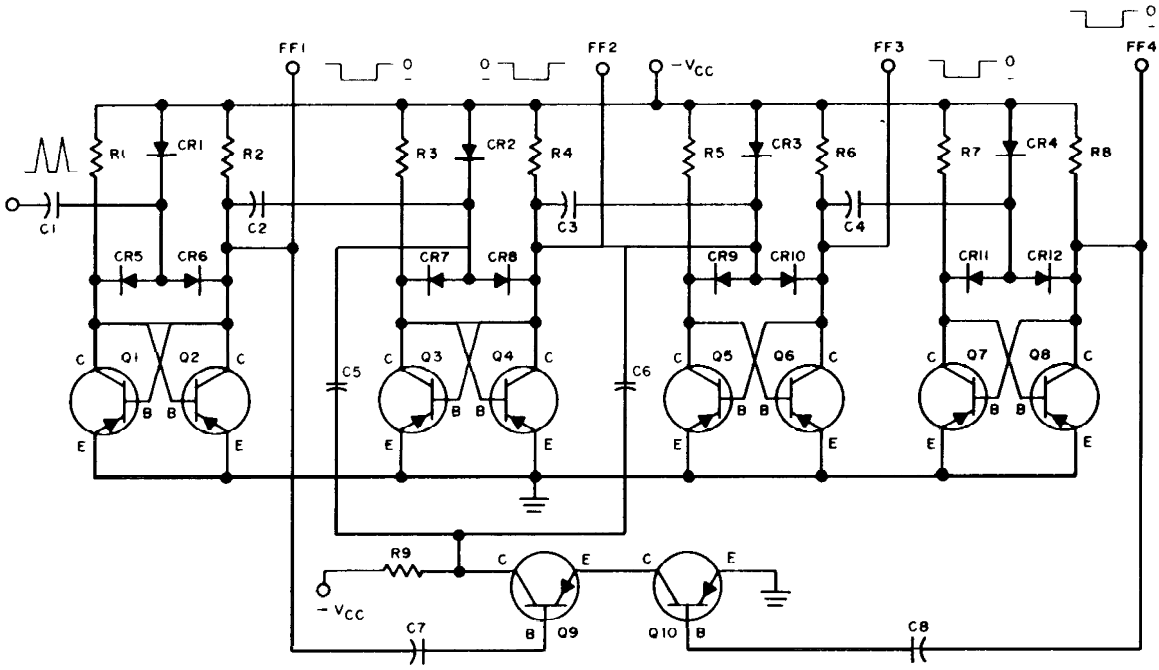
Four flip-flop stages are required.
PNP transistors are used.
Diode steering is used to trigger the flip-flops.
Flip-flops are capacitively coupled.
The scale of the counter changes from 16 to 10.
Counter is reset to zero by the IOth input pulse.

Circuit Analysis.

General. The decimal or decade counter counts binary numbers sequentially up to a decimal equivalent of the number 9 (at the count of 10 the counter is reset to zero). This is accomplished by capacitively coupling a series of four flip-flops to perform the counting function and providing feedback to two stages to prevent the decimal equivalent count from increasing to a value more than 10, since the binary count with four flip-flops would normally be 15 when all are at logic 1. The counting process occurs when positive trigger pulses are applied through diodes to the collectors and directly coupled to the opposite bases of the flip-flop transistors. Each trigger pulse causes the first flip-flop to change state; every other trigger pulse causes the second flip-flop to change state; every fourth trigger pulse causes the third flip-flop to change state; and, every eighth pulse causes the fourth flip-flop to change state. When the fourth flip-flop and the first flip-flop are triggered on, or when the equivalent to the decimal number 9, their logic 1 output pulses supply two inputs to an AND gate. The output of the AND gate trigger the second and third flip-flop stage so that they also produce logic 1 outputs. This allows the next trigger

pulse to change the states of all flip-flop stages to logic O and renew the counting cycle at the IOth trigger pulse.

Circuit Operation. The schematic of a typical decimal counter is shown in the following illustration. Transistors Q1 and Q2, Q3 and Q4, Q5 and Q6, Q7 and Q8 form four flip-flop stages. Transistors Q9 and Q1 O are series AND gate transistors, which apply feedback to the second and third stage. Diodes CR1, CR2, CR3, and CR4 prevent negative triggering of the flip-flops, and diodes CR5 and CR6, CR7 and CR8, CR9 and CR1O, together with diodes CR11 and CR12, are steering diodes for the flip-flops, which permits the trigger voltage to change the state of the flip-flops. Capacitors Cl, C2, C3, and C4 couple trigger pulses to each flip-flop stage; capacitors C5 and C6 couple the AND gate feedback voltage to the input of the second and third flip-flop stage; and capacitors C7 and C8 couple the outputs of the first and fourth flip-flop stages to the series AND gate transistors Q9 and Q1O. Resistors R1 through R9 are collector load resistors.

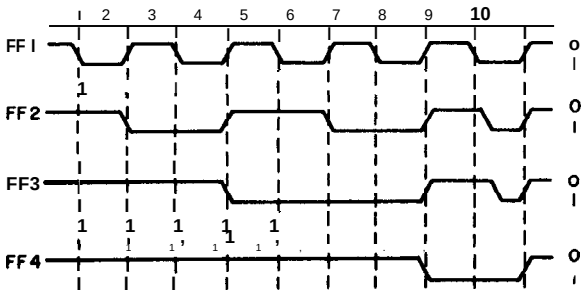


Decimal Counter

If, initially, all of the flip-flops are in a logic O state transistors Q 1, Q3, Q5, and Q7 are not conducting, and transistors Q2, Q4, Q6, and Q8 are conducting. When a positive pulse is applied to the trigger input, it is coupled through capacitor Cl to forward bias diode CR5. Since the cathode of CR5 is connected to a negative voltage, the diode conducts. The positive trigger pulse is applied to the collector of Q1 (which forward biases Ql), and is also fed directly to the base of Q2. Transistor Q2 is thus reverse-biased stopping collector current flow, and causing the collector voltage of Q2 and the base voltage of Q1 to rise toward the negative collector supply voltage. Transistor Q1 is then forward-biased and conducts. The collector current of Q1 develops a voltage drop across R1, which drops the collector voltage of Q1 to zero. Thus, a logic 1 negative output is obtained from the first stage flip-flop at transistor Q2. The negative voltage swing at the collector of Q2 is coupled to the next flip-flop stage through capacitor C2. Since the negative pulse is provided with a current path through diode CR2, it is absorbed by the supply, but diodes CR7 or CR8 will not conduct with a negative anode potential. As a result, the second, third, and fourth

flip-flop stages are not triggered and do not change state. The counter output after one trigger pulse is then a logic 1 from the first stage, anda logic O from the remaining stages. The output is read as 001, which is equivalent to the decimal number 1.

The accompanying waveform chart shows the relationship of the input and output waveforms for the sequence of operation described in the following paragraphs.



Waveform Chart

When the second positive trigger pulse is applied to the trigger input diode CR6 conducts and drives the collector of Q2 and the base of Q1 positive. The positive voltage pulse on the base of Q1 reverse-biases Q1 to cutoff, no collector current flows through resistor R1 and no voltage drop appears across R1. The voltage at the collector of Q1 then rises to the negative supply voltage value. This negative collector voltage also appears at the base of Q2, and increases the forward bias of Q2. Transistor Q2 now conducts heavily and collector current flows through resistor R2, producing a voltage drop across R2. The voltage at the collector of Q2 now swings positive rising to the zero voltage level. The first stage flip-flop output at FF1 is now at logic O. The positive voltage swing at the collector of Q2, however, is coupled across capacitor C2 to the junction of diodes CR2, CR7, and CR8. Diode CR2 does not conduct because the positive voltage reverse biases the cathode; diode CR8 does not conduct because the zero collector voltage of Q4 appears at the cathode of CR8 and no potential appears across the diode. Diode CR7, however, conducts, since the negative collector supply voltage at the collector of Q3 is applied to the cathode of CR7 and forward biases the diode.

When diode CR7 conducts, the positive voltage swing from the collector of Q2 forward biases the collector of Q3 and reverse biases the base of Q4. Transistor Q3 conducts and Q4 is thus biased to cutoff. The collector voltage of Q4 then rises to the negative collector supply voltage value and supplies a logic 1 output at FF2. This negative voltage is also fed back to the base of Q3, further biasing Q3 into conduction. Saturation current flows through collector load resistor R3, and drops the collector voltage. The collector voltage of Q3 then swings positive toward the zero voltage level. The negative voltage rise at the collector of Q4 is coupled to the next stage through capacitor C3, and this negative pulse is absorbed by the supply as diode CR3 conducts. Since the anodes of diodes CR9 and CR1O are reverse biased, the third and fourth stages are not triggered and no not change state. The output after two trigger pulses is a logic O from the first stage, a logic 1 from the second stage, and logic O from the third and fourth stages. The output is read as 0010, which is equivalent to the decimal number 2.

When a third positive trigger pulse is applied to the trigger input, diode CR5 conducts and drives the collector of Q1 and the base of Q2 positive. The positive voltage on the base of Q2 reverse-biases Q2 to cutoff. No collector current flows through R2 and no voltage drop is produced across resistor R2. The voltage at the collector of Q2 then rises to the negative supply voltage value. This negative voltage also appears at the base of Q1, causing the forward bias of Q1 to increase. Transistor Q1 then conducts, and collector current flows through resistor R1, producing a voltage drop across RI. The voltage at the collector of Q1 is now at the zero voltage level, and the first stage flip-flop now produces a logic 1 output at FF1. The negative voltage rise at the collector of Q2 is coupled to the second flip-flop stage through capacitor C2, and is absorbed by the supply as CR2 conducts. Since diodes CR7 and CR8 are reverse-biased and do not conduct, the second, third, and fourth flip-flop stages do not change state. Because the second flip-flop still remains in the 1 state, the output after the third trigger pulse is then a logic 1 from the first and second stages, and logic O from the third and fourth stages. This output is read as 011, which is equivalent to the decimal number 3.

A fourth positive trigger pulse, similarly, causes the first stage flip-flop to change state from logic 1 to

logic O. The positive voltage swing at the collector of Q2 is coupled across capacitor C2, through diode CR8 to the collector of Q4 and the base of Q3, resulting in the negative collector supply voltage appearing at the collector of Q3 and zero voltage appearing at the collector of Q4 and at output FF2. This represents a logic O output from the second flip-flop. The positive voltage swing produced at the collector of Q4 is coupled across capacitor C3, through diode CR9 to the collector of Q5 and the base of Q6. As a result, Q6 is cutoff and Q5 is driven into saturation. The voltages at the collector of Q5 is now zero and the voltage at the collector of Q6 rises to the negative supply value. This represents a logic 1 output from the third stage flip-flop at FF3. Since the collector of Q6 is at a negative voltage, there is no positive pulse generated by the collector of Q6 to drive the next flip-flop stage. The fourth stage thus remains in the initial logic O output state. The output after the fourth trigger pulse is a logic O from the first, second, and fourth flip-flop stages, while the third flip-flop is in the logic 1 state. This output is read as 0100, which is equivalent to the decimal number 4.

When a fifth positive trigger pulse is applied, it causes the first stage flip-flop to change state from logic O to logic 1. None of the other stages change state, however, since the collector voltage swing of Q2 is negative and will not drive the second flip-flop stage. The output after the fifth trigger pulse is a logic 1 from the first and third stages, and a logic O from the second and fourth stages. This output is read as 0101, which is equivalent to the decimal number 5.

The first stage flip-flop again changes state when the sixth positive trigger pulse is applied. The change of state from a logic 1 to a logic O of the first flip-flop causes a positive voltage swing to be developed at the collector of Q2. This positive pulse voltage is coupled through capacitor C2 and through diode CR7, to the collector of Q3 and the base of Q4. Consequently Q4 is cutoff and the collector voltage of Q4 rises to the negative supply value. Meanwhile, Q3 becomes saturated causing zero voltage to appear on the collector of Q3. Thus, a logic O output is produced by the second state at FF2. This negative output voltage on the collector of Q4 will not drive the third flip-flop stage, so the following flip-flop stages do not change state. The output after the sixth trigger pulse is a logic O from the first and fourth stages, and a logic 1 from the second and third stages. This output is read as 0110, which is equivalent to the decimal number 6.

A seventh trigger pulse again changes the state of the first flip-flop stage from logic O to logic 1. The collector of Q1 becomes zero and the collector of Q2 rises to the negative collector supply voltage value. The remaining flip-flops do not change state, however, since the negative voltage on the collector of Q2 will not drive the second stage flip-flop and cause it to change state. The output, then, after the seventh trigger pulse is a logic 1 from the first, second, and third flip-flop stages, and a logic O from the fourth flip-flop stage. This output is read as 0111, which is equivalent to the decimal number 7.

The eighth positive trigger pulse again causes the first stage flip-flop to change state from a logic 1 to a logic O. The positive voltage swing developed on the collector of Q2 of the first flip-flop stage is coupled across capacitor C2 and through diode CR8 to the collector of Q3 and the base of Q3, which changes the state of the second flip-flop from logic 1 to logic O. The positive collector voltage of Q4 is coupled across capacitor C3 and through diode CR1O to the collector of Q6 and the base of Q5, which changes the state of the third flip-flop from logic 1 to logic O. The positive swinging collector voltage of Q6 is coupled across capacitor C4 and through diode CR11 to the collector of Q7 and the base of Q8. The positive voltage on the base of Q8 reverse biases Q8 to cutoff. The negative collector supply voltage on the collector of Q8 also appears at the base of Q7, forward-biasing Q7 to saturation. A zero voltage on the collector of Q7 and a negative voltage on the collector of Q8 represents a logic 1 output from this fourth flip-flop at FF4. The output after the eighth pulse is then a logic 1 from the fourth stage flip-flop and a logic O from the first, second, and third stages. The output is read as 1000, which is equivalent to the decimal number 8.

The ninth positive trigger pulse changes the state of the first flip-flop from logic O to logic 1. The negative voltage at the collector of Q2 is not capable of driving the following flip-flop stages, so the second, third, and fourth flip-flop stages remain in their previous states. The output thus becomes 1001 after the ninth trigger pulse, or a decimal equivalent of the number 9. However, the logic 1 outputs of flip-flop: no. 1 and no. 4 also appear at the two inputs of the series AND gate (the bases of Q9 and QIO) through

capacitors C7 and C8. As a result both Q9 and Q1O are forward biased into conduction. The current flowing through resistor R9 develops a voltage drop across R9, and produces a positive-going voltage at the collector of Q9. This positive-going voltage is coupled through capacitors C5 and C6 to the second and third flip-flop stages. As a result, the second and third flip-flops change states from logic O to logic 1, and all of the flip-flops are in the logic I state at some time between the ninth and tenth trigger pulse. This output, since it occurs between the trigger pulses, does not appear as an output, but merely prepares the counter to be triggered to an all logic O output with the application of tenth trigger pulse.

The tenth positive trigger pulse changes the state of the first flip-flop from logic 1 to logic O. The positive swinging voltage at the collector of Q2 is coupled through capacitor C2, through diode CR7 to the collector of Q3, and the base of Q4, which brings Q3 to saturation and Q4 to cutoff. The state of the second flip-flop stage changes from logic 1 to logic O. The positive voltage at the collector of Q4 is coupled through capacitor C3, through diode CR9 to the collector of Q5 and the base of Q6, which biases Q6 to saturation, and bring Q5 to cutoff. The state of the third flip-flop stage changes from logic 1 to logic O. The positive voltage at the collector of Q6 is coupled across capacitor C4 through diode CR11 to the collector of Q7 and the base of Q8, which biases Q8 to saturation and brings Q7 to cutoff. The state of the fourth flip-flop stage then changes from logic 1 to logic O. The output of the counter is now read as 0000. At the tenth trigger pulse application, then, the counter returns to its original state of O and the cycle begins again.

PART 16-5. REGISTERS

LOGIC REGISTERS (GENERAL)

A logic register is used to digital computers to temporarily store the logic of one binary word. The storage or memory elements of a register may be magnetic cores of flip-flops, and the latter is most commonly used. The logic 1 or logic O state of the storage elements of a register represents bits; the combined bits form a word. The number of bits in a word determines how many storage elements are required, and thus determines the size of the register. The stored word is produced by input potentials from accompanying circuitry for each bit. The series of logic bits remain in the register with altering or blocking any signal applied to accompanying circuitry. When the word is to be used in the performance of a specific operation, such as multiplication or division, it may be completely removed from the register to operate a circuit (destructive read out), or the word may be used by a circuit and still remain in the register (non-destructive read out). Non-destructive read out can also be used to sample single bits of a stored word without removing the bit from the register. Non-destructive read out register must also be provided with a clear input, which permits each flip-flop in the register to be returned to the initial all logic O state.

The various types of registers and their circuit operation are discussed in detail in the following paragraphs. Generally speaking, the clear register is used as a temporary storage device to clear a group of flip-flops and return them to their original state. The shift register moves over or shifts the output one place for each input pulse, and the complement register is used to trigger or complement a series of flip-flops into the next state of operation. A double-line transfer register is used to transfer information from one line to another, and the circulating register is used to insert information into a register and continuously circulate it, or to introduce a specific delay for each trigger. The accumulator register usually stores numbers and adds them together to form a new sum for each bit introduced. Although functionally and schematically registers may appear similar, each is named and used specifically to perform a definite operation in the computer.

CLEAR REGISTER

Application.

A clear register is used in digital computers as a temporary storage device for a one or more bit word. Each memory element in the register is capable of being set to logic 1 by individual circuits, but is capable of being cleared by only a single reset source.

Characteristics.

Register uses three flip-flops.

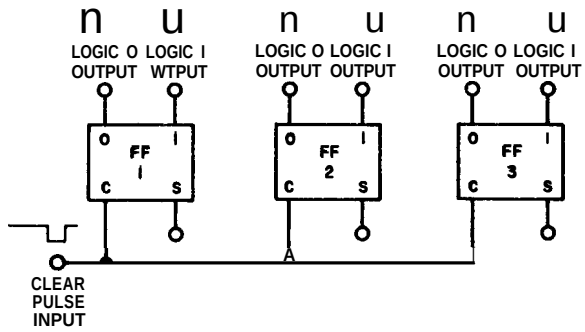
Each flip-flop has two inputs and two outputs.

Each flip-flop is triggered by an individual set-source.

Each flip-flop is cleared by a common reset source.

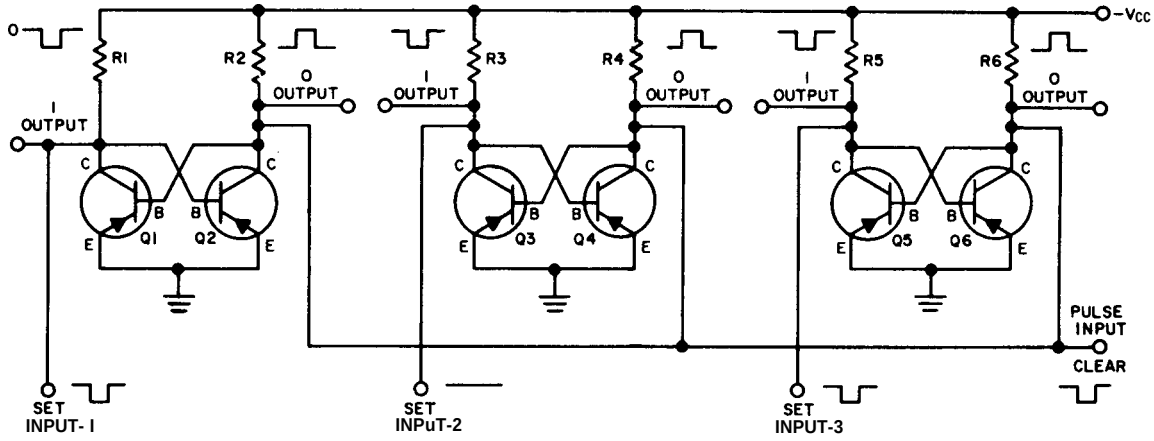
Circuit Analysis.

General. A clear register consists of a series of individual flip-flops which have nothing in common except for a common clear input. Each flip-flop has a separate set-input which is connected to an individual triggering circuit. When the triggering circuit supplies a trigger pulse to the set-input of a tlip-flop, the flip-flop produces a logic 1 output; when the triggering circuit does not supply a trigger pulse, however, the associated flip-flop develops a logic O output. When a pulse is applied to the common clear input of the register, all outputs of the register change to logic O, regardless of the state of the out-puts prior to application of the common reset pulse. The block diagram of a typical three stage clear-register is shown in the following illustration.



Clear Register

Circuit Operation. The schematic diagram of a typical three-stage clear-register is shown in the following illustration. In the first flip-flop stage, resistors R1 and R2 are collector load resistors. Resistors R3 and R4 are the second stage flip-flop collector load resistors, and resistors R5 and R6 are collector load resistors of the third stage. Transistors



Clear Register

Q1 and Q2 are the first stage flip-flop transistors; transistors Q3 and Q4 are second stage flip-flop transistors; and transistors Q5 and Q6 are third stage flip-flop transistors.

In the initird state, the three flip-flop stages produce a logic 1 at their O outputs. A logic 1 from each O output is obtained when the first transistor of each stage, QI, Q3, and Q5, are conducting heavily, and the second transistor of each stage, Q2, Q4, and Q6, are not conducting. As a result of the heavy conduction of Q1, Q3, and Q5, current flows through collector resistors R1, R3, and R5 and the negative supply voltage is dropped across these resistors, leaving the collectors of Ql, Q3, and Q5 at the O volt level. As a result of Q2, Q4, and Q6 not conducting, no current flows through resistors R2, R4, and R6, and no voltage is dropped across them, leaving the collectors of Q2, Q4, and Q6 at the negative supply voltage value. This negative collector voltage is also applied to the cases of Q1, Q3, and Q5 keeping them forward biased and heavily conducting.

When a negative pulse is applied to the set inputs of the first and third stages, the collectors of Q1 and Q5 are driven negative by the applied trigger pulse. This negative voltage also appears at the bases of Q2 and Q6, which forward biases Q2 and Q6. Collector current then flows through resistors R2 and R6, dropping the negative collectors supply voltage across these resistors and the collectors of transistors Q2 and Q6 swing positive to the O-volt level. Since the bases of Q1 and Q5 are directly coupled to the collectors of Q2 and Q6, respectively, the positive collector swing reverse-biases on the bases of Q1 and Q5. As a result, Ql and Q5 do not conduct, no current flows through the collector load resistors, and no voltage is dropped across the resistors. The voltage at collectors of Q1 and Q5 then rises to the negative collector supply voltage. The negative voltage at the collectors of QI and Q5 represents a logic 1 output. The output of the register is then logic 1 from the first and third stage l-outputs and a logic O output from the second stage l-output. The register output remains in this state until a negative reset or clear pulse is applied.

When a negative clear pulse is applied, it appears at the collectors of each of the second flip-flop transistors, Q2, Q4, and Q6. The negative clear pulse also appears at the bases of Q1, Q3, and Q5, forward biasing each of these transistors. Q3, however, is already forward biased, since the flip-flop stage containing this transistor was not changed from logic O to logic 1 at the 1-output when the other stages previously were triggered, and the clear trigger has no

effect on this stage. Q1 and Q5, on the other hand, conduct and produce a collector current flow through resistors RI and R5, which drops the voltage across these resistors. The voltage at the collectors of Q1 and Q5 then swing positive to the O volt level. This positive swing appearing at the bases of Q2 and Q6 reverse-biases them and represents the removal of all forward bias to these transistors, resulting in the non-conduction of Q2 and Q6. Because Q2 and Q6 no longer conduct, no current flows through collector load resistors R2 and R6, and no voltage drop appears across these resistors. The voltage on the collectors of Q2 and Q6 then rises to the value of the collector supply voltage. The collectors of Q1, Q3, and Q5 are now at O volts, and the collectors of Q2, Q4, and Q6 are at the collector supply voltage. These same conditions existed for the initial state. Therefore, the application of a negative clear or reset pulse causes the register return to its initial state of all logic O output at the 1-outputs.

SHIFT REGISTER

Application.

The shift register may be used for temporary bit storage in a computer, and to shift in or out a series of pulses. It can also supply a predetermined time delay for a digital operation, or be used to insert characters into the computer.

Characteristics.

Either series or parallel outputs maybe employed.

Series operation requires a train of pulses equal to the number of stages to provide an input. A similar number of pulses is required to clear the register.

Flip-flop stages are used for pulse storage.

Delay "lines are used to prevent coincident triggering by input and shift pulses.

A shift occurs when a preceding flip-flop changes state from 1 to O output, and a shift pulse is applied. Each flip-flop is triggered sequentially.

The shift progresses from left to right, but the output is read from right to left.

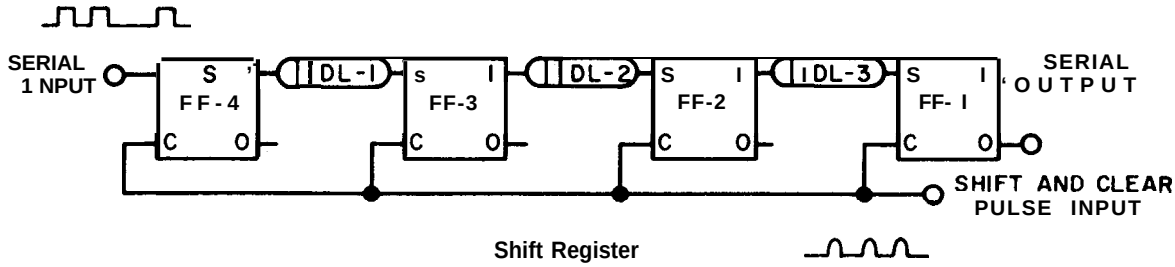
Circuit Analysis

General. The shift register uses a series of flip-flops for temporary storage of a binary word. Each information bit of the binary word appears in the register after the application of a shift trigger pulse to the shift and clear input. Each subsequent trigger pulse moves the previously applied bits one place to the right in the register and allows room for another bit to be accepted by the last (or input) stage of the register. The number of trigger pulses is equal to the number of stages minus one so that the first bit of the binary word appears in the first stage of the register and each succeeding bit appears in each succeeding stage of the register. The word then remains in the register until additional trigger pulses are applied to the clear input to remove the word from the register. One bit of the stored word is removed for each additional trigger pulse applied after the amount required to situate the word properly in the register.

Circuit Operation. The logic diagram of a series shift register is shown in the accompanying illustration.

The series shift register consists of four tlip-flops (FF1 through FF4) corresponding to four binary places. A delay line is connected between the 1-output of each flip-flop and the set-input of the following flip-flop (DL1 through DL3). A train of three short shift pulses is applied to the shift and clear pulse input, and occur midway between the binary word pulses to produce the step-by-step or sequential shifting of the flip-flops.

Assuming that the logic word to be stored is a binary 1101, a logic 1 corresponding to the extreme right digit of the word, appears at the serial set-input of flip-flop no. 4 at the start of operation. Flip-flop no. 4 which is initially in the O state, assumes a logic 1 state, and remains in this state even after the first



Shift Register

binary input pulse ends. A shift and clear pulse is applied at a time midway between the end of the first stored bit pulse and the beginning of the next word bit. This shift and clear pulse changes the logic 1 pulse appearing in flip-flop no. 4 to a logic O, and clears it from this flip-flop. Meanwhile, the logic 1 pulse which was applied to the input of delay line DL-1, is delayed for the remainder of the shift and clear pulse. After the short shift and clear pulse has ended, the logic 1 pulse in DL-1 emerges and appears at the set-input of flip-flop no. 3. Flip-flop no. 3 then assumes a logic 1 state. Thus, the initial bit is now shifted from FF-4 to FF-3.

A short time later the next digit of the binary word appears at the input of flip-flop no. 4. This digit, is a logic O, and has no effect on the logic O state of flip-flop no. 4. After the logic O pulse ends another shift and clear pulse occurs. The logic 1 appearing in flip-flop no. 3 is now cleared from the flip-flop and made to appear at the input of the second delay line, DL-2, by the second shift and clear pulse. After the end of this shift and clear pulse, the logic 1 pulse emerges from the delay line, and changes the state of flip-flop no. 2 from logic O to logic 1. The initial bit is thus transferred from FF-3 to FF-2, and the second bit (a logic O) is transferred to FF-3.

The next digit of the binary word, logic 1, appears at the serial input to flip-flop no. 4, changing the state of flip-flop no. 4 from logic O to logic 1. Another (the third) shift and clear pulse again occurs after the word pulse ends. The logic 1 appearing flip-flop no. 4 is thus cleared again and is applied to the input of DL-1, while the logic 1 appearing in flip-flop no. 2 is also cleared and is applied to delay line DL-3. The logic 1 present in each delay line is retarded until after the end of the final shift and clear pulse, at which time all the delayed logic ones emerge, and appear at the input to the following flip-flops. The logic 1 delayed by DL-3 appears at flip-flop no. 3, which changes state from logic O to logic 1, and the logic 1 delayed by DL-3 appears at flip-flop no. 1, which also changes state, from logic O to logic 1. Flip-flop no. 1 now contains a logic 1, FF-2 a logic O, and FF-3 a logic 1.

The final digjt of the binary word now appears at the serial input of flip-flop no. 4. Since this digit is a logic 1, flip-flop no. 4 again assumes the logic 1 state. Since no more shift and clear pulses are applied at this time, the register now contains the binary word made up of the bits 1101, which is equivalent to the decimal number 13. To remove the word from the shift register, a pulse train of four shift and clear pulses is required.

COMPLEMENT REGISTER

Application.

A complement register is used in digital computer - circuitry to temporarily store a logic word or the complement of a logic word applied to the register.

Characteristics.

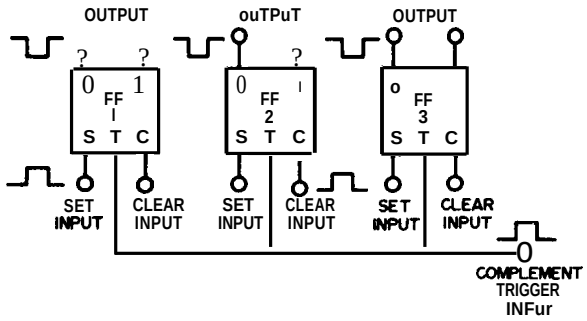
Flip-flops are used to provide bistable operation states.

Each flip-flop has a separate set and clear input.

AU flip-flop stages are complemented simultaneously by a single trigger pulse.

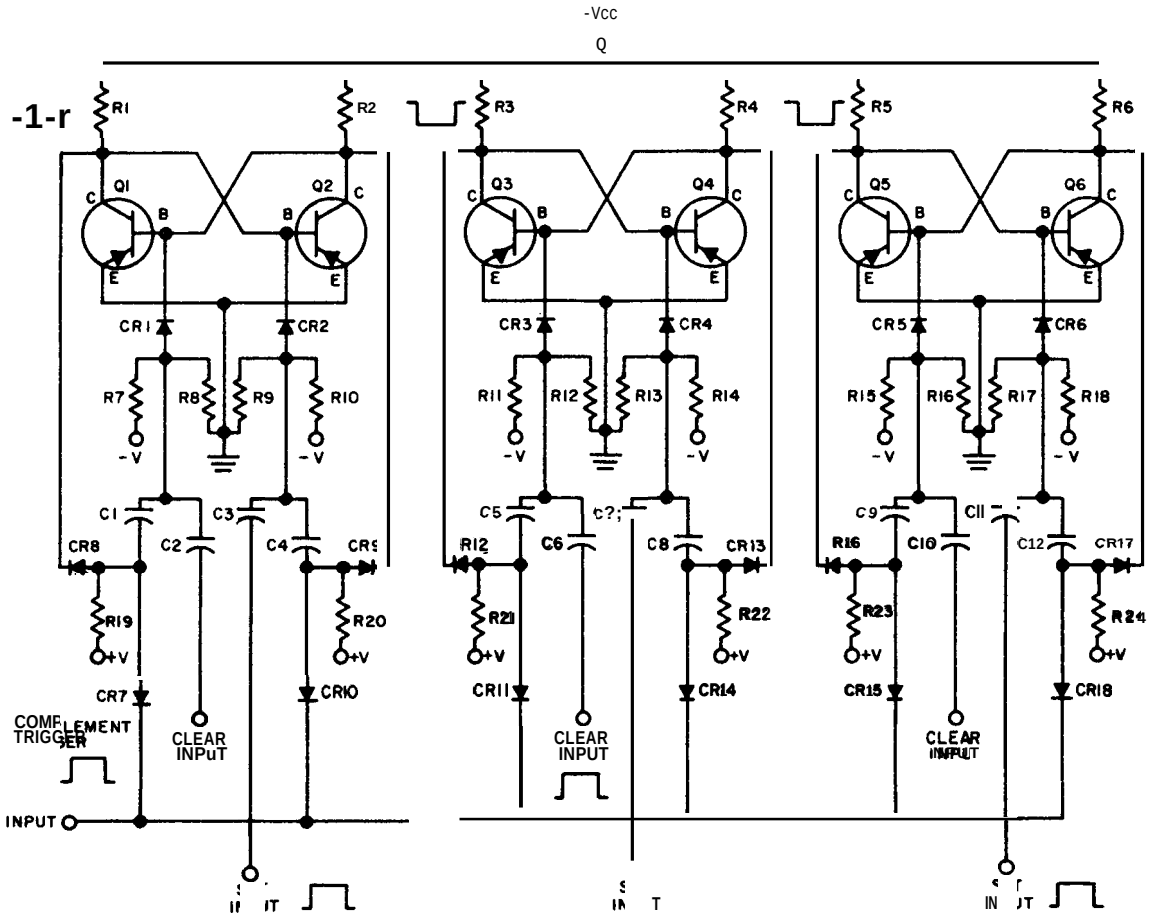
Circuit Analysis.

General. The logic diagram of a typical three stage complement register is shown in the following illustration. The register consists of three flip-flops, each having three inputs: set (S), complement (T), clear (C), and two outputs-one and zero. Each of the flip-flops are activated individually to a logic 1 or logic Ooutput state depending upon the individual set input trigger voltages of each stage. Each flip-flop is, likewise, individually cleared by pulses applied to the individual clear inputs of each stage. The word stored in the register, however, can only be complemented when a single complement trigger pulse is applied to the complement trigger pulse input. This trigger pulse appears simultaneously at one input of three individual AND gates. The other input of each AND gate is a logic 1 obtained from the zero or one output of each flip-flop. The output of the AND gate then is applied to the other half of the flip-flop, resting in either the one or zero state, which did not produce a logic 1. Thus, by simultaneously triggering the clear and set inputs, the flip-flops are all changed in state, or complemented.



Circuit Operation. The schematic of a typical three stage complement register is shown in the following illustration. Resistors R1 through R6 are collector load resistors: resistors R7 through R18, in conjunction with voltage source –V, form a voltage divider networks for providing anode voltages for triggering diodes CR] through CR6. Resistors R19 through R24 drop the voltage from voltage source +V to AND gate diodes CR7 through CR18. Transistors Q1 through Q6 are flip-flop transistors.

Complement Register



Complement Register

Prior to any input pulses being applied, all of the flip-flops are in the logic O state. In this condition, transistors Q2, Q4, and Q6 are conducting, and transistors Q1, Q3, and Q5 are not conducting. Assume a positive input is then applied to the set inputs of the first and the last flip-flop stage, representing a logic 1 input. A logic O input is represented at the second flip-flop stage, since no positive pulse is applied to the set input of the second flip-flop stage.

The positive pulse applied to the set input of the first stage flip-flop is coupled across capacitor C3, is greater in amplitude than the negative anode supply voltage of diode CR2, and forward biases CR2 causing CR2 to conduct. Thus, a positive reverse bias voltage appears on the base of transistors Q2. As a result, Q2 stops conducting, collector current no longer flows through load resistor R2, and no voltage drop appears across R2. The collector of Q2 then rises to the supply voltage and the base of Q1 is forward biased, hence, transistor Q1 conducts. Collector current flows through collector load resistor R1, producing a voltage drop across R], and the collector voltage of Q1 rises to the zero volt level. The state of the fLip-flop is now opposite to the initial logic O state; a logic 1 output state is now represented.

The positive (logic 1) pulse applied to the set input of the last flip-flop causes a reversal of state in the same manner. Since there is no positive (logic 1) pulse applied to the set input of second flip-flop stage, the second stage remains in the initial logic O state.

At the end of the first series of applied set input pulses: Q1 is conducting, Q2 is not conducting, Q3 is not conducting, Q4 is conducting, Q5 is conducting, and Q6 is not conducting. The positive going (zero) voltage on the collectors of Q1, Q4, and Q5 appear at the cathodes of diodes CR8, CR13, and CR16, respectively. These diodes are thus prevented from conducting while the flip-flops are in this state. When a positive pulse is applied to the complement trigger input, didoes CR7, CR1O, CR11, CR14, CR15, and CR18, can not conduct. At this time, a coincidence of positive pulses exists at the cathodes of some of the AND gate diodes. Diodes CR7 and CR8 of the first AND gate have positive cathodes voltages, thus preventing them from conducting. As a result, no current flows through resistor R19 and no voltage is dropped across R19. Therefore, the positive supply voltage, +V, overcomes the negative voltage on the anode of CR1, allowing CR1 to conduct. A positive voltage appears on the base of Q1, reverse biasing Q1 so that it does not conduct. No collector current flows through resistor RI, and no voltage drop occurs across R1. The negative collector supply voltage which now appears at the collector of Q1 also appears at the base of Q2, forward biasing Q2 into conduction. The state of this first flip-flop in the complemented position now corresponds to the initial logic O state.

Diodes CR13 and CR14 of the third AND gate have positive voltages applied to their cathodes, reverse biasing them and preventing current flow through resistor R22. The voltage applied to C8 rises towards the positive supply voltage, +V, and this positive swing is applied to the anode of diode CR4, which now conducts and applies a positive swinging voltage to the base of transistor Q4. Transistor Q4 is thus held reverse-biased so it will not conduct. Consequently, no collector current flows through collector load resistor R4, allowing the collector of Q4 and the base of Q3 to rise to the negative collector supply voltage. Transistor Q3 is now forward biased and conducts. Collector current now flows through resistor R3, and the supply voltage is dropped across R3. The state of the complemented second flip-flop now corresponds to a logic 1.

Diodes CR15 and CR16 of the fifth AND gate have effectively positive voltages applied to their cathodes resulting in a change of state of the last flip-flop from logic 1 to logic O by reverse biasing Q5 through CR5 and capacitor C9 in the same way that the first flip-flop changed state. The logic of each stage is, therefore, reversed with the application of a single complement trigger pulse.

If it is necessary to clear the register, a positive clear pulse must be individually applied to each stage containing a logic 1. Since the second flip-flop stage is the only one in a logic 1 state, a positive clear pulse must be applied to the second stage clear input, across capacitor C6, through diode CR3 to the base of Q3. Q3 is thus reverse biased so that it does not conduct. No collector current flows through resistor R3, and no voltage is dropped across it. The collector of Q3 and the base of Q4 then rise to the negative collector supply voltage. Q4 is then forward biased, so that it conducts heavily. The second flip-flop stage is now returned to the logic O state, and the register is completely cleared.

DOUBLE-LINE TRANSFER REGISTER

Application.

The double-line transfer register used in digital computers, when it is desirable to retain a logic word in one register, but also to be able to transfer the logic word to another register with the application of a single pulse.

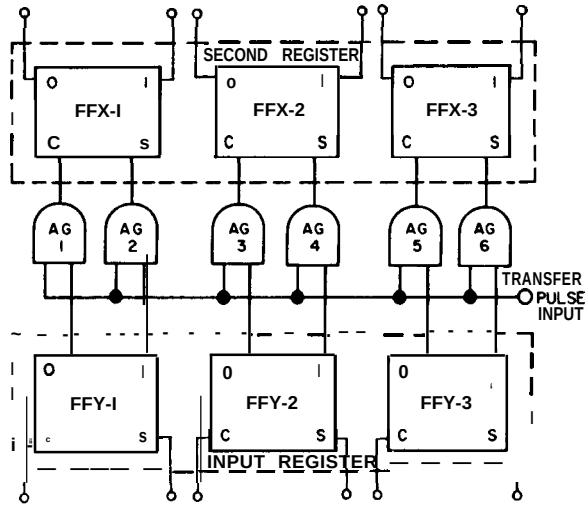
Characteristic.

Two single registers make up the double-line register.

Each single register consists of a series of flip-flops.

A series of AND gates couple one register to the other.

A transfer pulse input is required to complete the transfer of the logic word from one register to another.



Double-Line Transfer Register

Circuit Analysis.

General. The double line transfer register consists of two single flip-flop registers connected by means of a series of AND gates. A logic word is originally recorded in one logic register. The logic of the word is applied to one input of the applicable AND gate. With the application of single transfer pulse, certain AND gates will have the required simultaneous presence of two input pukes, and conduct. The conduction of the AND gate applies a pulse to an input of a flip-flop in the second register, corresponding to the output of the first register flip-flop. In this way, the second register logic corresponds to the first register logic.

Circuit Operation. The logic diagram of a typical double-line transfer register is shown in the accompanying illustration. The primary register consisting of flip-flops FFY-1, FFY-2, and FFY-3 is the storage input register to which the logic word is applied. AND gates AG1, AG2, AG3, AG4, AG5, and AG6 transfer the logic stored in the input register to the second register, flip-flops FFX-1, FFX-2, and FFX-3.

A logic 1 pulse applied to the set input of flip-flop FFY-1, and FFY-2, and a logic 1 pulse applied to the clear input of flip-flop FFY-3, develops a logic word of 110 in the input register. Logic pulses then appear at AND gates AG no. 2, AG no. 4, and AG no. 5 from the input register. When a transfer pulse is applied, it appears simultaneously at the other input of each of the AND gates. Since AND gates AG no. 2, AG no. 4, and AG no. 5 now have pulses simultaneously applied to both inputs they each produce an output. The output of AND gate AG no. 2 is applied to the set input of flip-flop FFX-1; the output of AND gate AC no. 4 is applied to the set input of flip-flop FFX-2; and output of AND gate AG no. 5 is applied to the clear input of flip-flop FFX-3. The second register now has a logic word of 110 inserted, which corresponds to the stored logic word of the input register. If it is desired to clear the second register, individual clear pulses must be applied to each flip-flop of the input register, and a transfer pulse must be applied to activate AND gates AG no. 1, AG no. 3, and AG no.

5 which are coupled to the logic zero output of the input register. The outputs of AND gates AG no. 1 AG no. 3, and AG no. 5 are coupled to the clear inputs of the second register flip-flops FXX-1, FXX-2, and FFX-3. Thus, each of the second register flip-flops is cleared to a logic O state.

CIRCULATING REGISTER

Application.

The circulating register is used in digital circuitry as a dynamic storage device to continuously circulate a logic word through the register until another logic word is applied.

Characteristics.

A shift register, two AND gates, an OR gate, and a flip-flop form a circulating register.

Three inputs and one output are provided.

A separate train of pukes operates the shift register.

Circulation continues as long as a circulate input is applied.

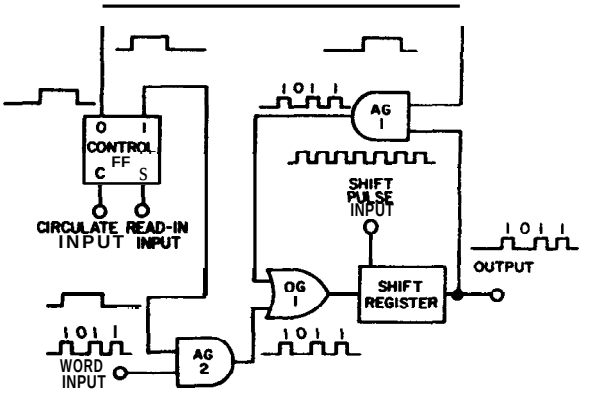
A read-in input will clear the register.

The output may be used over and over again.

Circuit Analysis.

General. The circulating register, consisting of a control flip-flop, a shift register, two AND gates and an OR gate. Also, it retains a logic word when the applied word occurs at the same time that a pulse is applied to the read-in input of the flip-flop. The logic word is then retained in the shift register portion of the circulating register. This word continues to circulate through the register once an input is applied to the circulate input of the control flip-flop. When the flip-flop changes state again the shift register is cleared, and will accept a new logic word if it is applied to the word-input terminal.

Circuit Operation. The logic diagram of a typicrd circulating register is shown in the accompanying illustration. The two states of the control flip-flop determine whether or not a new logic word will be accepted in the register, or if the word already inserted in the register will be recirculated. AND gate no. 1 has one its two inputs supplied with pulses from the output of the shift register, and the other input is supplied with pulses from the zero output of the control flip-flop. An output from AND gate no. 1 applied to OR gate no. 1 causes the recirculation of a logic word in the register.



Circulating Register

One input to AND gate no. 2 is from the one output of the control flipflop, and the other input to AND gate no. 2 consists of the pulses or bits of the new logic word which is to be inserted into the register. The output from AND gate no. 2 applied to OR gate no. 1 then, causes the word in the shift register to be replaced with a new logic word. OR gate no. 1 allows an output from either AND gate no. 1 or AND gate no. 2 to be used to operate the shift register, and to either circulate the word, or to insert the new word, respectively.

If a logic word of 1011 is applied to the word input, a logic 1 output must be generated by the control flip-flop at the one output, and last for the entire period of the applied word pulses. The control flip-flop produces this logic 1 output when a logic 1 pulse is applied to the set input (S) of the control flip-flop. The logic 1 output of the control flip-flop and the 1011 applied logic word appear at the two inputs of AND gate no. 2 and produce a 1011 output from AND gate no. 2, which also appears at the input of OR gate no. 1. OR gate no. 1 then produces a 1011 output. The logic word 1011 thus is serially applied to the shift register, and it may then continue to circulate the logic word, accept a new logic word, or be cleared. To continue to circulate the logic word, logic 1 pulses must continually be applied to the shift pulse input to serially move the logic word of 1011 through the shift register to the output, and then to one input of AND gate no. 1. The control flipflop is

then made to change state by applying an input pulse to the circulate (C) input of the flip-flop, so that a logic 1 is now produced at the zero output. The logic 1 at the zero output of the control flip-flop also appears at the other input of AND' gate no. 1. As a result, AND gate no. 1 produces a serial output of 1011, which appears at one input of OR gate no. 1. Hence, OR gate no. 1 applies the logic word 1011 to the shift register, which flop, so that a logic 1 is now produced at the zero output. Serially accepts the word as soon as three shift pulses are completed. Continuous application of the shift pulses causes the word to be read-out into AND gate no. 1 again and back through OR gate no. 1 into the shift register. This circulation continues as long as the control flip-flop zero output remains at a logic 1 and shift pulses continue to be applied to the shift register.

When a new logic word, say 1100, is to be inserted into the register, it is applied to the word input of AND gate no. 2 and a read-in pulse is applied to the (S) input of the control flipflop. Hence, the flip-flop changes state so that a logic 1 is produced at the one output of the flip-flop and is simultaneously applied to the other input of AND gate no. 2. Meanwhile, AND gate no. 1 no longer produces an output, since one of its inputs from the zero output of the control flip-flop is no longer a logic 1 and circulation ceases. AND gate no. 2 now produces an output of 1100, which passes through OR gate no. 1 to the shift register. With the application of three shift pulses this word is accepted in the register. Additional shift pulses bring the logic word of 1100 to the output of the register and apply it as one input to AND gate no. 1. If the control flip-flop remains in the same state (a logic 1 from the one output) and there is no new logic word applied, the circulating register is cleared. If the flip-flop is made to change state again, the logic word 1100 is now circulated.

ACCUMULATOR REGISTER

Application

The accumulator register is used in digital circuits to store a given binary number, or to add another binary number to the stored number, and store the sum of the two binary numbers.

Characteristics.

The accumulator register consists of a series full-adder and a shift register.

With a two stage adder and a three stage shift register, two OR gates, two inhibit gates, two AND gates, three delay lines, and three flipflops are used in the accumulator register.

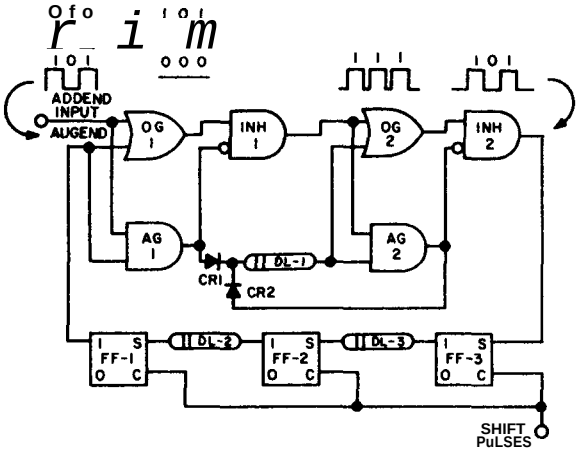
The output of the full-adder is the input to the shift register, and the output of the shift register is the augend input of the adder.

Circuit Analysis

General. The accumulator register consists of a combination of two logic circuits previously discussed in this section of this handbook-the series full-adder and the shift register. A logic word or binary number is applied to the addend input of the series full-adder. If there is no logic word or binary number applied to the augend input of the series full-adder, the word applied to the addend appears at the output of the adder as the sum. The logic word is then sequentially read into the shift register by applying the required number of shift pulses to the shift register. This logic word or binary number then remains in the shift register until additional shift pulses remove it.

A binary number which is stored in the shift register may be added to another binary number. It is ordy necessary to apply the proper number of shift pulses to the shift register to remove the binary number, and simultaneously apply it to the augend input of the adder when the number to be added appears at addend input of the adder. The two numbers are then added together in the adder and appear at the sum output of the adder. This sum is read into the shift register by applying the proper number of shift pulses to the shift pulse input.

Circuit Operation. The logic diagram of a three-bit accumulator register is shown in the following illustration. One half of the series full-adder is made up of OR gate no. 1, AND gate no. 1, and inhibit gate no. 1. Diodes CR1 and CR2 and delay line DL-1 separate the first half-adder from the second half-adder consisting of OR gate no. 2, AND gate no. 2, and inhibit gate no. 2. The shift register consists of flip-flops FF-1, FF-2, and FF-3, and delay lines DL-2 and DL-3.



Accumulator Register

If a logic word of 101 is applied to the accumulator register, it appears at the addend input. OR gate no. 1 passes the logic word on to the non-inhibiting input of inhibit gate no. 1. Since AND no. 1 does not have simultaneous logic inputs, no output is produced. Therefore, no input is applied to the inhibiting input of inhibit gate no. 1; likewise, no input is applied to diode CR1. Inhibit gate no. 1 now passes the logis word 101 to one input of OR gate no. 2, and AND gate no. 2. Since there is nothing applied through diode CR1 to delay line DL1, no input appears at the other inputs to OR gate no. 2, and AND gate no. 2. OR gate no. 2 therefore passes the logic word of 101 to the non-inhibiting input of inhibit gate no. 2. Since there is no input applied to the inhibiting input of inhibit gate no. 2, the logic word emerges from the inhibit gate and appears at the set input of flip-flop FF-3. Since a flip-flop is only capable of reacting to one pulse at a time, flip-flop FF-3 becomes a logic 1 as a result of the first logic 1 pulse of the logic word. A shift pulse is timed to occure between the first and second word bit pulse. This shift pulse returns FF-3 to logic O and passes the logic 1 pulse to flip-flop FF-2 after a slight delay, caused by delay line DL-3. The delay is used to prevent the bit from appearing at FF-2 while the shift pulse is still being applied. Flip-flop FF-3 remains in the logic O state even after the second pulse of the logic word appears at FF-3, since the second pulse is a logic O. Some time after the second word pulse, another shift pulse is applied to the clear input of all flip-flops. Flip-flops FF-2 and FF-3 shift the word pulses retained in them to the subsequent flip-flop stage after another short delay, so that flip-flop FF-1 is now a logic 1, FF-2 is a logic O, and FF-3 is a logic O and awaiting the next word pulse. The third and final word pulse of logic 1 appears in FF-3, The word is then retained in the shift register until additional shift pulses are applied to the shift register.

If a binary number is to be added to the binary number already in the register, the number is applied to the addend input of the series full-adder. Shift pulses are applied to the shift register to move the binary number to the augend input. The first shift pulse is applied so that the first bit of the stored word appears at the augend input when the first bit of the applied word appears at the addend input. Subsequent shift pulses are timed so that additional bits of the stored word coincide with additional pulses of the applied word. Assume that a binary number 010 is to be applied to the addend input of the series full-adder and the binary number 101 is stored in the register. When a shift pulse is applied to the flip-flop stages of the shift register it moves each pulse of the stored word one place to the left, causing the first logic 1 bit of the stored word to appear at the augend input; the first bit of the applied word (logic O) appears at the addend input at the same time. Since the addend bit is a logic O and the augend bit is a logic 1, only the OR gate will produce a logic 1 output. This logic 1 appears at the non-inhibiting input of inhibit gate no. 1. Since AND gate no. 1 produces no logic 1 output, there is no logic 1 applied to the inhibiting input of inhibit gate no. 1. Inhibit gate no. 1, therefore, develops a logic 1 which then passes through OR gate no. 2, and inhibit gate no. 2, in the same way it passed through the first half of the adder. The logic 1 emerges from the adder and appears at the set input of flip-flop FF-3 changing the state to logic 1. Another shift pulse is then applied to the shift register, and moves each pulse of the stored word one place to the left. The next bit of the stored word (logic O) appears at the augend input of the adder. The logic 1 bit, developed by the adder and accepted by FF-3, is shifted to FF-2. When the logic O stored

word bit appears at the augend input, the second bit of the applied word also appears at the addend input. In this case, as in the case of the first augend and addend bit, there is only one logic 1 applied to the adder. As a result, another logic 1 is developed at the output of the adder, and appears at the set input of FF-3, changing flip-flop FF-3 to logic 1. Another shift pulse moves the bits stored in the accumulator register one place to the left. The last logic 1 bit of the originally stored word now appears at the augend input of the adder. At the same time, the last bit of the applied word (logic O) appears at the addend input of the adder. Since, as in the first and second addend and augend bits, there is only one logic 1 appearing at the inputs of the adder, the output of the adder is a logic 1. This logic 1 now appears at the set input of flipflop FF-3 resulting in all flip-flops being a logic 1. The resulting logic word is the sum of the initially applied word –101, which was also the first word stored in the register, and the second applied word -010. The following examples of a logic sum indicates the validity of the sum of the two applied words.

	Binary		Decimal	
	1st Addition	2nd Addition	1st Addition	2nd Addition
Augend	000	101	0	5
Addend	101	010	5	2
Sum	101	i i i	5	7

PART 16-6. MEMORY DEVICES

MEMORY DEVICES (GENERAL)

Memory is a term which describes the ability of circuits used in computers to retain binary logic in electrostatic, ferroelectric, magnetic, acoustic, optical, chemical, electronic, electrical, or mechanical form. In addition to storing binary information, the memory device must readily provide logic information to other circuits in the computer; this ability is referred to as access. The amount of binary information which is capable of being stored is referred to as ***capacity.*** The access time, as well as the degree of capability of the memory to retain binary information when no power is applied to the computer is called ***volatility. Permanence*** is the degree by which binary information can be removed. Access time can be further broken down into random (static) access or sequential (dynamic) access. Random or static access provides information to a desired circuit from any portion of the memory without requiring the physical movement of the memory device. On the other hand, sequential access only provides information after the physical movement of the memory device, whether it be cyclic or progressive.

The magnetic core memory, which is a random access memory and the magnetic drum, the magnetic disc, and the magnetic tape memories, which are sequential access memories and fully discussed in the following paragraphs. The memory driver circuit and the data memory circuit, which are merely related memory operating circuits are also discussed.

MAGNETIC CORE MEMORY

Application.

A magnetic core memory is used for the retention and storage of binary logic information until it is needed by other sections of the computer.

Characteristics.

Each core is capable of retaining a single bit of logic information.

A typical magnetic core memory may retain between 10 and 100,000 characters of logic information.

The core memory provides low access time (rapid access).

The access is either static or random.

The stored logic information may be erased.

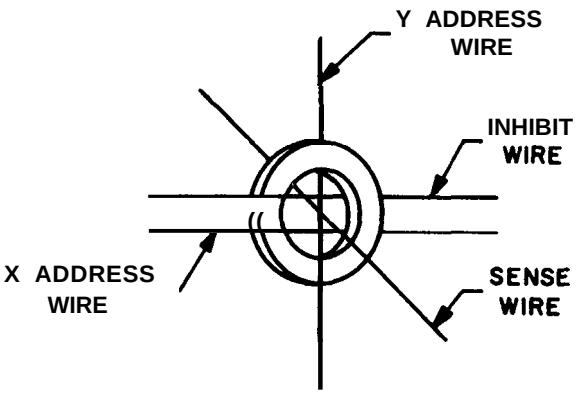
Logic information is not removed if power is removed.

Memory core consists of ferromagnetic material threaded with four conductors.

Circuit Analysis.

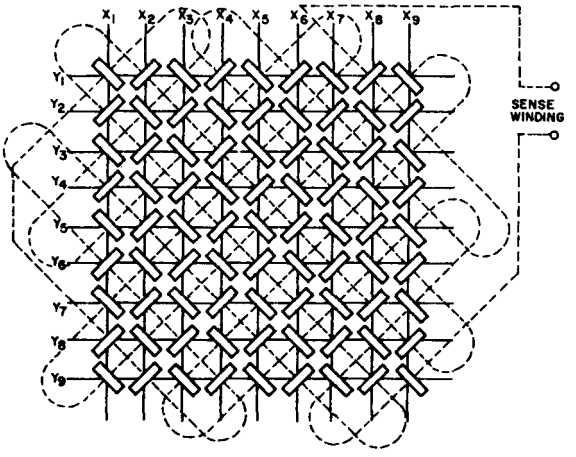
General. The core type of memory consists of a number of ferromagnetic cores arranged in matrix planes.

Every core within the memory has four conducting wires extending through it. One wire extends through every core in a horizontrd line, another wire extends through every core in a vertical line as shown in the following illustration. There are then as many vertical wires as there are vertical lines of cores, and as many horizontal wires as there are horizontal lines of cores. These vertical and horizontal lines are called address wires. A current flowing through one horizontal and one vertical wire induces magnetic lines of force about one core. The lines of force may be produced in either of two directions, depending upon the direction of current flowing through the address wire. Lines of force in one direction represents a logic 1, and lines of force in the other direction represents a logic O. Once the lines of force are produced they remain about the core, even after the activating current is removed. Cores through which either, but not both, conducting wires extend do not react, since one wire supplies only half of the current needed to change the direction of the lines of force. In addition to the address wires there are two other wires which pass through the core. One of these wires is the sense wire, which is used to read out logic information. The other wire is the inhibit wire which prevents cores in other planes, that also have the conducting address wires passing through them, from simultaneously changing the direction of their magnetic lines of force. By using more than one memory plane a logic word can be stored in the core matrix either vertically, horizontally, or through the planes (one bit of a logic word in each plane). If a single plane is used, the logic word may only be stored vertically or horizontally. An inhibit wire is not necessary in a single pkme matrix.



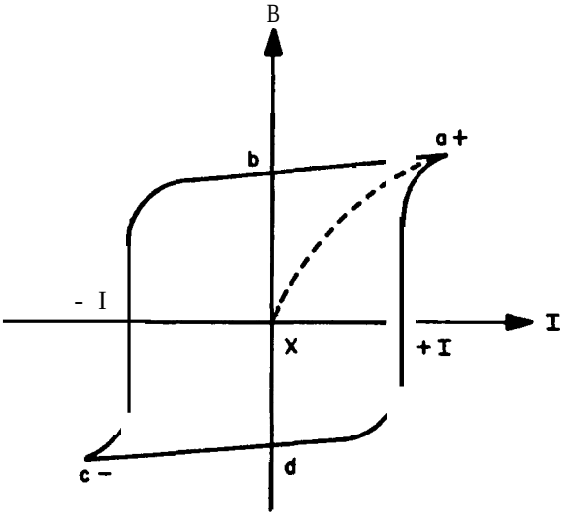
Typical Memory Core

Circuit Operation. The representation of a magnetic core memory plane utilizing single cores is shown in the following illustration. The complete plane contains eighty-one ferromagnetic cores. The wires Xl through X9 are the vertical address wires; wires Y1 through Y9 are the horizontal address wires; and the dotted line running through every core represents the sense wire or winding.



Core Memory Plane

In the case of the single-core memory plane, shown in the preceding illustration, nine 9-digit logic words may be stored horizontally or vertically. If the memory consisted of nine planes, eighty-one nine digit words could be stored. If logic words are to be stored horizontally, a current, which is half the current required to change the magnetic lines of force about any of the cores, is applied to the appropriate Y wire, and a current, which is half the current required to change the magnetic lines of force about any of the cores, is applied to the appropriate X wires. The hysteresis characteristics of a magnetic core prevents any of the cores, supplied with only half of the required current value from changing state. A typical core hysteresis curve is shown in the following illustration. The vertical axis in the hysteresis loop represents the flux density of a core. The flux density is in one direction (logic 1) above the origin (where it crosses the horizontal line) and in the opposite direction (logic O) below the origin. The horizontal axis of the hysteresis loop represents current through the conducting address wires. To the right of the vertical axis the current is positive, and to the left the current is negative. A core is in the logic O state between points c and d of the hystersis curve,



Hysteresis Loop

Assume initially that the core has no magnetism. This is represented by point X (the origin). If sufficient current is now passed in the positive direction the magnetic flux increases along the dotted line and eventually reaches saturation at point a. (The core is said to be saturated when an increase in current does not result in an increase in magnetic flux.) If the

current is then removed, a slight decrease in magnetism occurs, causing the magnetic flux point to move from a to b, where it is held by residual magnetism. If the core is now magnetized by a current flowing in the negative direction, the magnetism will be reversed. The magnetic flux will now reduce and traverse around the knee of the curve down to point c. This point corresponds to saturation in the opposite direction. When the pulse is removed, the point on the curve will change to d which represents the residual magnetism induced by that pulse. From here on, when the magnetism is switched (reversed) in either direction, the change in flux will follow the path a, b, c, d.

If a binary word of 101111001 is to be stored along the Y5 horizontal address line, a positive current is applied to Y5 and to vertical address lines Xl, X3, X4, X5, X6, and X9. Since the current of each of these address points (the core where the conducting X and Y wires would intersect) is positive the flux density increases to point a on the hysteresis curve representing a logic 1 state (regardless of the previous state of the cores, since those already saturated positively will not change). Hence, all the ones are inserted at once. A negative current is then applied to Y5 and to the vertical address lines X2, X7, and X8 of the matrix. Since the current at these address points is negative, the flux density decreases to point d on the hysteresis curve, presenting a logic O state. All the zeros are now inserted and the logic word now exists in the memory. The logic word remains in the memory until removed by applying negative current to the horizontal Y5 wire and to each of the vertical X wires. This allows the stored logic word to be applied to some other area of the computer, but removes the logic word from the memory completely. In this way, use of the stored logic word destructs the stored word in the memory. In order to avoid this destructive read-out, additional citcuitry must be used to return the logic word to the same position in the memory.

MEMORY DRIVER CIRCUIT

Application.

The memory driver circuit provides a means of reinserting any logic word, read out of a core memory, into the same address in the memory, for further storage.

Characteristics.

Each vertical address line has a separate memory driver circuit.

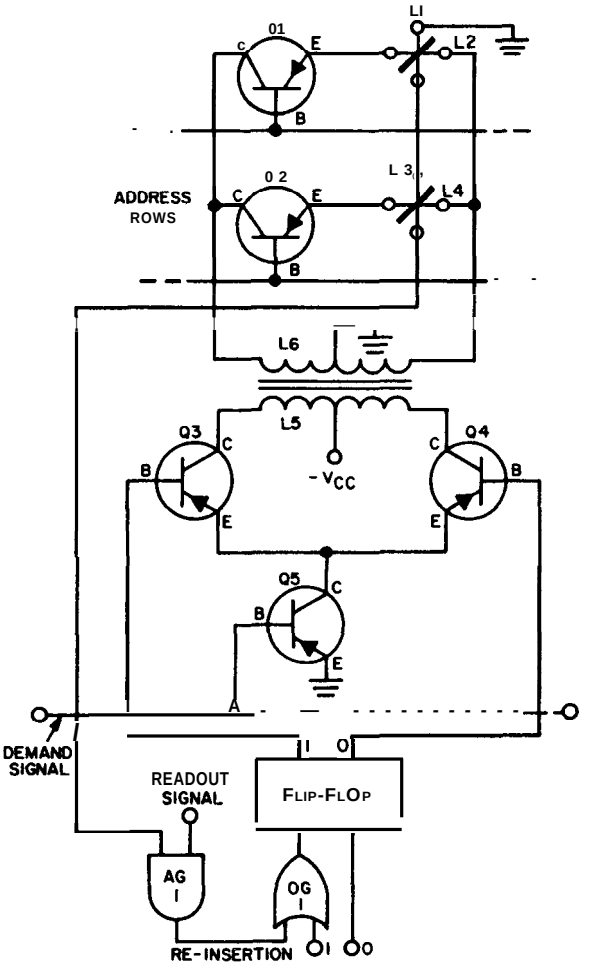
The memory driver circuit consists of three transistors, a center tapped transformer an AND gate, and an OR gate.

Requires simultaneous application of a read-out pulse and an output from the memory core.

Circuit Analysis.

General. A memory-driver circuit re-inserts the stored logic word into a magnetic core memory after it is read out into the sense winding for use elsewhere in the computer. The circuit, consisting of three transistors, a center-tapped transformer, an AND gate and an OR gate, provides the necessary feedback action to return the digit flip-flops, which are connected to the vertical address rows, to the previous storage logic state. Two of the Transistors respond to the state of the flip-flop, after being gated on by the other transistor and, in turn, activate an address winding of a memory core to correspond to the flip-flop state. When the logic in a core is to be read out, the associated flip-flop is placed in the zero state, and the gating transistor activates the other two transistors to respond to the logic O state. If the core is in the logic 1 state the current flow through the transformer and the address winding develop a logic 1 in the sense winding. This would normally leave the core in a logic O state; however, the logic 1 from the sense winding is fed back through the AND gate and the OR gate to the logic 1 input of the flip-flop. The core is then returned to the logic 1 state. If the core was originally in the logic O state there is no change in the state of the core and, thus no need to activate the output of the sense winding to change the flip-flop state.

Circuit Operation. The schematic of a typical memory driver circuit is shown in the following illustration, along with one vertical and two horizontal address lines. Windings L] and L3 are sense



Memory Driver Circuit

windings of the two memory cores; windings L2 and L4 are address windings of the two cores; L5 and L6 are the primary and secondary windings of a center-tapped transformer used to couple logic information from the flip-flop through either of transistors Q3 or Q4 to the data memory circuits consisting of transistors Q1 and Q2 (this circuit is discussed later in this section of this handbook). AND gate no. 1 couples the output of a sense winding through OR gate no. 1 to the flip-flop when a readout signal is applied to the other input of the AND gate. OR gate no. 1 allows the flip-flop to be activated to a logic 1 state by either a pulse applied to the input or a re-insertion signal.

If, initially, the flip-flop is placed in a logic 1 state by a negative pulse applied to the l-input of the flip-flop through OR gate no. 1, the flip-flop develops a negative pulse at its l-output. This negative pulse forward biases transistor Q3. Q3 ordy conducts if a negative demand signal pulse is applied to the base of Q5, so that Q5 conducts to provide a complete current path for Q3. The conduction of Q3 allows current to flow from $-V_{cc}$, through L5, through Q3, and through Q5 to ground. As a result of current flow through L5, L6 develops a current flow 180° out of phase (or in the opposite direction) to the current flow in L5. The current then flows from ground through one half of L6, from the collector of Q2 or Q1 to the emitter, and through L4 or L2 and the other half of L6 to ground. The activated address line determines the current flow through Q1 and L2 or Q2 and L4. As a result of the current flow through L2 or L4, the associated core is driven to a logic 1 state. The current developed in the sense winding of the activated core is 180° out of phase with the current of the address winding; the sense winding, then, produces a logic O output.

When the logic 1 is to be read-out of the activated core, the flipflop is placed in the logic O state by a negative pulse applied to the O input, and a negative demand signal is applied to the base of Q5 to cause Q5 to conduct. A negative pulse is produced at the O output of the flip-flop and appears at the base of Q4. Q4 is thus forward biased into conduction, and provides a current path for half of transformer primary winding L5. Current then flows from $-V_{cc}$ through half of L5, through Q4 and Q5 to ground. The current flow through L5 induces a current through L6 which is 180° out of phase with the current through L5.

Note that the polarity of the voltage induced in winding L6 is now reversed and that transistors Q1 and Q2 have a positive voltage applied to the collector from one side of L6, and a negative polarity applied to the emitter through L2 and 1A and the other side of L6. This corresponds to the special condition (discussed in section 3 of this handbook) where the transistors act as if they were connected in the inverted condition (emitter connected to what would normally be the collector lead, and the collector connected to what would normally be the emitter lead). As a result there is a change from normal operation. When operated as a switch, a transistor will

conduct in either direction, depending upon the applied polarity. Normally, the emitter is forward biased and the collector is reverse biased, and the electron current flow is in the direction opposite the arrow on the schematic symbol. When operated in the inverted condition, the normal emitter and collector leads may be transposed, or, the biasing polarities are reversed. Thus forward biasing the collector and reverse biasing the emitter produces exactly the same result as the transposed connection. Likewise, when inverted, the collector actually acts as an emitter, while the emitter serves as the collector. Both functions are interchanged and current flows in the opposite direction just as if the schematic symbol was reversed. The reverse current flow is usually from 0.3 to 0.6 times the normal value. (When analyzing the switching operation of transistor circuits bear in mind the fact that the transistor will always conduct in either direction as long as the base bias is such as to bias either junction in a forward direction. Similary, the transistor will be cut off only when both junctions are biased in the reverse direction.)

As a result of the reversed polarity connection, current now flows from ground through half of L6, through L4 and L2, from emitter to collector of Q1 or Q2, through L2 or L4 and through the other half of L6 to ground. The direction of current flow through L4 or L2 now is opposite in direction to the normal flow when a logic 1 was developed. The associated core is driven to a logic O, and the 180° out-of-phase current through the sense winding represents a logic 1 in the sense winding. This logic 1 (negative) pulse appears at one input of AND gate no. 1. If a negative readout signal pulse appears at the other input of the AND gate, a logic (negative) pulse output is developed and appears at the re-insertion input of OR gate no. 1. OR gate no. 1, in *turn,* develops a logic 1 output, causing the flip-flop to develop a logic 1 (negative) output. Q3 then conducts when Q5 conducts to provide Q3 with a current path as a result of the negative pulse appearing at the base of Q3. The conduction of Q3 develops a current flow through L5, which develops an opposite current flow through L6 (by induction) and produces a logic 1 in the address winding (L2 or L4) which formerly was activated to logic O, so that a logic 1 is developed in the associated sense winding.

If the state of the core (and the flip-flop) is originally in the logic O state, there is no need to activate the output of the sense winding to the flip-flop when reading-out, since the flip-flop is put in the logic O state and will read out a logic O.

DATA MEMORY CIRCUIT

Application.

The data memory circuit is used to insert (write-in) and read out logic information in a magnetic core of a computer memory bank.

Characteristics.

The circuit primarily operates as a transistor current switch.

The y-axis pulses are supplied by flip-flops.

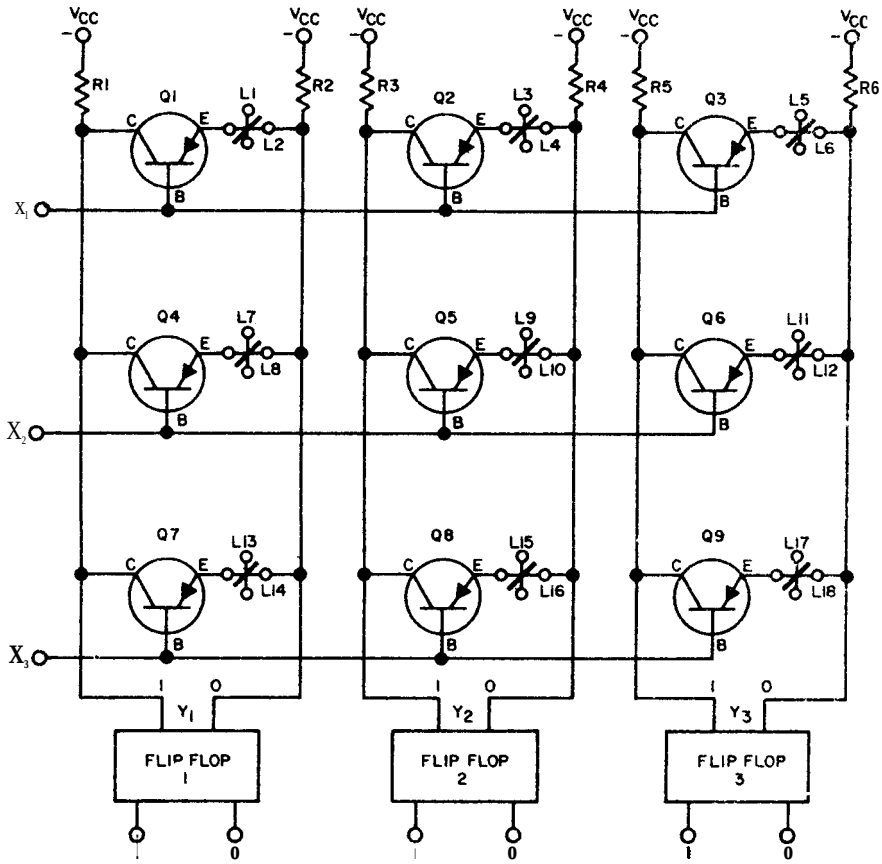
The y-axis pulses are applied to either the emitter or the collector of the driving transistor.

The x-axis pulses are applied to the base of the transistor.

Circuit Analysis.

General. A data memory circuit uses a single PNP type transistor to control each magnetic core in the memory. The x-input is applied to the base of the transistor, and the y-input is applied to either the emitter or collector of the transistor. The transistor then produces a logic 1 or logic O output (which is stored in the core). Thus, this circuit provides a means of controlling the state of the memory core by an external input signal, which requires only a single address winding through the core to produce this result.

Circuit Operation. A typical three-line data memory circuit is shown in the following illustration. Resistors RI through R6 are flip-flop load resistors. Transistors Q1 through Q9 are connected as emitter-follower transistors which are capable of conducting in either direction to activate the logic core winding to a logic 1 or logic O state. Windings L2, L4, L6, L8, L1O, L12, L14, L16, and L18 are the address windings for memory cores; windings Ll, L3, L5, L7, L9, L11, L13, L15, and L17 are the sense windings. Xl, X2, and X3 are the three horizontal address lines. Y1, Y2, and Y3 are vertical address lines. Flip-flop 1 supplies vertical address line Y1; flip-flop 2 supplies vertical address line Y2; and flip-flop 3 supplies vertical address line Y3.



Data Memory Circuit

To write a logic word into the core memory, the states of the memory flip-flop must correspond to the applied logic word. If a logic word of 101 is to be stored in the memory, flip-flop 1 must be in the logic 1 state, flip-flop 2 in the logic O state, and flip-flop 3 in the logic 1 state. The state of the flip-flops are controlled by inserting either a 1 or a O (the O input is opposite in polarity to the 1 input) into the respective 1 and O inputs. The flip-flop states do not affect the memory, however, until one of the horizontal (x) address lines is activated by a negative logic 1 pulse, since zero base bias exists without an x-input. If, for example, line X2 is activated by a negative pulse, the bases of Q4, Q5, and Q6 are forward biased and conduct. Transistor Q4 has a negative pulse applied from the 1 output of flip-flop 1 to the collector, while a zero or effective positive voltage is applied to the emitter from the O-output. Thus, Q4 conducts from collector to emitter producing an electron current flow through address winding L8, which causes the associated memory core to become a logic 1.

Note that transistor Q5 now has a negative pulse applied to the emitter from the O output of flip-flop 2, while the collector of Q5 has an effective positive pulse or a O applied from the l-output, since flip-flop 2 is in the opposite state to flip-flop 1. This corresponds to the special condition discussed in section 3 of this handbook where the transistor acts are if it were connected in the inverted condition (emitter connected to what would normally be the collector lead, and the collector connected to what would normally be the emitter lead). As a result there is a change from normal operation. When operated as a switch, a transistor will conduct in either direction, depending

491-044 0 73 89

upon the applied polarity. Normally, the emitter is forward biased and the collector reverse biased, and the electron current flow is in the direction opposite the arrow on the schematic symbol. When operated in the inverted condition, the normal emitter and collector leads may be transposed, or, the biasing polarities are reversed. Thus, forward biasing the collector and reverse biasing the emitter produces exactly the same result as the transposed connections. Likewise, when inverted, the collector actually acts as an emitter, while the emitter serves as the collector. Both functions are interchanged and current flows in the opposite direction just as if the schematic symbol was reversed. The reverse current flow is usually from 0.3 to 0.6 times the normal value. (When analyzing the switching operation of transistor circuits, bear in mind the fact that the transistor always will conduct in either direction as long as the base bias is such as to bias either junction in a forward direction. Similarly, the transistor will be cut off only when both junctions are biased in the reverse direction.)

As a result of the inverted polarity, Q5 now conducts in the opposite direction from emitter to collector producing an electron current flow through address winding L1O (in a direction opposite to that in L8) which causes the associated memory core to become a logic O. Because of the negative logic 1 pulse applied to the collector of Q6 from flip-flop 3, Q6 conducts in the normal direction from collector to emitter making the memory core associated with L12 a logic 1. This logic word remains in the core memory until the word is read out of the memory.

When the word is to be read from the memory, a negative pulse is applied to the X2 line, and a negative pulse is developed by the O output of each flip-flop. Current flows in the inverted direction from emitter to collector in each of the X2 transistors, and the original direction of current flow in L8 and L12 is reversed. This current reversal induces a current in sense windings L7 and L11, which is 180° out of phase with the original direction of current through L8 and L12. Since L8 and L12 are now a logic O, sense windings L7 and L1 1 now produce a logic 1. Since there was no change in the direction of current through L1O, no current is induced in the associated sense winding, L9, and a logic O is read out. The logic word read out then corresponds to the logic word which was stored in the memory. Once the logic word is read out, however, no logic word remains in the core memory along with X2 address line. This is known as a destructive read-out, since the X2 memory cores are now effectively empty.

MAGNETIC DRUM MEMORY

Application.

The magnetic drum memory is used in computers to provide an inexpensive means of storing large amounts of binary information.

Characteristics.

Magnetic drum memory has sequential and cyclic access capabilities at medium speeds.

The magnetic drum memory has large storage capabilities.

Stored logic is not lost when power is removed, but stored logic may be erased.

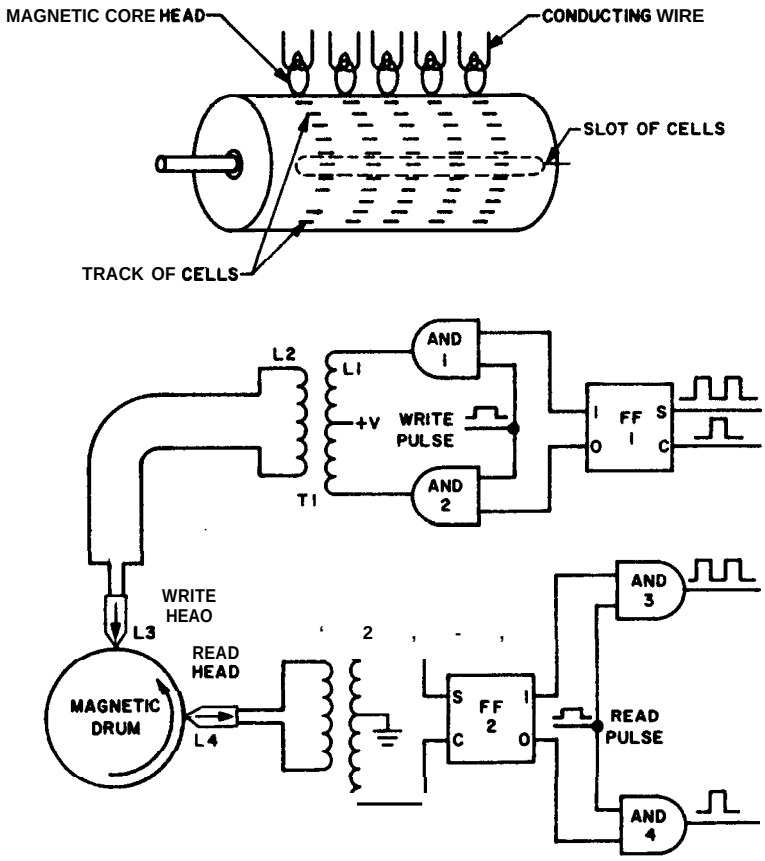
Circuit Analysis.

General. A magnetic drum memory consists of a large metal cyclinder, which is dipped or sprayed with an oxide coating to provide magnetic hysteresis characteristics similar to those of magnetic cores, and external magnetic core heads for writing in and reading out binary logic. The drum is arranged in radial rows (around the drum) and horizontal rows of cells. The radial rows of cells are called tracks, and the horizontal rows are called slots. Each cell is capable of storing one bit of logic. The drum continually rotates under but does not touch the horizontally aligned cores. (The number of cores corresponds to the number of cells in a slot). Conducting wires extend through and are wound around each core. When binary digits are to be read into certain cells of the drum, current is applied through the core windings at the time a particular slot of cells passes under the heads. The current through the core windings causes a magnetic flux to be developed through and around the core which, in turn, polarizes a cell surface of the dmm to a logic 1 or a logic O. The magnetic flux about all of the cores then causes all of the cells in a specific slot to retain the appropriate logic in the memory.

When the binary logic in a slot is to be read-out the precedure is reversed. The slot appears under the horizontal row of read-out heads, where the magnetic polarization of the cells develops the appropriate direction of magnetic flux about and through the cores, which, in turn, induces a current through the

conducting wires would around the cores. The direction of current flow through the conducting wire determines if the bit being read-out is a logic 1 or logic O.

Circuit Operation. A pictorial representation and a one-line diagram of a typical magnetic-drum memory is shown in the following illustration.



Magnetic Drum Memory

The pictorial representation shows the magnetic drum with its arrangement of cells and magnetic core heads. The one-line diagram shows the magnetic drum, the write head used to write-in binary data to the cells of the magnetic drum, and the read head used to read-out data from the cells of the magnetic drum. AND gate no. 1 is used to supply logic-l write pulses to the write head when write logic-l pulses and write timing-pulses are applied to the AND gate inputs at the same time. AND gate no. 2 is used to supply write logic-O pulses to the write head when logic-O pulses and write timing-pulses are applied to the AND gate inputs at the same time. Flip-flop no. 1 provides logic-l data and logic-O data to AND gates 1 and 2. Transformer T1, consisting of primary L1 and secondary L2, couples the logic data from AND gate nos. 1 and 2 to the write head and the drum through L3. Winding L4 couples logic data read from the magnetic drum to transformer T2. Transformer T2 provides logic-l and logic-O pulses to flip-flop no. 2 The logic-l pulses developed by flip-flop no. 2 are applied to AND gate no. 3, which develops an output when the read timing-pulses appear at the other input of AND gate no. 3 at the same time the logic-l pulses are applied. The logic-O pulses developed by flip-flop no. 2 are applied to AND no. gate 4, which develops

an output when the read timing-pulses appear at the other input of AND gate no. 4 at the same time the logic-O pulses are applied.

If a logic word of 101 is to be read-in on a track of cells, a positive pulse is first applied to the set input of flip-flop no. 1, which develops a positive pulse at the l-output. If this positive pulse appears at one input of AND gate no. 1 at the same time a write timing-pulse is applied, AND gate no. 1 conducts and produces current flow through half of winding L1 to voltage source +V. The current flow through L1 induces a current 180° out of phase with the L1 current winding L2. The current induced in L2 flows through winding L3, which develops a flux in the write head. The flux of the write head causes a cell on the magnetic drum, which happens to be directly under the write head as the flux is developed, to become polarized. The polarization of the cell represents a logic 1.

The next bit of the applied word is a logic O. In this case a positive pulse is applied to the clear input of flip-flop no. 1, causing the O-output of the flip-flop to develop a positive pulse. If this positive pulse appears at one input of AND gate no. 2 while a write timing-pulse is still being applied, AND gate no. 2 conducts and produces a current flow through the other half of winding L1 to voltage source +V. The current flow through L1, which is now in the opposite direction from when a logic 1 pulse was applied, induces a current 180° out of phase with the L1 current in winding L2. This current flows through L3, which develops a flux in the write head and causes the next cell in the same track to become polarized (in an opposite direction to the preceding cell) and this cell represents a logic O.

The final bit of logic word is again a positive pulse representing a logic-l. The positive pulse applied to the set input of flipflop no. 1 allows AND gate no. 1 to produce a positive logic-l pulse output, and causes current to flow through half of L2 to +V. The current then induced in L2 flows through L3, developing flux in the write head and causes the third consecutive cell in the track to become polarized to a logic 1.

The drum continues to rotate with the stored logic bits until the cells containing the stored logic pass under the read head for that track. As the cell containing the first stored logic bit passes under the read head, the read head develops flux according to the polarization of the cell. The flux of the read head causes current to flow through L4 and winding L5 of transformer T2. The current through L5 induces a current in half of L6, which is 180° out of phase with the current through L5. The current through half of L6 flows from ground to the set input of flip-flop no. 2, developing a positive pulse at the l-output of the flip-flop. This positive pulse appears at one input of AND no. 3. If the pulse appears at the same time a positive read timing-pulse appears at the other AND gate input, AND gate no. 3 produces a positive (logic-1) voltage pulse at its output.

As the next cell containing a stored logic bit appears under the read head, the read head develops a current according to the polarization of the cell. The induced flux causes current to flow through L4 and in turn, through L5, also inducing current in half of L6 which is 180° out-of-phase with the current through L5. Current in half of L6 flows from ground to the clear input of flip-flop no. 2, developing a positive voltage at the O-output. This positive pulse appears at one input of AND gate no. 4, while the positive read timing-pulse appears at the other AND gate input, causing a positive pulse to be developed at the output of AND gate no. 4, which represents a logic *o.*

The next cell, which contains the last bit of stored logic, induces a current in the read head, and causes current to flow through L4 and L5. Current is induced in half of L6, flowing from ground to the set-input of flip-flop no. 2, which produces a positive pulse at the l-output of the flipflop. The positive pulse appears at AND gate no. 3 with the read timing-pulse, producing a positive pulse at the output of AND gate no. 3, which represents a logic-l. The logic word of 101 is thus written into the memory drum and read-out as 101.

MAGNETIC DISC MEMORY

Application.

The magnetic disc memory is used in a computer to store a large quantity of binary information at medium access speeds.

Characteristics.

The magnetic disc memory resembles an automatic record player in appearance and operation.

Logic is stored on iron-oxide coated discs.

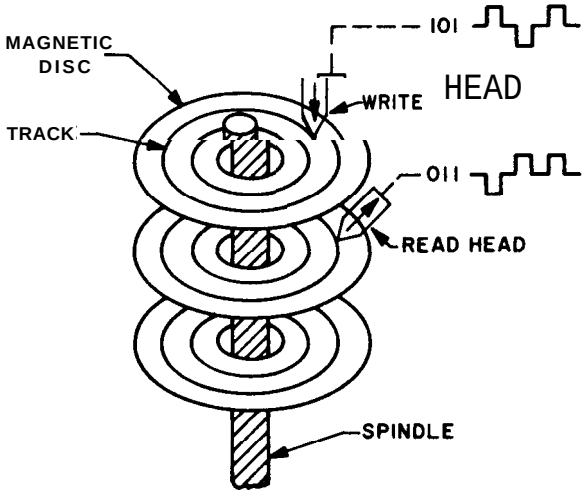
Logic is entered on and removed from the disc by writing and reading brush-type heads.

This memory is capable of storing up to 5,000,000 bits.

Circuit Analysis.

General. The magnetic disc memory consists of a number of vertically stacked iron-oxide coated discs which continually rotate. Each disc contains a number of circular tracks for storing binary logic. These circular tracks are similar to the spiral tracks of phonograph records. The track which contains a specific binary word is the address of word. A word is written on to a disc by placing a brush write head, to which the logic information is applied, directly on the specific track of a specific disc. As the disc rotates below the write head, the lines of force of the track change in accordance with current applied to the write head. The lines of force, and thus the logic word, remain on the track of the disc until the word is to be read out. At that time, a read head is placed on the track containing the logic information stored on the disc.

Circuit Operation. A pictorial diagram of a magnetic disc memory is shown in the following illustration. The metal oxide coated discs are stacked vertically on a rotating cylindrical spindle. Movable brushtype heads are placed on the tracks of discs where logic information is to be stored or obtained.



Magnetic Disc Memory

If a logic word of 101 is to be stored on the first track of the upper disc in the memory, a series of three current pulses (one positive, one negative, and another positive) are applied to a write head which is placed on the first track of the upper discs. The current flowing through the write head develops lines of force around a certain amount of the track, depending on how fast the disc is moving and how long the current pulse is applied. The first positive current pulse (1) applied through the write head develops magnetic lines of force in the portion of the track below the write head at the time the pulse is applied. Magnetic lines of force are not developed on the section of the track below the write head when the pulse ends. The second current pulse (0) applied through the write head is negative. This pulse also develop lines of force on the section of the track below the write-head. In this case, however, the magnetic lines of force are oriented in the opposite direction to those of the first applied pulse. The third current pulse applied through the write head is a (1) which is again positive. This pulse causes lines of force to be developed on the section of the track below the write head in the same direction as those developed for the first applied pulse. The disc then continues to rotate with the lines of force of oriented sections remaining on the disc until they are read out.

If a binary number of 011 is to be read from the first track of the second disc a read head is positioned on this track. As the first stored bit approaches the read head, the lines of force representing the bit, develop a current in the read head. This current is positive, since the lines of force were oriented to represent a logic 1. As the disc continues to rotate, the lines of force col!apse, representing the end of the logic pulse. The next stored bit is again a logic 1; the section of the track appearing below the head then has lines of force oriented in the same direction as the first bit lines of force. These lines of force end as the disc continues to rotate past the read head and represent the end of the bit, the third stored bit is a logic O; the section of the track now appearing below the head has lines of force oriented in a direction opposite to those developed for the two logic 1 bits. This concludes the reading out of the logic word stored on the first track of the second disc. This word has to be recentered into the memory if it is to be used again, since it is erased from the memory when read out.

MAGNETIC TAPE MEMORY

Application.

The magnetic tape memory is used in computers as an inexpensive method of storing extremely large amounts of logic information, but at the coast of long access time.

Characteristics.

The magnetic tape memory has a sequential and progressive type access mode.

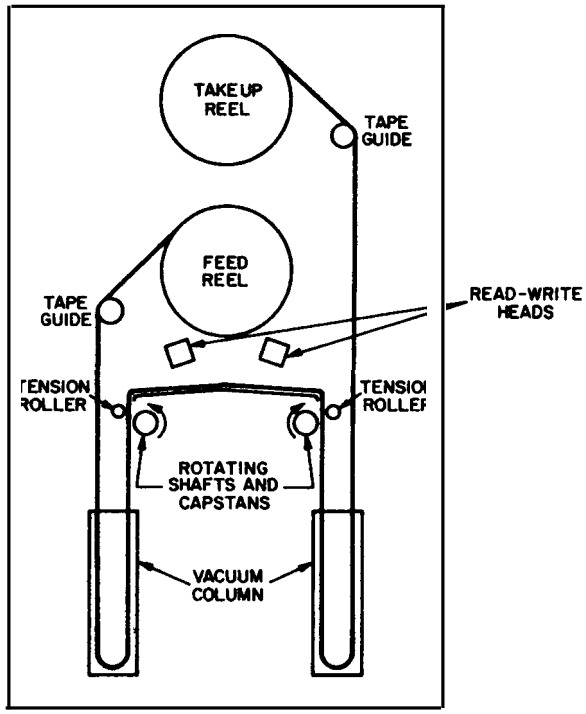
The logic information is erasible, but it is not removed when the power is shut off, and it will not fade away.

The magnetic tape memory provides only slow-speed, external storage and long access time.

Circuit Analysis.

General. The magnetic tape memory uses a unit similar to an audio tape recorder. The tape is passed across a set of read and write heads and is moved across the heads by means of rotating shafts and capstans. As the tape is moved across the heads it is wound around one reel and taken (unwound) from another reel. The magnetic tape memory, however, operates at higher speeds than audio tape recorders, and the memory tape is started and stopped much quicker. The tape used for a magnetic tape memory is, therefore, much stronger than audio tape, since it is exposed to the greater stress of rapid starting and stopping. The use of vacuum columns relieves some of the stress by providing several feet of slack as the tape enters and leaves the area of the heads. In this way, immediate movement of the tape occurs before the reels begin their rotation.

Circuit Operation. A pictorial drawing of a typical magnetic tape memory is shown in the following illustration. The magnetic tape is originally wound on the feed reel. The tape then extends around one tape guide, which keeps the tape taut and untangled. The tape is given slack but is prevented from tangling by its passage over a vacuum column. The tape passes over a rotating shaft and capstan, across the read and write heads, and around another rotating shaft. Depending upon which one of two tension rollers is pressed to the tape across from where a rotating shaft contacts the tape, the tape moves from feed reel to takeup reel or vice versa. The reel to which the tape is directed rotates, so that the tape is reeled in. After the tape passes over the second rotating shaft, it passes across a second vacuum column, across a second tape guide and on to the take up reel.



Magnetic Tape Memory

If a logic word of 100 is to be written into the memory, a negative current pulse (representing logic O) is first applied to the write head. As a result of the applied current pulse, the iron oxide particles on the portion of the tape appearing below the write head from magnetic lines of force, oriented toward one direction. The tension roller presses against the tape across from the point where the clockwise rotating shaft contacts the tape. As a result, the tape moves from the feed reel toward the take up reel. After the tape has moved a small distance, another negative current pulse (representing logic O) is applied to the write head, causing the iron oxide particles on the area of the tape now below the write head to become oriented in the same direction as the lines of force of the first bit. The tape continues to move from the

feed reel toward the take up reel. After the tape has again moved a short distance a positive pulse (representing a logic 1) is applied to the write head. The particles on the section of tape below the write head are now oriented along magnetic lines of force in an opposite direction to those of the first two pulses. The tape then continues to move from the feed reel to the take up reel until the tape is completely wound on the take up reel. When the logic word is to be read out, the tension roller pressed against the tape on the other side of the clockwise rotating shaft is released, and the other roller is pressed against the tape across from the point where the counterclockwise rotating shaft contacts the tape. The tape now rewinds on the feed reel from the take up reel. After most of the tape is wound on the feed reel, the roller accompanying the counterclockwise rotating shaft is released from the tape and the other tension roller is again pressed against the tape across from where the clockwise rotating shaft contacts the tape. The tape then moves from the feed reel to the take up reel across the read and write heads. If the read head is activated as the magnetized sections of tape pass by the heads, currents are induced into the read head from the magnetized particles on the tape. The first section of magnetized tape represents a logic O. As this section of tape appears under the read head, a negative current pulse is induced into the read head. As the second section of magnetized tape, representing a logic O, appears under the read head, another negative current pulse is induced in the read head. The remaining section of magnetized tape represents a logic 1. In this case, a positive pulse is induced in the read head as that section of tape appears under the read head. The current pulses read out of the memory then represent the logic word of 100. It should be noted that the last bit of a logic word is written in last and is read out of the memory first, and the first bit of the logic word is written in first and read out of the memory last.
