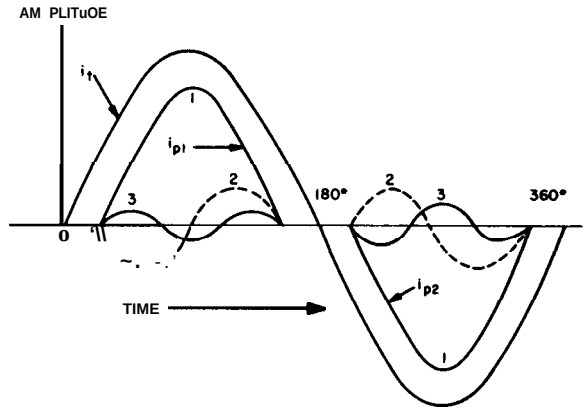
obtained. When r-f excitation is applied to coil L1 a similar r-f voltage is induced in tank coil L2. Since the center tap of L2 is bypassed to ground for rf it is effectively at r-f ground potential (zero voltage) and the ends of the coil to which the grids of V1 and V2 are attached are at equal and opposite r-f potentials. When a positive voltage appears on the grid of Vl, a negative voltage appears at the grid of V2. With a balanced input the voltages are of equal amplitudes and of opposite polarities. Grid tank capacitor Cl tunes the input tank to resonance at the frequency of the drive voltage. The maximum current flows in the closed tank circuit, and maximum drive voltage is developed across the parallel-connected tank and applied to the grids. Assuming a sine wave exciting signal going positive on the grid of V1, the grid of V2 is driven further negative into cutoff and no plate current flows in V2. As long as the signal on VI grid is below the cutoff level no current flows in V1 also, and both tubes remain cut off. As the positive-going input signal rises above the bias level on VI, the tube is eventually driven into conduction, and plate current flows. Since the tubes are fixed biased beyond cutoff, plate current flows only during the time the grid is above cutoff, or for about 120 degrees of the positive half cycle of excitation signal. As the positive grid voltage increases, plate current increases, reaching its peak at the same time the excitation voltage reaches its crest. At the beginning of the conduction cycle the grid voltage is only sufficiently positive to reduce the fixed bias voltage so that the effective bias is just above cutoff (but still negative). However, as the amplitude of the drive voltage increases, the grid is driven to the zero bias level and then positive. At or near zero bias grid current also begins to flow, increasing to its peak value at the crest of the cycle. Grid current flow is from the cathode of V1 to the grid, through coil L2 and the center tap to grid resistor R1, then to the bias supply and ground. In flowing through Rl, a negative voltage is developed across R1 which adds to the instantaneous bias. The value of RI is chosen so that the maximum desired bias is produced with a specified grid current drive before the crest of the cycle is reached, with light saturation for Class B amplifiers, and with heavy saturation for Class C amplifiers (see Single-Ended (Class B or C) R-F Power Amplifier circuit in this section of the handbook for an explanation of saturation, and the introduction to this section for a discussion of signal bias).

When plate current flows in V1 there is a flow of electrons from the cathode through the grid wires to the plate, and from the plate through the top half of tank coil L3, out the center tap to the plate supply and ground. Current flow through half of L3 produces an electric field around the coil (which acts as the primary of a transformer), and the magnetic lines of force link output coil L4 (which acts as the secondary) inducing an output voltage in it. At the same time, the field around the lower half of L3 induces a voltage which is in a direction to continue current flow through L3. This induced current charges the lower half of split stator capacitor C5 negatively, while the upper half of the capacitor is charged positive. The effect is the same as if the split capacitor were a single capacitor connected across L3 with the upper plate positive and the lower plate negative. Since tank L3 and C5 are parallel resonant at the output frequency, a circulating current is built up within the tank which continues to oscillate back and forth. Reinforced first by V 1, and then by V2 as it operates. The resonant tank selects the desired output frequency and discriminates against any harmonics which also tend to develop across the tank impedance. The tank impedance is a maximum at the fundamental output frequency and very low at any of the harmonic frequencies. Thus maximum voltage is developed across the maximum impedance presented at the desired fundamental frequency. The tank coil also acts as a tapped autotransformer with a turns ratio of one half to one (2 to 1). Since transformer impedance always varies as the square of the turns ratio, it presents a load impedance to the single tube of one quarter the plate to plate load impedance. At the positive crest of the drive cycle the voltage drop across the tank impedance is maximum and causes the effective plate voltage to be at a minimum value. At this time the tank is absorbing, or being charged with r-f energy, and only a small amount is applied to the plate for dissipation in the form of heat. This is the most efficient part of the operating cycle.

As the excitation voltage passes the crest and reduces the amplitude it becomes negative going. The effective bias becomes more negative and plate current flow is reduced. This action continues until zero bias is reached and grid current flow, likewise, reduces and ceases. From here until cutoff the plate current continues to reduce, and ceases when cutoff bias is reached. While the plate current is reducing, it induces a tank current flow in the opposite direction

causing the tank capacitor to discharge. This discharge continues beyond cutoff when both VI and V2 are non-conducting, and is the so-called "flywheel" effect of the tank, which continues to supply an r-f output even though neither tube is operating. When the positive half cycle of drive is completed, the negative half cycle starts, the grid of V1 is driven further into cutoff and is held inoperative for the remaining portion of the half cycle.

V2 grid is now being driven positive by the negative half-cycle of input signal. (The input signal is inverted by the push-pull input tank.) During the negative half-cycle, tube V2 is made to operate exactly as described above for VI. The effective bias is reduced until plate current flows, and as the bias decreases grid current flow starts near zero bias, reaching its peak at the negative crest of the drive signal (the grid voltage applied V2 is positive). Plate current flow through V2 and the lower half of the tank coil, now flows in the other direction and charges C5 in the opposite direction to the previous half-cycle of operation. Actually, operation is only over 120 degrees as mentioned before, and the tubes are quiescent over 60 degrees of the 180 degree half-cycle. Thus it can be said that the tank alone supplies energy for a total of 120 degrees, and the tubes for 240 degrees out of a single cycle of operation. Operation of V2 is identical in every respect with that of V1, their currents and voltages are, however, 180 degrees out of phase, but there is no canceling effect since each tube operates separately. The tank circuit, meanwhile, continues to oscillate first in one direction for 180 degrees and then in the other direction for the remaining 180 degrees of the complete cycle, being reinforced each half-cycle by a different tube. Output coil L4 supplies a continuous r-f output to the antenna or transmission line from the tuned tank circuit to which it is inductively coupled. Since the tank is tuned to the fundamental frequency, even harmonic content is almost entirely cancelled in the secondary (L4) since equal and opposite voltages are produced. The closer the circuit is to a balanced condition the more nearly is the even harmonic output reduced to zero. Since the odd harmonics occur in-phase a small amount also appears in the output. The amount is dependent upon the impedance the tank presents to odd harmonics. Usually it is so small as to be considered negligible. However, in extremely high powered stages (megawatts) this output may be on the order of tens of watts (or more) and require extra filtering to prevent it from being radiated on the undesired harmonic frequency. The manner in which the tank current and the fundamental and harmonic plate current components vary is shown in the accompanying figure to illustrate the manner in which the even harmonics are cancelled.



Tank Current Versus Fundamental and Harmonic Plate Currents

The instantaneous tank current varies continuously throughout the cycle flowing first in one direction (shown as positive) and then flowing in the opposite direction (shown as negative). During a portion of this time i_{P1} and i_{P2} (curve 1) flow alternately as V1 and V2 operate. Any second and third harmonic currents flow as shown in curves 2 and 3, respectively. Since the second harmonic current is always out-of-phase with the fundamental plate current it cancels out. The third harmonic current (curve 3) in in-phase more than it is out-of-phase, therefore, a small amount of odd harmonic distortion remains in the output. The selectivity of the output circuit also helps discriminate against any harmonics, since the impedance it offers to these frequencies determines the output amplitude, and most output circuits are resonant at the fundamental frequency.

With the grid V1 and V2 cross connected to the opposite tube plate through neutralizing capacitors C3 and C4, equal and opposite feedback voltages are applied which cancel out any in-phase plate to grid feedback and prevent the stage from going into self-oscillation. The additional capacitance added by the neutralizing circuit reduces the input impedance,

hence, triodes are only used when necessary, or the push-pull grounded-grid circuit is used instead. The use of a well shielded tetrode or pentode makes neutralization unnecessary, because the plate and grid are shielded from each other by the screen grid and its associated bypass capacitor, which hold the screen at r-f ground potential. The low excitation requirements of the tetrode or pentode makes them especially suitable for use in the intermediate stages of a transmitter. When the power used by the screen grid is considered, however, the overall efficiency of these tubes is not as great as the triode. Because of the easier drive requirement and the lack of neutralization provisions, the tetrode, or beam power tube is generally favored over the triode. Particularly in band-switching transmitters where a neutralizing adjustment is not required for each band.

Failure Analysis.

No Output. Loss of excitation (drive), bias, supply voltage, or defective tube(s) can cause a no-output condition. If input coil L1 is open, no drive will be obtained and the tubes will rest in the cutoff condition. Lack of both grid current and plate current will be indicative of this condition. Check L1 for continuity with the POWER OFF. If drive is present in L1, but L2 is open, or C 1 is shorted or nonresonant, a similar condition will exist. If L2 is open the symptoms will be the same as when L1 is open. However, if Cl is shorted no drive will appear on VI or V2 grid and the fixed bias supply will be grounded through RI. Usually extremely heavy grid current will flow and R1 will heat, may smoke, and will eventually burnout if the condition is prolonged. Meanwhile, the plate current will also be extremely high because of loss of bias and will usually blow the plate fuse or open the plate circuit breaker, if provided. The same symptoms will occur also if grid bypass capacitor C2 is shorted. Check VI and V2 grids with a voltmeter for the proper negative bias. If L2 is not open and C 1 or C2 is not shorted the proper dc bias will appear on both tubes (make this check with driver plate voltage OFF, otherwise, r-f drive may burn out the meter). If Cl is not tuned to resonance, sufficient drive may exist to produce a low output, but normal loading and output will not be obtained. Normal bias voltage also indicates that both neutralizing capacitors C3 or C4 are not shorted. When either C3 or C4 are shorted, plate voltage will be applied to the grids of both VI and V2, cause heavy plate current, and blow the fuse or breaker.

When the loss of output is caused by lack of plate voltage it may be due to shorted plate bypass C6, or defective power supply, shorted tank capacitor C5, or defective tube(s). Check the supply voltage first with a voltmeter, be certain to observe all safety precautions since the plate voltage is dangerously high. Make certain that the transmitter plate switch is OFF when checking the supply. If either C5 or C6 is shorted and the supply is good the plate fuse or breaker will operate, and high plate current with normal or slightly higher than normal grid current indication will be obtained momentarily. Usually C5 can be checked visually since arcing will occur as the rotor is varied throughout its range and whenever it touches or moves too close to the stator. If not, make certain the plate voltage is removed, and use a shorting stick to discharge the capacitors in the plate circuit. Disconnect plate bypass capacitor C6 and check continuity to ground with an ohmmeter, no continuity should exist and resistance should be infinite. Then disconnect C5 and L3, and again check for continuity to ground. With the tank disconnected check the plates of VI and V2 to ground; any resistance other than infinity probably indicates a defective tube. Note: be certain to observe the polarity of the ohmmeter so that a negative potential is applied from plate to ground. Otherwise, if the plate is made positive and the tube filament is operating there will be a flow of current, and a false resistance-to-ground reading will be obtained. Check output coil L4 for continuity at the same time to avoid making a later check.

If proper grid current indication is obtained, but a very low plate reading (or a high plate reading) rapidly tuned C5 back and forth to determine if a minimum dip indicating resonance can be obtained. With a sharp minimum and a reduced plate current either L4 is open, and load is not connected, the drive is too low, or L4 is not coupled sufficiently close to tank coil L3. In the case of heavy plate current and broad dip, usually some output will be obtained, and too large, or an overcoupled load is indicated.

Use of grid and plate meter indications, plus the tuning of Cl and C5, should be made to determine whether normal currents and tuning are obtained, since these offer a quick means of trouble-shooting. In most instances, moderate and high power transmitters and tanks are constructed mechanically and

electrically rugged so that visual observation will locate grounded parts (usually some sign of an arc such as charred insulation or a black spot will mark the point of improper grounding due to the high voltage and currents involved).

In the event of tube trouble, usually both tubes must be defective to cause no output in a push-pull circuit, since the stage is capable of operating at reduced output with only a single tube.

Reduced Output. Low drive, grid bias, or plate voltage, as well as a defective tube can cause a reduced output. Low drive will be indicated by a low grid current reading usually with reduced plate current, and output. Low grid bias will usually cause operation in the Class A or AB region with a higher than normal plate current. Check the bias with a voltmeter from the junction of C2 and Rl to ground; this will indicate the sum of both the fixed bias and the signal bias, and should be made with C 1 tuned to resonance and normal grid current. Closer coupling between L1 and L2 will increase the drive if necessary. If the plate current suddenly increases and the output reduces, particularly during voice modulation (or while being keyed off and on), improper neutralization can be suspected. Remove the plate voltage and tune tank capacitor C5 through resonance, the grid current indication should hardly change as resonance is passed. If it flicks sharply, adjust C3 and C4 in small increments, simultaneously, first in one direction and then in the other. No change in grid current will be observed at the point of proper neutralization.

Normal plate voltage and loading accompanied by reduced plate current indicates the possibility of low tube emission. If plate voltage is low with normal load the power supply rectifiers are probably in need of replacing. A dynamic check on the power supply can be made by quickly detuning and resetting C5 to resonance. The heavy off-resonance current should not cause the plate voltage at C6 to drop more than approximately 25 or 30 volts. If it does, the power supply regulation is poor. A poor soldered joint or bad connection can introduce a high resistance in the plate circuit and cause a reduction in applied plate voltage with a low plate current indication. To check this, remove plate voltage from the driver AND finally, discharge the filter capacitor with a shorting stick, and check the resistance between the tap on L3 and the plates of V 1 and V2. Indications should be zero or a few tenths of an ohm.

TRAVELING-WAVE TUBE R-F AMPLIFIER

Application.

The traveling-wave tube r-f amplifier is used at super-high frequencies as an untuned r-f amplifier (or mixer) in microwave receivers, as a linear amplifier in transmitters, and in test equipment. Its broad-band characteristics make it particularly useful for high-band television and electronic countermeasures (ECM) applications.

Characteristics.

Range of operating frequencies is from approximately 200 MHz to 15,000 MHz.

Efficiency varies from 10 to 40 percent.

Power handling capabilities vary from as low as 100 microwatt to 1 kilowatt for continuous-wave emissions. Peak power capabilities for pulsed operation extend up to 50 kilowatts.

Power gain in a single tube varies from 20 to 60 dB maximum.

Noise figures from 5 dB to 30 dB can be obtained, depending on the frequency (increases with frequency, but not linearly).

Uses positive bias and high voltage to control emission of an electron gun.

Amplifies by virtue of a distributed interaction between an electron beam and a traveling wave.

Is a nonresonant device inherently capable of enormous bandwidths.

Usually employs magnetic focusing of the electron beam; however, electrostatic focusing is sometimes employed.

Circuit Analysis.

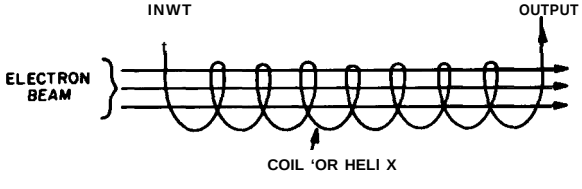
General. Traveling-wave tubes are used for both large and small signal applications; each tube is rated for a specific power-handling capability over a certain frequency range. They supplement the presently available microwave tube types, such as planar triodes, klystrons, and magnetrons. They are particularly useful for wideband applications where a large range of frequencies must be covered. Since the tube is completely self-contained and nonresonant, it has no bulky cavities or large magnets to pose a design problem. Either coaxial or waveguide input and output fittings are provided, depending upon the frequency range in use, so that only filament and collector power are needed in addition to the input and output leads to provide an operating amplifier.

Although the traveling-wave tube has high gain and is easily tuned by changing the collector voltage, it possesses noise characteristics that are somewhat less desirable than those of some of the other types of microwave tubes. Recent improvements along this line have produced noise figures of 6 dB at 3000 MHz and 11 dB at 10,000 MHz or better, as compared with 30 dB for the early versions. The 6-dB figure is approximately the same as that obtained with a crystal mixer. It is well known that crystals are easily damaged by r-f energy. However, the traveling-wave tube is not so easily damaged since an input over-load will merely cause saturation (instead of burnout as in the case of the crystal); hence, with this tube, a simpler duplexing system maybe used.

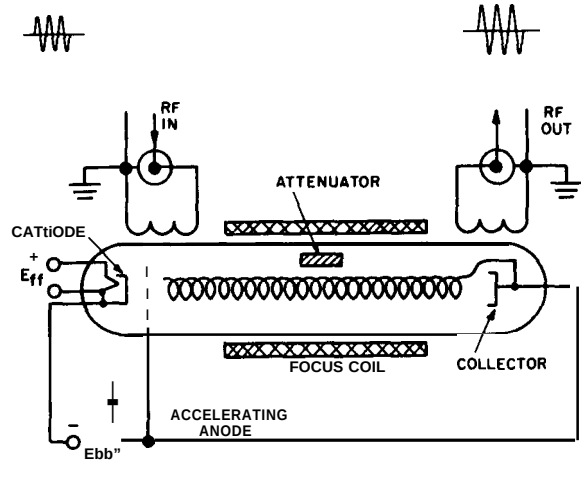
Circuit Operation. The accompanying figure shows the essential elements of a traveling-wave tube. These are a long, narrow electron beam and a circuit capable of sustaining a slow electromagnetic wave with a longitudinal component of electric field, which can travel along in synchronism with the beam. The slow-wave circuit usually consists of a helix or long coil of wire. In such a circuit the wave travels along the wire with approximately the speed of light. If the length of the wire is 13 times as long as the axial length of the coil or helix, the wave will travel along the electron beam at one-thirteenth the speed of light, and the electrons in the beam, passing through the center of the coil, will be in synchronism with this slow traveling wave if they are accelerated by about 1500 volts. The speed of the electron beam is controlled by the potential applied to the accelerating anode. Since the helix is connected to the collector at the end opposite the cathode, the helix also serves as an additional accelerating anode. An axial magnetic field is used to focus the electron beam, to keep the beam from spreading and to guide it through the center of the helix.

When the electrons travel along in synchronism with the slow wave, there is a cumulative interaction which results in amplification of the traveling wave. At wavelengths of around 10 centimeters, the power gain may be of 1000 to 10,000 times or even greater, in a distance of 10 inches. Because no resonant circuits are involved, the traveling-wave tube is inherently broad-band; substantial gain has been obtained over bands of thousands of megahertz and of several octaves. Waves traveling backward, against the electron stream, are practically unaffected by its presence. To make a stable and useful amplifier, attenuation of the backward wave must be added in the slow-wave circuit. Usually, it is lumped near the center of the tube, and introduces a loss to the backward wave which is much greater than the amount by which it reduces the forward gain. The necessity for the attenuator and its reduction of forward as well as backward gain is a basic limiting parameter, which hinders high-power tube development.

The following figure illustrates a typical traveling-wave tube amplifier using a solenoid type of magnetic focus coil. The electronic beam is obtained from a PIERCE electron gun, which produces a series of essentially parallel-path electrons. The tendency of the parallel electrons to be deflected or to stray from the parallel path is overcome by adding a solenoid on the glass envelope of the tube whose axis is in the longitudinal direction. The focusing field of the solenoid deflects any stray electrons back into the electron stream so that ehy must travel through the center of the helix.



Basic Traveling-Wave Tube Elements

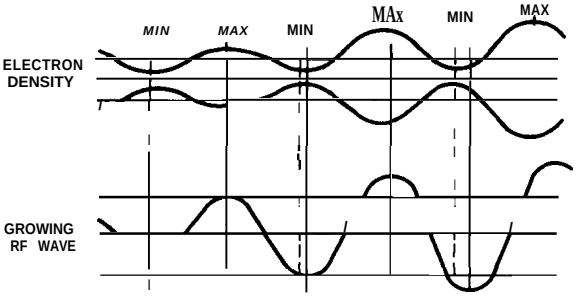


Typical Traveling-Wave Tube Amplifier

The r-f input signal is fed into the helix at the cathode end of the tube, while the r-f output signal, is taken from the opposite end of the tube, near the collector (or anode). The accelerating anode creates the initial electric field which attracts the electrons from the cathode, while the collector (or anode) serves to collect the spent electrons after they have passed through the helix, and return them to the power source. The helix is connected to the collector internally, and also acts as an accelerating anode for the electron beam. The r-f signal is coupled to and from the helix inductively. There is no direct connection between the helix and the input and output circuits. The helix consists of a continuous spiral of wire or strap 10 to 12 inches in length, whose natural resonant frequency is much lower than the range of operation so that it acts as a nonresonant device. The purpose of the helix is to provide a path for the input signal in proximity to the electron beam so that interaction can occur between the beam field and the signal fieid. When the r-f input signal is induced on the helix, a conductive path is provided by the helix from the cathode end to the collector end of the tube, through which the r-f signal current flows. Signal current flow induces a field around the helix which travels with the signal from input to output; thus, a traveling wave is produced along the helix. While the electron beam and r-f signal both travel at the speed of light, the path around the helix is longer. Therefore, the signal field progresses from turn to turn through the helix at a much slower speed than the electron, which travels through the center of the helix and follows the shorter direct path between cathode and collector.

When the input signal field opposes the field of the electrons passing through the center of the helix the electrons are decelerated, and are overtaken by other electrons. During the time the beam electrons are decelerated, they relinquish kinetic energy to the field of the r-f signal, and tend to form in bunches. When the signal field increases, it enhances the electron field and accelerates the electrons, and energy is transferred from the r-f field to the electron field. As the signal field and electron beam progress through the tube, more bunching occurs. Thus, more electrons are available to give up kinetic energy while a particular bunch is passing through a decelerating field. Since more time is spent by an electron in a decelerating field than in an accelerating field, it gives up more energy to the r-f field than it receives. Thus, as the signal progresses along the helix, it increases in strength, and is amplified.

No energy transfer is possible until electron bunching commences. As bunching increases, the signal amplitude increases and causes even greater deceleration of the electrons (in the following bunch). This causes the signal strength to increase exponentially, as shown in the accompanying illustration. Eventually, a point is reached at which the electrons in the bunches are slowed to the extent that they are no longer in synchronism with the signal field. At this time the forward speed of the beam electrons and that of the signal are no longer near the same value, and the efficiency drops.



Development of Growing Wave

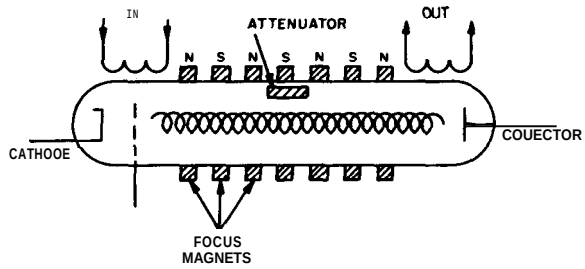
Operation of the traveling-wave tube is sometimes explained on the basis of a total of four waves existing within the tube, three forward waves and one backward wave. The three forward waves are the result of the division of the input into three components, each with an amplitude of one-third the input strength. The first wave (which is the one we have been discussing) travels more slowly than the electron beam, and increases in strength. Another wave also travels at this same speed and diminishes in strength (as it gives up its energy to the first wave). The third wave travels at the fastest speed, faster than the electrons, and maintains a constant strength. The resultant of these three waves is the constantly growing signal or output.

The gain of the traveling-wave tube is also affected by the input and output coupling circuits. For amplifying a wide frequency band, high gain can be maintained by changing the helix voltage with frequency to maintain the necessary synchronism between the

helix velocity and the beam velocity. In addition, the maximum output power depends upon the input (drive) power, and the power-handling ability of the helix. The amount of power in the beam input power is a factor. Also, since the output end of the helix is heated by r-f currents and electron bombardment, if the beam disperses before passing the output end, the power-handling ability of the helix is another factor. Dispersement of the beam and bombardment by beam electrons can be caused by a maladjustment of the magnetic focusing field. Since a helix mounted in glass has a low heat-dissipating ability, the power output at the present state of the art is limited to values less than 100 watts unless special cooling systems are employed. High-power tubes use either water or forced-air cooling.

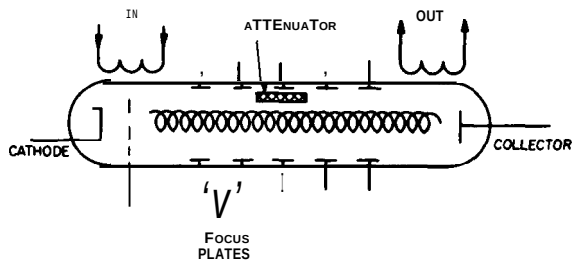
The thermal noise of the electrons in the beam affects the noise figure of the traveling-wave tube amplifier, just as it affects the noise figure of other types of amplifiers. The noise signal is induced onto the helix and is amplified in the same manner as any other signal. Lowering the operating voltage will generally result in a slower beam velocity and less thermal noise. If the gain per unit length is low, less noise amplification will also occur; tight focusing of the beam will also produce less noise. Uneven cathode emission, particularly from an aging tube, will produce a nonsymmetrical beam and noise, as will ion movement caused by gases within the tube. When the signal injection point is properly spaced from the end of the electron gun, a reduction in noise occurs because of certain periodic fluctuations in noise current within the tube. Thus, injection of the signal at a point of low noise current results in a greater signal-to-noise ratio.

When the long solenoid focusing coil of the traveling-wave tube is replaced by a series of small coils spaced along the tube, as shown in the accompanying illustration, less energy is required to focus the electron beam, and tighter focusing is achieved. The same effect is produced by using a series of permanent magnets to produce a periodic magnetic field. These types of tubes are called PPM (periodic permanent magnet) traveling-wave tubes. Better over-all efficiency is obtained, since the loss of beam current through dispersion of stray electrons is prevented.



Periodic Electro Magnet Focusing

When a series of opposing electrodes.or plates are placed along the tube inside the glass and connected to a dc source as shown in the accompanying illustration, an electrostatic field is produced between the electrodes. This is similar in all respects to the magnetic field produced by the solenoid or the periodic permanent magnets. Focusing in this instance, is done electrostatically, and no change in operation occurs. Because the construction of this tube is more difficult and more expensive, and since the performance is about the same, the electrostatic type of traveling-wave tube is seldom used.



Electrostatic Focusing

The attenuator which prevents the backward wave from causing oscillation and loss of amplification is provided by spraying a resistive film (produced by an aquadag solution) on the helix and tube envelope at

the proper location. In a high-power tube the attenuation is concentrated near the center of the tube, while in a low-power tube it is usually not more than one-third the distance from the cathode.

Whife more could be said about the various phases of design, the discussion above is sufficient to acquaint the reader with the primary functioning of traveling-wave tubes. Since the tube is a freed package, there is nothing the electronic technician can do to change its operation. of course, faulty operation can result from incorrect connections or operating voltage and polarities. Therefore, further discussion at this time is unnecessary. Additional data can be obtained, when desired, by reference to other texts or to manufacturers' information sheets.

Failure Analysis.

No Output. Lack of input signal, an open output circuit, or a lack of filament or plate voltage can cause loss of output. Use a voltmeter to determine whether the fdament and plate voltage are correct. WARNING: ***High plate voltage*** exists between the collector and ground; be certain to observe ***all safety precautions*** when measuring this voltage. Since the cathode is usually connected to one side of the filament, measure the fdament voltage *only* when *the plate voltage is off.*

The input and output circuits can be checked for continuity with an ohmmeter, with the power off. If the external circuits appear to be satisfactory, use a signaf generator to supply an input to determine whether there is loss of input signal. Likewise, in the output a dummy load may be substituted. If the input and output circuits are apparently satisfactory and proper electrode voltages are applied, a no-output condition will probably indicate a defective tube.

Low Output. Low output can be caused by improper plate or filament voltage, low drive, or a defective tube. Check the plate and fdament voltages, observing all safety precautions. In transmitting applications, insufficient r-f drive will cause reduced output. In the special case where sweep voltages are used to tune automatically over a band of frequencies, it is important that the drive waveform and sweep waveform be of the shapes and amplitudes specified; otherwise, reduced performance will occur. Low tube emission can sometimes be found by noticing that the output fluctuates in amplitude and that a high noise is developed in the output. The beam current in this case will be reduced, and low output will occur. Unfortunately, other conditions, such as load reflections or a change in accelerating voltage or collector voltage, will also change the beam current. Where solenoid focusing coifs are used, lack of sufficient field will also cause a reduction in the beam .current, and can be caused by a defective coif, low focusing voltage, or loss of power to the coil. In this case, the focus supply can be checked with a voltmeter and the resistance of the coif determined by means of an ohmmeter, with the power off. Comparison with a good coil will indicate whether the resistance is high, low, or normal.

Because of the few parts involved, usually a voltage check, a waveform check, and a beam current check are the only simple checks possible. In tubes having a low noise figure, disconnecting the antenna from the input in receiving applications will reduce the noise, and serve as a rough indication that the tube is functioning. However, in tubes having high noise figures this change may be masked by the tube noise. Thus, a more positive check is to insert a signaf from a known source and determine whether normal amplification is obtained. A change in load should also cause a change in beam current, as should a change in focusing-magnet current.

In the case of overdrive, increased current usually occurs, followed by a reduction in output as the collector is heated by electron bombardment. Once saturation is reached, no further increase in current occurs as the drive is further increased; this indication can sometimes be mistaken for reduced output.

MULTICAVITY KLYSTRON R-F AMPLIFIER

Application.

The multicavity klystron r-f amplifier is used to supply high r-f power to the transmitting antenna of television, radar, microwave, and electronic countermeasures equipment operating in the VHF, UHF, SHF, and EHF regions.

Characteristics.

Uses a positive grid voltage.

Uses a number of cavities tuned .to the same frequency for narrow-band operation (synchronous tuning), or is stagger-tuned to different frequencies for wide-band operation.

Power gain is on the order of 30 to 50 dB.

Power-handling capabilities range from microwatt

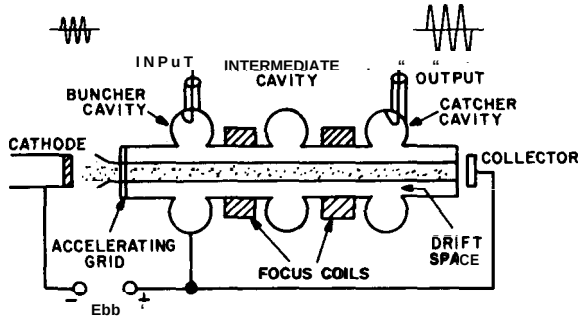
in receiving or test equipment applications, to the tens of megawatts in transmitting applications.

Efficiencies of 40 to 50 percent are possible.

Uses velocity modulation of an electron beam to form electron bunching for amplification.

Each cavity provides additional amplification, and extremely high gain is thus obtained.

External magnetic beam-focusing is usually employed to improve efficiency.



Simplified Klystron Multicavity Amplifier

Circuit Analysis.

General. The basic multicavity klystron consists of an electron gun, an input (buncher) cavity, an output (catcher) cavity, and a collector anode. The cavities may be integral within the tube or constructed externally so that the tube can be inserted within them. A focusing coil arrangement is usually included to prevent divergence of the electron beam, loss of electrons, and consequent ieduction in efficiency. Any number of cavities can be used by increasing the tube length, as long as the transit time across the lips of the cavity is short as compared with the wavelength of the signal. The high-power klystron operates at voltages of 25 to 100 kilovolts or more, and the current is in terms of amperes or tens of amperes, rather than milliamperes. The unit is usually shielded as a protection against high voltage, and special lead shields minimize the X-radiation produced as a consequence of the high electron voltages used. Since the physical construction of the various tubes available are slightly different for different manufactures, the following discussion applies generally as far as basic theory is concerned. The effects of cavity shape and construction, windows, and apertures or coupling loops are generalized so that the discussion will be applicable to most types of klystrons. Moderate-power tubes use forced-air cooling, while the high-power units use hollow water jackets with forced-water circulation to provide artificial cooling.

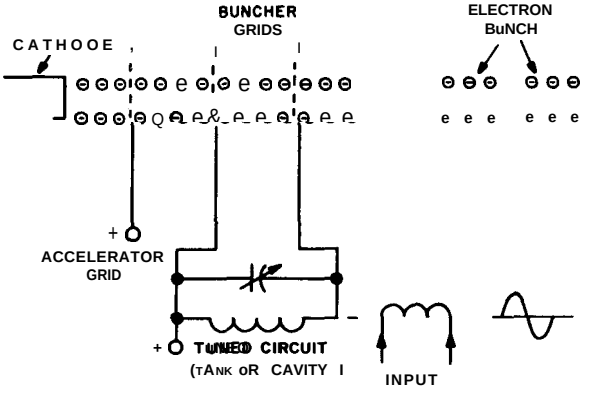
Because of the noise produced by the electron beam (noise figure averages 25 dB, the multicavity klystron is normally used for transmitting applications instead of receiving applications. While feedback can be employed between the cavities to provide oscillation, the multicavity klystron is generally used as a linear r-f amplifier, being driven by a lower-power klystron or a traveling-wave tube.

Circuit Operation. The simplified schematic of an elementary multicavity klystron is shown in the accompanying illustration.

At the left is the cathode of the electron gun, from which the long electron beam is accelerated, and at the right is the collector, which finally collects the beam. The electron beam first passes through the input resonator. The input signal produces a longitudinal electric field across the part of the resonator through which the beam passes. This field alternately retards and accelerates the electrons passing through the resonator. The retarded and accelerated electrons all travel along through the drift space between the cavities. There, some of the accelerated electrons catch up with some of the retarded electrons which left the input resonator earlier, so that bunches are formed. These bunches are composed of electrons, which pass through the input resonator while the field was changing from retarding to accelerating. These bunches eventually pass through the output resonator (or catcher) and induce a current from which the output is derived. In the 3-cavity klystron, an intermediate resonator is placed between the input and the output cavities to provide, in effect, a two-stage amplifier in one tube envelope. The bunched electron beam produces a field across the intermediate resonator, and this again retards and accelerates the beam (that is, velocity-modulates it anew). In tubes for very broad-band operation, several intermediate resonators may be used.

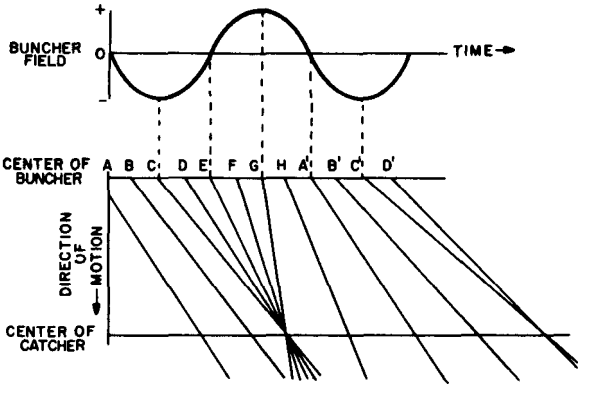
The manner in which the eiectron beam is formed and bunched can be understood by following the action step by step. The initial electron beam is produced by a Pierce-type electron gun. The electrons emanate from a flat cathode under the attraction of a positive accelerating field produced by an accelerating

grid located near the cathode (between it and the input resonator). This electrode is shaped to permit passage of the electrons through a small orifice. In low-power guns the electrode may contain an actual grid structure through which most of the electrons pass without hindrance and from an essentially parallel-path beam of electrons. The tendency of these electrons to expand around the axis of the beam and disperse is corrected by a magnetic field placed along the axis of the tube by a focusing coil (permanent magnets are also used). Any electrons which tend to fly off at a tangent, or in a radial direction, are forced back into the beam path by the parallel flux lines from the coil. In extreme cases they cause the recalcitrant electrons to follow a spiral path back to the axis of the beam. The parallel beam of electrons, all traveling at the same speed, passes through a pair of buncher grids, as shown in the accompanying illustration. Each of the buncher grids is connected to one side of a tuned circuit (cavity). (The tuned circuit and the buncher grids are at the same dc potential as the accelerator grid.) The input signal is usually inductively coupled into the tuned circuit or cavity, and produces an ac field between these grids. Assuming a sine-wave input, when the buncher grid closest to the cathode is positive, the buncher grid farthest away is negative. These voltages add to or substract from the applied dc accelerating voltage. Therefore, the alternating (signal) voltage between the buncher grids causes the velocity of the electron leaving the buncher grids to differ, depanding upon the time at which each electron passes these grids.



Electron Gun and Buncher Grids

An electron that passes the center of the buncher cavity at the same time the input signal is passing through zero leaves the buncher at the same velocity at which it entered (since no change in accelerating potential occurs). The position of the electrons plotted against time is shown in the following Applegate diagram, which indicates how bunches are formed. The slope of the lines in the figure represents the velocity of the electrons.



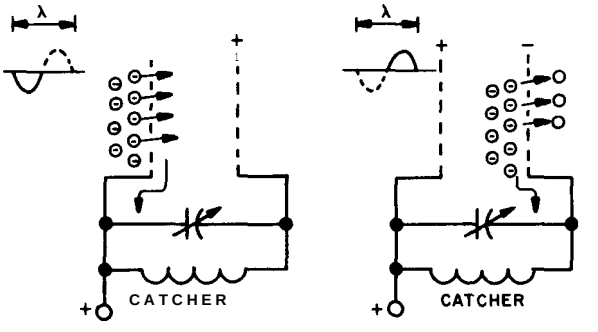
Applegete Diagram of Electron Bunching

Electrons which pass the center of the buncher a few electrical degrees earlier than the point of zero voltage (such as at C and D in the diagram) encounter a negative opposing field, and leave the buncher with reduced velocity, since the decreased voltage of the buncher slows them up. Electrons which pass a few electrical degrees after the instant of zero voltage, as at F and G in the diagram, leave with increased velocity since the buncher voltage is now slightly higher than the voltage of the accelerator grid (positive signal adds to positive electrode voltage). In the field-free drift space between the buncher and the intermediate cavity, faster electrons F and G catch up with electron E, which previously passed the bunch with no change in velocity. Slower electrons C and D lag behind, and hence draw near to E. At some point between the two cavities, electrons C, D, E, F, and G draw close together in a group. Now consider electron A', which leaves the buncher a half-cycle later than E. In this case its neighboring electrons draw away, since H is slightly slower and-B' will be slightly faster. Consequently, the electron stream along the tube consists

of electron bunches separated by regions in which there are few electrons. From the diagram, it appears as though bunching occurs in the first half-cycle of operation. Actually, bunching really occurs two or three cycles later in the relatively free drift-space between cavities. Also, bunching occurs twice in the three-cavity klystron (once between the input and center cavities, and once again between the center and output cavities). Since it is less complex and somewhat easier to understand, this diagram is used to emphasize bunching action, although it really is a representation of a two-cavity klystron with the retardation and acceleration of electrons overemphasized by using a much greater electron-line slope than actually occurs.

Since a continuous stream of electrons enters the buncher grids, the number of electrons accelerated by the alternating (signal) field between the buncher grids on one half-cycle of alternation is exactly equaled by the number of electrons which are decelerated on the other half-cycle. Therefore, the net energy exchange between the electron stream and the buncher is zero over a complete cycle (assuming a sinusoidal signal), except for any losses that occur in the tuned circuit or buncher cavity. As the electrons travel down the tube, they pass through the intermediate cavity grids and induce an oscillation into the middle cavity. Thus, an ac potential similar to the input signal is produced between the middle cavity grids. When the middle cavity is tuned to a frequency slightly higher than that of the buncher cavity, it presents an impedance with an inductive component. This provides a phase relationship between the cavity voltage and the electron stream which causes further velocity modulation of the electron stream. In this case, since the cavity is a high-Q resonant circuit, it causes a voltage build-up which is larger than that of the input signaL Therefore, the electrons are again bunched; this time they are formed into denser bunches, and the free electrons between the bunches are still further reduced (some are absorbed into the new bunches). The new bunches of electrons form in the drift space between the middle cavity and the output (or catcher) cavity, pass down the tube, and enter the catcher cavity.

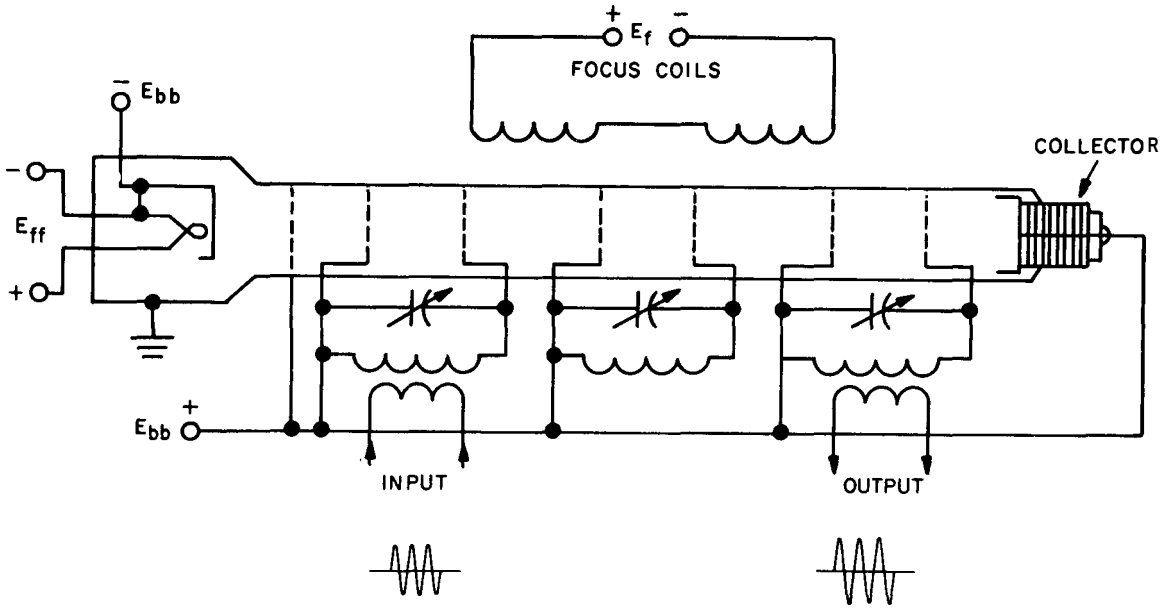
The conditions at the catcher cavity are somewhat different. This cavity is located along the tube so that the passage of the electron stream in bunches through the first grid creates a negative potential upon it. This negative potential retards the electrons, and, in slowing them down absorbs energy from them. The spacing between the two catcher grids is equivalent approximately to a half-wavelength at the frequency of operation. Thus, by the time the first bunch reaches the second catcher grid, the first catcher grid has reversed polarity and becomes positive, while the second catcher grid is now negative, as shown in the accompanying illustration.



Catcher Grid Polarity

Since the second grid is also negative, it further slows down the electrons and again absorbs energy from them. Thus, in delivering energy to the tuned cavity connected to the catcher grids, the speed of the electroni is greatly reduced. After passing this - second set of catcher grids the spent electrons are collected and removed from the tube by the positive collector plate.

A complete multicavity klystron r-f amplifier can be shown schematically as illustrated in the accompanying figure. The operation is exactly as described in the paragraphs above; therefore, it will not be repeated.



Multicavity Klystron R-F Amplifier Schematic Diagram

Failure Analysis.

No Output. Lack of or improper accelerating voltage, loss of drive power, or improper cavity tuning can result in loss of output. Usually, excessive beam current indicates improper tuning or voltage. A voltage check will indicate whether the voltage is sufficient. WARNING: ***Dangerous High Voltage*** is present; all safety precautions should be taken to make certain that no shock hazard exists. In practice, the shell of the tube is grounded and a high negative voltage is applied to the cathode. It is particularly important ***not to remove any lead shielding*** while troubleshooting; otherwise, X-radiation effects will produce a hazard to maintenance personnel. Normally, a no-output condition will be caused by an open circuit (or short circuit) or by a defective tube, rather than by mistuning or low voltage, since in these latter cases some small output normally occurs. When both filament and anode voltages are correct and the proper drive voltage exists, the tube is probably at fault. Substitution of a tube will not immediately restore full output, since the proper tuning and adjustment procedure must be followed to enable the tube to function properly. Use the manufacturer's recommended procedure for tuning and placing the unit in service, and note any deviations in performance or any abnormal indications as the procedure is followed. Investigate each deviation as it occurs, and make certain that it is cleared up before proceeding further.

Reduced Output. Low filament, drive, or anode voltage, as well as mistuning, can cause reduced output. Check the filament and plate voltages with a voltmeter, observing all safety precautions. An increased beam current can result from improper tuning or improper load. Check the drive, using a dummy load at the input to be certain that sufficient power is available. With sufficient drive established, connect a dummy load to the output and follow the proper tuning procedure. As the tuning procedure is performed, the beam current should reduce, more r-f drive should be required, and a greater output should result. Where focusing coils are used, loss of focus magnetism will show as a reduction in focusing-coil

current and a reduction of beam current (the stray electrons are absorbed before reaching the collector). An increase in beam current can usually be traced to improper cavity tuning. For maximum output, both the input and output cavities should be tuned to the same frequency. In broad-band operation it is necessary that each cavity be tuned to the proper frequency; otherwise, loss of output or of frequency range will occur. As with all other power amplifiers, the proper load must be attached; otherwise, improper impedance relationships will cause unwanted reflections and a loss of power. In receiving applications, low cathode emission will usually cause an increase in noise because of uneven electron emission.

PART 5-7. RF FREQUENCY MULTIPLIERS

RF FREQUENCY MULTIPLIERS

General.

Several applications exist for use of r-f frequency multipliers. For example, a harmonic generator consists merely of a number of frequency-multiplier stages connected in cascade. They are used in receivers, being driven by a stable local oscillator which operates at a low fundamental frequency and is multiplied through several stages to supply an oscillator signal to a VHF or UHF mixer. Likewise, in test equipment, a suitable oscillator has its output frequency multiplied for use as a signal generator or frequency standard, or for other purposes. In a transmitter, the multiplier stage (or stages) allows the use of a single crystal to provide drive for r-f amplifiers operating on harmonically related output frequencies, or it may be used to supply a crystal-controlled output at higher frequencies, where crystal operation at the output frequency is not feasible.

The power output of the multiplier stage varies roughly as the reciprocal of the number of multiplications. Thus, a frequency doubler produces about one-half the output power of a conventional Class C r-f amplifier stage, and a frequency tripler produces about one-third the power; hence, the necessity for cascaded operation at the higher multiples. For example, two doubler stages operated in cascade will deliver twice the power of a single quadruple stage.

The loaded tank circuit impedance increases roughly in proportion to the number of harmonic multiplications required, since the output power decreases and a greater impedance is necessary to provide the same voltage drop across the tank. This places a practical limit on the number of multiplications possible in a single stage.

Although either triode or pentode tubes may be used as frequency multipliers, the pentode is more commonly used because of the reduced grid drive required for pentode operation, plus the larger power output obtainable for the same plate voltage. Since grid current flows in Class C operation, the multiplier stage requires a slight amount of power from the oscillator to drive it. The reduced drive of the pentode, therefore, allows the oscillator to operate more stably, and permits a lower-rated oscillator tube to be used. Normally, a Class C amplifier is biased at 2 to 2½ times cutoff. The frequency multiplier is essentially a Class C stage which utilizes its rich harmonic content, or, rather, is operated so as to develop a greater harmonic content than normal. Selection of the desired harmonic by a tuned output circuit produces a relatively large output at that harmonic. To produce the distorted plate current with its rich harmonic content, the stage must be biased higher than for normal Class C operation, and must be driven harder than normal. Thus, plate current flows only during a small fraction of the cycle, roughly from 60 to 120 electrical degrees (depending upon the amount of harmonic multiplication desired). Therefore, the normal grid bias for a multiplier is usually 3 to 4 times cutoff. Because the plate output tank is tuned to a different frequency from that of the input (drive) signal, no plate-to-grid feedback occurs. Therefore, neutralization is never required, regardless of whether triodes or pentodes are used.

PENTODE RF FREQUENCY MULTIPLIER

Application.

The frequency multiplier stage is used to provide an output frequency which is some integral multiple of a fundamental crystal-controlled, or self-excited oscillator frequency. It is universally used in receivers, test equipment, and transmitters.

Characteristics.

Uses Class C operation at all times.

May be self-biased, fixed biased, or a combination of both.

Output frequency is always some multiple of the fundamental.

Normally doubles or triples, but can operate up to about the seventh harmonic.

Efficiency varies inversely with frequency.

Maximum usable efficiently is on the order of 70 percent, and lowest efficiency is about 45 percent.

Grid bias is higher than in the normal Class C amplifier.

Requires more grid drive than would be necessary for operation at the fundamental frequency.

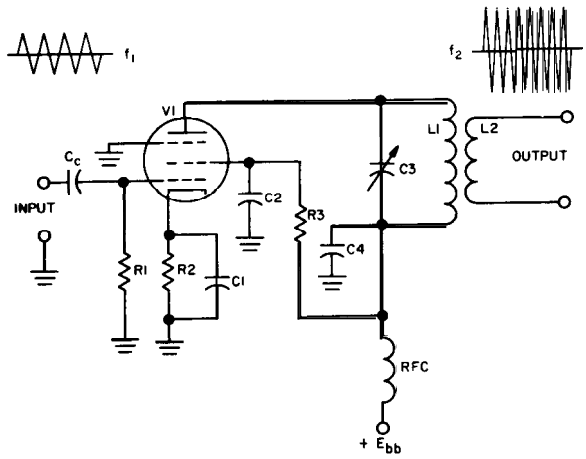
Does not require neutralization.

Circuit Analysis.

General. Schematically, the pentode r-f frequency multiplier appears identical with that of the conventional Pentode R-F Voltage Amplifier or the Pentode R-F Buffer Amplifier previously discussed. However,

there are differences in parts values to provide the correct bias and operation, and the plate tank resonates at a multiple of the fundamental frequency. Detailed differences in operation are discussed below.

Circuit Operation. A typical frequency multiplier circuit is shown in the accompanying illustration. In this configuration, the oscillator output is capacitively coupled through C_c to the grid of VI. Grid bias is obtained through grid current flow in R1, and protective cathode bias is supplied by R2, which is bypassed for rf by Cl. The screen voltage is dropped to the proper value by screen resistor R3, bypassed for rf by C2. Variable capacitor C3 and inductance LI form the output tank circuit, which is inductively coupled to output coil L2. While series plate feed is employed, one end of the tank is bypassed to ground by C4, and the radio-frequency choke (RFC) insures that any residual rf remaining flows to ground by way of C4 rather than through the low impedance of the power-supply filter.



Typical Fraquency Multiplier Circuit

With no signal applied no grid bias is developed, and the plate and screen current flow through cathode resistor R2 provides sufficient cathode bias to limit the static current flow to a safe value. When the oscillator signal is applied, the low reactance of coupling capacitor C_c allows practically all of the input to appear across RI and the V1 grid. On the positive half-cycle of the input signal the plate current increases, and on the negative half-cycle it decreases. During the positive half-cycle C_c charges, and during the negative half-cycle it discharges from the capacitor to ground, a negative bias is developed across R1; this grid bias voltage and the cathode voltage stored in Cl produce a high bias many times the cutoff value. (See the introduction to this section for a further discussion of cathode bias and grid-drive, or signal bias.)

Because of the extremely high bias, the plate current conduction period is reduced to a small fraction of the total cycle. Actually, it is less than a half-cycle and varies with the amount of multiplication desired. For a frequency doubler it is about 120 electrical degrees, and for a quintuple it is about 60 degrees. The short time during which plate current flows produces a very distorted plate pulse which is rich in harmonics. When plate tank C3, L1 is tuned to the desired output frequency, it offers a high impedance at the frequency, so that a large drop in plate voltage occurs across the tank. With an increasing plate current, caused by the positive input signal, the plate voltage is dropped toward zero; during cutoff, produced by the negative portion of the input signal, the plate voltage increases to almost the full value of the supply voltage. A decreasing plate voltage induces a negative output signal in L2 by transformer action, since it is coupled via tank coil L1, while an increasing plate voltage induces a positive output signal in L2.

The instantaneous current and voltage relationships in a frequency doubler are graphically illustrated in the accompanying illustration.

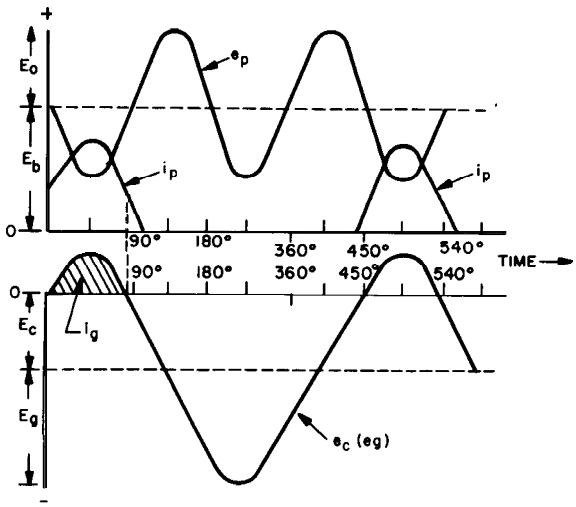


Plate Current and Grid Voltage Relationships

As can be seen from the figure, the plate current flow time is longer than the grid current flow time, but both maximums occur together. Thus, as instantaneous grid voltage e_c starts its positive excursion, no plate current or grid current flows until the grid voltage reaches cutoff. At this time plate current starts to flow. Slightly later, at zero bias, grid current flows also. The grid current flow is supplied from the oscillator or drive source. The increasing plate current (obtained from the power supply) causes a voltage drop across the plate tank impedance (tuned, for example, to twice the frequency of the oscillator). When the plate current is at its maximum, the plate voltage is at its minimum. At this time some plate power is absorbed by the tuned tank circuit. As the drive signal reverses and causes the instantaneous grid voltage to fall toward zero, the plate current decreases and the plate voltage increases. The grid signal continues to swing in the negative direction while the plate voltage rises (in a positive direction). At the static dc level of plate voltage (E_b), the grid drive is approximately equal to the dc bias (zero bias), and as the grid voltage increases toward cutoff, e_p continues to rise. At cutoff, the tank circuit supplies power, and e_p rises, even though the plate current ceases. This is the so called "flywheel" action of the tank circuit, which continues operation during the time the tube is inactive beyond cutoff. When the instantaneous negative grid voltage reaches the dc bias level (EC), plate voltage e_p reaches its positive peak and is approximately equal to E_o, the output voltage.

As the instantaneous grid signal continues to decrease beyond the dc bias level, the plate voltage now falls and becomes negative-going, since the tank is operating at twice the grid frequency, and the input signal, being highly negative, has no effect on the plate current. At the negative peak of drive voltage E_g, plate voltage e_p completes its second negative excursion and starts its second positive excursion. The drive voltage also swings positive again and now starts back toward cutoff and zero bias. When the drive is again equal to the dc grid voltage, the second positive peak excursion is reached and the plate voltage starts dropping. As the grid voltage passes cutoff, plate current is again drawn and the plate voltage continues to drop until it reaches the third minimum, when the plate and grid currents are again at a maximum. Once again the plate power is absorbed by the tank to overcome the losses in the tank and to recover the energy supplied to the circuit during the inactive period.

With the tank replenished; it is again ready to supply the flywheel effect of the next cycle of operation. Note that always during the short pulses of plate current flow, the tank is absorbing power from the plate circuit. While on the negative grid swing (where the tube plate current is normally cut off and no output should occur), the tank circuit continues to oscillate and thus supplies the missing portion of the signal. Since the tank oscillations are twice that of the fundamental oscillator frequency, two peaks occur for every fundamental peak (in the tripler three peaks occur). The greater the number of oscillations required between the periods of pulses of plate current, the more the energy required from the tank to sustain these oscillations. Hence, the efficiency and output drop off as the multiplication of frequency is increased. In addition, the flywheel action of the tank maintains an approximately sinusoidal waveform in the output, while the fundamental plate current pulses are greatly distorted. When the grid bias and drive voltage amplitudes, as well as plate voltage, are adjusted for maximum output at a particular frequency, a slightly distorted output may be obtained; however, this can usually be compensated for by a slight adjustment of the tank tuning capacitor.

491-044 0- 73 34

While push-pull operation can be used to supply more power output, more drive is required and only the odd harmonics are multiplied, since the even harmonics cancel out in the pIate circuit. Therefore, push-push operation is employed, as explained in the next circuit discussion.

Failure Analysis.

General. The discussion of failure analysis for the Pentode R-F Voltage Amplifier, and for the Pentode R-F Buffer Amplifier, duscussed previously in this section of the handbook, are generally applicable to the frequency multiplier.

No **Output.** Lack of grid drive, plate, screen, or supply voltage, or a defective tank, output coil, or tube can cause loss of output. Check with a voltmeter to make sure that the supply voltage is normal. If the cathode voltage is also normal, the proper plate and screen currents probably exist, so that either the plate tank is detuned or insufficient drive is indicated. Connecting a milliammeter in series with R1 and ground will indicate the amount of grid current flow; this will shown that R1 is not oper and serve as a check on CC. If C_c is open, no drive would be present to cause current flow through R1; if it is shorted, the plate voltage of the preceding oscillator stage will bias the grid heavily positive, cause a large plate current flow, and produce a high cathode bias with practically no output. If cathode bypass capacitor Cl is open, degeneration will reduce the output but not completely eliminate it; if Cl is shorted, a large plate current will flow in the absence of drive voltage, but the plate current will appear normal as long as enough drive is present to produce sufficient signal bias. If screen capacitor C2 is open, self-oscillation and erratic operation (with some output) will probably occur; if C2 is shorted, the supply voltage will be normal but will be entirely dropped across R3. Therefore, R3 will heat, probably discolor or smoke, and eventually burn out. Meanwhile, no plate output will be obtained because of the lack of screen voltage to attract electrons from the cathode. Although a very small plate current may flow because of plate voltage attraction, this output will be practically negligible.

If plate bypass capacitor C4 is shorted, a similar condition will exist, with the entire supply voltage being dropped across the RFC, eventually causing the choke to burn out. Although screen voltage will be present, the plate voltage will be zero and no output can occur. In addition, the screen will tend to act as the plate and collect all electrons, so that excessive screen current will flow; in this case the screen will be overloaded and heat sufficiently to shown color, and if prolonged the tube may be damaged.

If C3 will not tune L1 to resonance at the desired harmonic, no output will be developed across the tank, since its impedance will be too low to produce an output. The resonant frequency of the tank can be checked with a grid-dip meter or a wavemeter. If all voltages are present, but the screen and plate voltages appear higher than normal while the cathode bias is lower than normal, and with low plate current and no output, either output coil L2 is open or the tube is defective. Check L2 (and the load) for continuity with the power off; if satisfactory, it is likely that tube V1 is defective.

Low Output. With a low screen or plate voltage, a low drive, a high-resistance plate circuit, or a defective tube, a reduced output will be obtained. The plate, screen, and cathode bias voltages can be checked with a voltmeter. Use an r-f choke in series with the meter and check the voltage across R1; this will determine whether grid bias exists and also whether sufficient drive exists. If the bias is low because of lack of drive, the stage will operate Class A, lose efficiency, and result in reduced power output. If screen resistor R3 increases in value with age, the screen voltage will be reduced, as will the output. A similar condition can be caused if screen bypass capacitor C2 is leaky. Check C2 with an in-circuit capacitance checker, or disconnect it from ground and check for a constant voltage between the capacitor and ground by use of a voltmeter. A similar condition can also occur if plate capacitor C4 is leaky. A high resistance in the tank can be caused by a poorly soldered joint. This will usually shown as a broad dip in plate current with tuning, rather than the normal sharp dip. Leaky insulation on C3 can also cause a loss of rf and output. Check the capacitor insulating supports for indications of an r-f burn, or accumulated dirt and moisture, which can produce a shunting resistance to ground (particularly salt deposits from spray). Remove the capacitor, and clean and dry it thoroughly if it appears to be dirty; normal grayish oxidation of plates and metal supports does not indicate the need for cleaning. Do not lubricate the capacitor bearings because of rotor binding (adjust the tension screw instead); otherwise, bad contact will create a high r-f resistance. When the bias and

voltage indications appear normal, but the plate current is low and cannot be increased to a normal value (or if it drops immediately after turn-on, or progressively decreases), low tube emission is probably the trouble.

PUSH-PUSH RF FREQUENCY MULTIPLIER (ELECTRON TUBE)

Application.

The r-f push-push frequency multiplier is used as a frequency doubler in transmitters and test equipments that require a greater output and better efficiency than is possible with the single-tube multiplier.

Characteristics.

Uses Class C bias at all times.

May be self-biased, fixed-biased, or a combination of both.

Provides approximately twice the output of a single-tube multiplier stage.

Provides efficiency almost equivalent to that of a normal Class C amplifier.

Requires a push-pull input connection and a paralleled-plate output.

May use triode or screen-grid tubes.

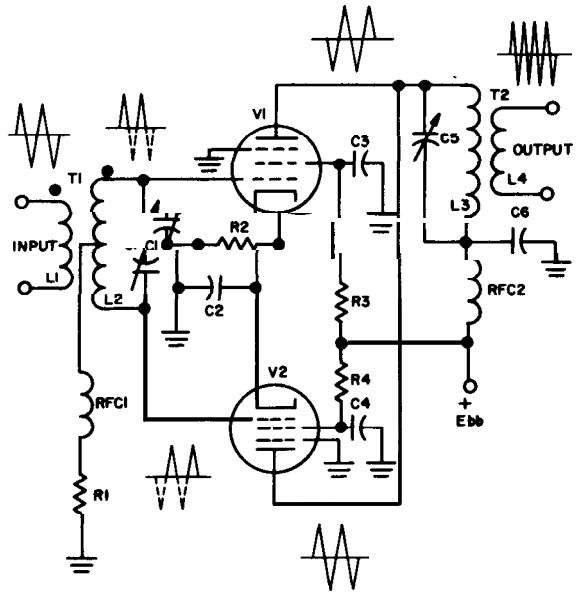
Operates push-push instead of push-pull (a plate pulse is provided for each cycle of operation).

Does not require neutralization, since output frequency is double the input frequency.

Circuit Analysis.

General. Like the single-stage frequency multiplier, previously discussed in this section of the handbook, pentodes are used in preference to triodes, since the low drive requirement provides less load on the input stage, and a greater output is obtainable than from a triode operating at the same plate voltage. Where the single-stage multiplier may be used to double, triple, or further multiply the input frequency, the push-push stage is usually operated only as a doubler. While it will also operate as a quadruple (since only even harmonics can be produced with appreciable output), the same output can be more easily obtained with two single-stage doublers, which require slightly less than half the drive power. Thus, push-push operation is more limited in its application than the basic single-stage multiplier. It is mainly used where a large doubler output is required, since it will produce this output without any loss because of multiplication. This is true because a plate current pulse is provided for each positive half-cycle of the input signal, or one for each output cycle. Thus, the tank circuit requires less replenishing, and greater output and efficiency are obtained. Although a push-pull input is required, this can easily be obtained with a grid tank circuit. In addition, harmonics of odd order, which can sometimes cause a final output on an unwanted frequency, are minimized, and a purer output waveform is supplied than that by the single-tube doubler stage.

Circuit Operation. The accompanying illustration shows a typical push-push doubler stage.



Push-Push Frequency Multiplier Stage

As is evident from the schematic, a push-pull input is provided by r-f transformer T1. L1 is the primary, and L2 is tuned by split-stator capacitor Cl to the fundamental frequency. Signal bias is supplied by grid drive, causing grid current flow through R1, with RFC1 keeping any rf out of the bias circuit. A protective cathode bias is also supplied by R2, which is bypassed for rf by C2. Tubes V1 and V2 are pentodes with their suppressors directly grounded, although tubes having the suppressor connected to the cathode

internally could also be used. Screen voltage for the tubes is dropped to the proper value by R3 and R4, which are bypassed for r-f by C3 and C4, respectively. The plates of V1 and V2 are parallel-connected to plate tank L3, C5. The secondary of r-f transformer T2, winding L4, provides an inductively coupled output, although capacitive coupling could have been used as well. Series plate feed is used, and the dc plate voltage is applied through RFC2 to the bottom end of L3, which is bypassed for rf by C6. Thus, any rf at this point flows to ground through C6 rather than through the power supply filter capacitor, and any body capacitance effects which otherwise would occur when tuning tank capacitor C5 are also eliminated.

When the input signal is applied to input transformer T1, the input voltage in primary winding LI induces a voltage into secondary winding L2 by transformer action. The center of the L2 secondary is connected to ground through RFCI and R1. The windings are polarized so that the top end of L2 (connected to the V1 grid) is positive when the top end of L1 is positive. Thus, when the top end of L2 is positive, the bottom end of L2 is negative. Since the bottom end is connected to the grid of V2, V2 is negative when the V1 grid is positive, and vice versa. Thus, a push-pull input connection is provided. Tuning capacitor C1 is a split-stator type which provides a balanced tank arrangement to ground, and also resonates L2 to the operating frequency of the oscillator, or input stage.

In the absence of an input signal, protective cathode bias is provided by plate and screen current flow through R2. The cathode bias and the signal bias are effectively series-aiding, so that the total Class C bias is a combination of both. (See the introduction to this section for a discussion of cathode bias and signal bias.) As the input signal is applied, either the VI or V2 grid conducts on the positive half-cycle of operation, and grid current flows through R1, producing the signal bias, which is added to the cathode bias. Since only one tube conducts at a time, the cathode bias at any particular instance is produced essentially by only one tube. (When signal bias is absent both tubes will conduct, so the protective bias is produced by both tubes.)

On the positive half-cycle of input signal when VI conducts, plate current flows for approximately 120 electrical degrees of operation. During the remainder of the cycle, tube V1 is cut off. When the input signal goes negative, a positive grid voltage is induced in L2 and applied to V2, while VI is held at plate current cutoff by a negative signal. The positive grid input to V2 causes plate current to flow for a period similar to that of V1. Both plates are parallel-connected, so that a pulse of plate current occurs for each half-cycle of input signal. During current flow, the plate voltage is dropped across the high impedance of output tank L3, C5, which is tuned to twice the input frequency. Each time the plate voltage is reduced to its minimum value, energy is absorbed by the plate tank. Hence, it receives a push to keep it oscillating each negative half-cycle, from which action the term push-push was derived. Note that in push-push operation each tube operates alternately while the other tube remains at rest; this should be distinguished from push-pull operation, where the current of one tube increases while the current of the other tube decreases (both simultaneously).

The relationships of the grid voltage and plate current, and grid current and plate voltage waveforms is shown in the accompanying figure.

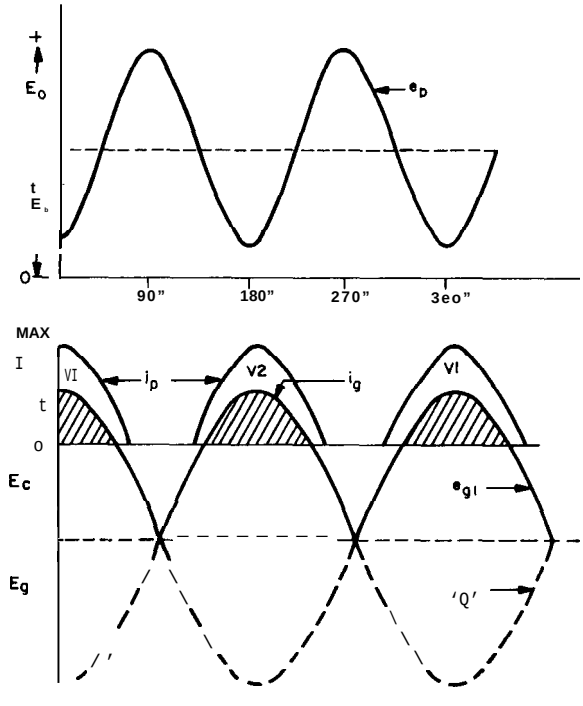


Plate and Grid Waveforms and Their Relationships

- d

As the grid voltage (e_{g1}) to VI rises in a positive direction, it drives the tube above cutoff, and plate current flows. Plate current i_p, in flowing through the tank impedance at the resonant frequency, produces a voltage drop which opposes the applied plate voltage and reduces it toward zero. As the grid voltage continues to increase grid current flows when zero bias is reached, and develops a bias voltage across R1. RFC1 prevents shunting of the r-f input to ground through Rl, so that only the rectified dc bias current flows through R1. The current flow is from ground through cathode bias resistor R2, to the cathode, to the grid, and back through R1 to ground. The cathode bias is increased by the small amount of grid drive current, but this bias remains constant as long as grid current flows, and averages to a somewhat smaller value over the entire cycle. Because of the low value of cathode resistance employed, the over-all bias is enhanced by only a volt or two. Most of the bias voltage is developed across Rl, which is a large value of resistance (1OK to 50K). As the grid current reaches its peak, so does the plate current of V1. At this time the plate voltage of V1 reaches a minimum value, and power is absorbed by the resonant tank circuit. When the input signal reaches its positive peak and changes direction (assuming a sine wave), it swings negative and falls toward zero. Meanwhile, the plate curraent and grid current also fall. When the grid voltage drops below zero bias, the grid current stops flowing and the plate current continues to decrease, while the plate voltage increases still further. The plate voltage continues to increase, even at cutoff when the plate current ceases, because of the flywheel action of the tank circuit. At this time the tank is supplying energy to the circuit while the tube is inoperative.

When the input signal on the V1 grid reaches zero and continues further in a negative direction (the negative half-cycle), a positive-going signal is induced on the V2 grid through T1. Thus, as the V2 grid rises above cutoff, plate current again flows, but this time in V2. The flow of plate current causes a plate voltage drop across the high tank impedance, and the effective plate voltage of V2 follows. At zero bias, grid current flows in V2 and produces a negative bias equal to that produced by VI on the opposite half-cycle. When the grid current in V2 is at a maximum, so is the plate current, and the effective plate voltage is again at a minimum. As the input signal reaches its negative maximum and reverses direction it swings positive, as does the plate voltage. Simultaneously, V2 plate current decreases, first zero bias and then cutoff is reached, and V2 stops conducting. Meanwhile, since the tank circuit is oscillating in synchronism, the plate voltage continues to rise until the positive peak voltage is reached. At this time e_{g1} and e_{g2} are equal to bias voltage E_c and to each other, plate current is completely cut off and the tank is again supplying energy to the circuit. As e_{g2} goes more negative, e_{g1} goes more positive. When cutoff is reached VI conducts again, and the plate voltage again drops toward its minimum value. At the plate voltage minimum, the plate current is again at its maximum value (as is the grid current), and the tank again absorbs power from the plate circuit. Since the tank oscillates in synchronism, completing one oscillation for each half-cycle of input, the output is twice the input frequency. Because the tank is reinforced for each half-cycle of the input, or once for each cycle of operation, not as much power is expended from the tank as in a single-stage circuit. The plate efficiency, therefore, increases over that of the single stage, since only half as much energy is expended by the tank, and less is absorbed from the plate. As the input signal continues, the action just described is repeated over and over again. Since L4 is inductively coupled to L3, the circulating tank current induces an r-f voltage in L4 by transformer action, and the output is approximately equal to the plate voltage drop developed across one tube. Any other harmonics in the plate circuit are offered a very small impedance, since the tank is not tuned to that frequency; thus, only the desired harmonic frequency exists in the output.

Although the pulses of plate current occur for only 120 degrees and are highly distorted, the flywheel action of the tank circuit tends to smooth the output into approximate sine waves at double the frequency. Since frequency multipliers are usually never modulated, any remaining waveform distortion is of little significance.

Failure Analysis.

No Output. Lack of an input (drive) signal, loss of screen or plate voltage, an open output circuit, or defective tubes can cause loss of output. Check the plate, screen, and supply voltages with a voltmeter. For no output it is usually necessary for both tubes to be defective; if one tube is operative, the output will be reduced rather than eliminated entirely. If

cathode bias resistor R2 is open, the circuit will be incomplete and no output can occur. If r-f transformer T1 or T2 is open or shorted, no output can occur. Lack of input (drive) is indicated by no bias voltage, as measured across RI. Likewise, no input will produce high plate and screen current because of the loss of grid bias, and thus cause the protective cathode bias voltage across R2 to be larger than normal. Similarly, if either RFC1 or RI is open, no grid bias will be obtained, and R2 will produce a larger than normal protective bias with no output. When in doubt, a resistance check of Ll, L2, R1, R2, and RFC1 with the power OFF can be quickly and easily made – or either an oscilloscope or a VTVM can be used to check the grids of VI and V2 for rf. If no drive exists and C2 is shorted, the tubes will show color and be damaged (if the short is prolonged), while no output will be obtained.

If screen resistor R3 or R4 is open, or if capacitor C3 or C4 is open or shorted, there will be a reduction in output, but not complete loss of output; however, if both resistors are open or if both capacitors are shorted, no screen voltage will appear and there will be no output. If either C3 or C4 is shorted, R3 or R4 will heat abnormally, show color, or smoke, and will eventually bum out. If plate choke RFC2 is open, no plate voltage will be applied to either V1 or V2, and there will be no output. A similar condition will result if C6 is shorted; in this case the supply is dropped across the r-f choke, which will probably cause it to smoke and burn out. If C5 does not resonate L3 to the proper frequency, little or no output will be developed. Check L3 for continuity with an ohmmeter, with the plate voltage OFF. Use a grid dip meter or a wavemeter to check the tank resonant frequency. If the condition of C5 is in doubt, coil L3 must be disconnected checking C5 with a capacitance checker. If secondary L4 opens, no load will appear on either V1 or V2 and a lower than normal plate current will be indicated. L4 can be checked for continuity with an ohmmeter.

A milliammeter can be inserted in the grid and plate circuits to faciliate the location of trouble. It will indicate the grid current, which shows whether sufficient drive is present; it will also indicate the plate current, which can be checked for a dip (indicating resonance) and for proper loading. A sharp dip in the plate current with very low minimum current and no output indicates that the load is not coupled sufficiently or that the output circuit is open.

Low Output. No voltage or low voltage on the screen or plate, insufficient drive, or a defective tube will cause low output. The screen and plate voltages can be checked with a voltmeter; the grid drive can also be checked with a voltmeter by measuring the grid bias voltage developed across RI. If either R3 or R4 is open, no screen voltage will be applied to VI or V2, respectively, and reduced output will result. Likewise, if either C3 or C4 is shorted, a similar condition will occur. Low screen voltage can be caused by a change in value of resistor R3 or R4, or by a leaky capacitor C3 or C4. A milliammeter inserted into the supply side of each screen resistor will indicate whether proper screen current is obtained. Inability to obtain the rated screen current at the correct voltage indicates a defective tube. If RFC2 is open or if C6 is shorted, no plate voltage will be applied to either VI or V2. In this case the screen will tend to act as the plate, get hot, and eventually be damaged (if the condition is prolonged). A high resistance due to a poorly soldered joint in the plate circuit of V1 or V2 will cause reduced voltage and output, and will usually be indicated by broad tuning of tank capacitor C5, with low plate current. If the output is low and the voltages appear normal, remove one tube at a time, noting whether the output rises or drops. A partially shorted tube can cause the output to rise when the defective tube is removed. Normally the output should drop to about half value; if no change occurs, the removed tube is probably defective.

Incorrect Output Frequency. If other than the desired output frequency is obtained, one of the tubes is probably inoperative. Since a push-push circuit can produce only even harmonics (2nd, 4th, 6th, etc.), an odd harmonic can be produced only by single-tube operation. In this case the output will usually be reduced. Normally, the tank circuit does not tune through more than one harmonic. However, in multiband equipment using shorting switches to change the inductance, it is possible for a poor or open contact to allow the incorrect value of inductance to be used, and thus cause resonance at some undesired harmonic.

PART 5-8.' DEFLECTION

DEFLECTION AMPLIFIERS

General.

A deflection amplifier is intended to accept, as an input, a signal whose waveform may be simple (as in the case of a direct-current waveform) or exceedingly complex (as in the case of several fundamental frequencies in combination with a multitude of their harmonics), amplify it, and furnish an output in which the original waveform remains unchanged. An amplifier intended for use as a horizontal deflection amplifier is required to increase the amplitude of the sawtooth sweep waveform, in order to produce sufficient horizontal deflection. In radar displays of certain types, a triangular type of sawtooth waveform is used for a horizontally swept timebase. An amplifier intended for use as a vertical deflection amplifier is required to increase the amplitude—sometimes to enormous proportions–of almost any type of waveform. Since the requirements of the vertical deflection amplifier are generally more stringent than those of the horizontal deflection amplifier, insofar as gain, bandwidth, and frequency response are concerned, the following discussion will be particularly applicable to the amplifier intended for vertical deflection.

The most complex waveform which may be required to be amplified is a perfect square wave. Such a wave contains a fundamental frequency and an infinite number of odd harmonics. It has zero rise and decay times, and a perfectly flat top and bottom. The voltage changes from a maximum positive value to a maximum negative value instantaneously. In order to amplify a waveform containing an infinite number of harmonics, without distortion, an amplifier having an infinite bandwidth would be required. Such a waveform and such an amplifier do not exist, for the following reasons: Any change in voltage, no matter how abrupt, requires a certain amount of time to occur. The presence of shunt capacitance, which in some amount is always present in a circuit, causes the rate of change of voltage to be further reduced. This results from the fact that the voltage across a capacitor cannot change instantaneously. In addition, every amplifier, no matter how careful the design, introduces some degree of distortion, which deteriorates the (perfect) square wave.

In actuality, the square wave applied to a vertical amplifier contains several hundred (rather than an infinite number) odd harmonics. The following illustration shows the output waveforms from amplifiers in which the high-frequency response was purposely restricted. The input to the amplifiers, in each case, was a "perfect" square wave. In A, the output was restricted to the tenth harmonic of the fundamental frequency. In B the output waveform contained frequencies as high as the one-hundredth harmonic of the fundamental, while in C the output contained over five-hundred harmonics. In order to reproduce a square wave with reasonable fidelity the vertical deflection amplifier should have a bandwidth sufficiently wide to pass the tenth odd harmonic of the fundamental frequency. Note that this is a frequency which is 21 times the fundamental. More accurate reproduction of the input waveform requires a bandwidth wide enough to pass the fortieth odd harmonic (81 times the fundamental) of the fundamental frequency.

A. IO HARMONICS D. 100 HARMONICS C. GREATER THAN 500 HARMONICS

Output Square Waves Having Restricted Odd-Harmonic Content

A waveform having a very short time duration, such as a timing pulse, requires a different method of calculating the minimum high-frequency response required of the deflection amplifier. The minimum upper limt of response required is inversely proportional to the pulse duration, as follows:

$$f_{max} \cdot \frac{1}{d}$$

where: f_{max} = required minimum upper limit of amplifier response, in megahertz

d = pulse duration, in microseconds

As an example, a l-microsecond rectangular pulse requires a minimum frequency response which is uniform up to 1 megahertz. A 1 /4-microsecond rectangular pulse requires a minimum frequency response uniform up to 4 megahertz.

In addition to pulse duration, the high-frequency response requirements of the vertical deflection amplifier also depend upon the rise time of the pulse to be amplified. The rise time is the time required for the pulse to increase from 10 percent to 90 percent of its maximum amplitude. The shorter the rise time required, the higher the frequency response of the vertical deflection amplifier must be to reproduce the waveform.

Finally, in order to accurately reproduce the original waveform in the amplified output, the vertical deflection amplifier must have an absolute minimum of phase shift. That amount of phase shift which is present must be proportional to the frequency of the component frequencies of the input waveform. As an example, suppose a complex waveform which is composed of a fundamental sine wave plus its second harmonic is applied to the vertical deflection amplifier. Suppose, further, that the amplifier delays the fundamental by the interval of time equal to onequarter cycle. In order to preserve the original waveform, it is necessary that the second harmonic be delayed by an equal interval of time, to maintain the time relationship between the fundamental and the second harmonic. In order to obtain the same interval of time delay, the second harmonic must be delayed by one-cycle. A third harmonic, if present in the input waveform, would have to be delayed by three fourths of a cycle. By this means a linear phase shift is produced in which the angular degree of phase shift is directly proportional to the frequency ratio of the harmonic to its fundamental.

BASIC DEFLECTION AMPLIFIER (ELECTRON TUBE)

Application.

The deflection amplifier is used to amplify the signals before they are applied to the deflection plates of an electrostaticdeflection type of cathode-ray tube or to the deflection coils of an electromagnetic-deflection type of cathode-ray tube. Two separate amplifiers are associated with each cathode-ray tube: the horizontal deflection amplifier, which normally amplifies the horizontal sweep signals, and the vertical deflection amplifier, which normally amplifies the input waveform to be displayed on the screen of the cathode-ray tube.

Characteristics.

Horizontal Deflection Amplifier. Input impedance is high; loading of the preceding horizontal generator circuit is thereby prevented.

Input capacitance is low; attenuation of high frequencies is thereby prevented.

High-frequency response is good, but not generally as good as the response of the vertical deflection amplifier.

Bandwidth usually covers 10 Hz to 100 kHz; certain applications may require a range of 1 Hz to 500 kHz; other applications (such as fixed sweeps of radar deflection) may require only a limited range in bandwidth.

Output impedance depends on intended application: impedance is high if amplifier is designed for voltage (electrostatic) deflection; impedance is relatively low to match the impedance of deflection coil if designed for current (electromagnetic) deflection.

Gain of the amplifier depends on application; the gain is usually lower than that of the vertical deflection amplifier, because the sweep generator output normally feeding the horizontal deflection amplifier is ordinarily higher and more constant than the input signal feeding the vertical deflection amplifier.

Balanced output (push-pull) is desirable, to prevent distortion caused by unequal amplification of positive and negative signals.

Vertical Deflection Amplifier. Input impedance is very high; loading of the preceding output circuit, with the consequent waveform distortion, is thereby prevented. (Special applications may require a low input impedance, which must then be matched to the source impedance of the input signal.)

Input capacitance is very low; attenuation of high-frequency components of input signal is thereby prevented.

High-frequency response is very good; application generally demands a better response than that of the horizontal deflection amplifier.

Bandwidth usually covers 10 Hz to 1 Mhz; certain applications may require a range of 2 Hz to 10 MHz; other applications may require a range which includes zero hertz (direct current), but at the same time they may require only a limited high-frequency response.

Output impedance depends on the intended application, in the same manner as in the horizontal deflection amplifier. The impedance is high if the

amplifier is designed for voltage (electrostatic) deflection; it is relatively low and must match the impedance of the load (deflection coil) if the amplifier is designed for current (electromagnetic) deflection.

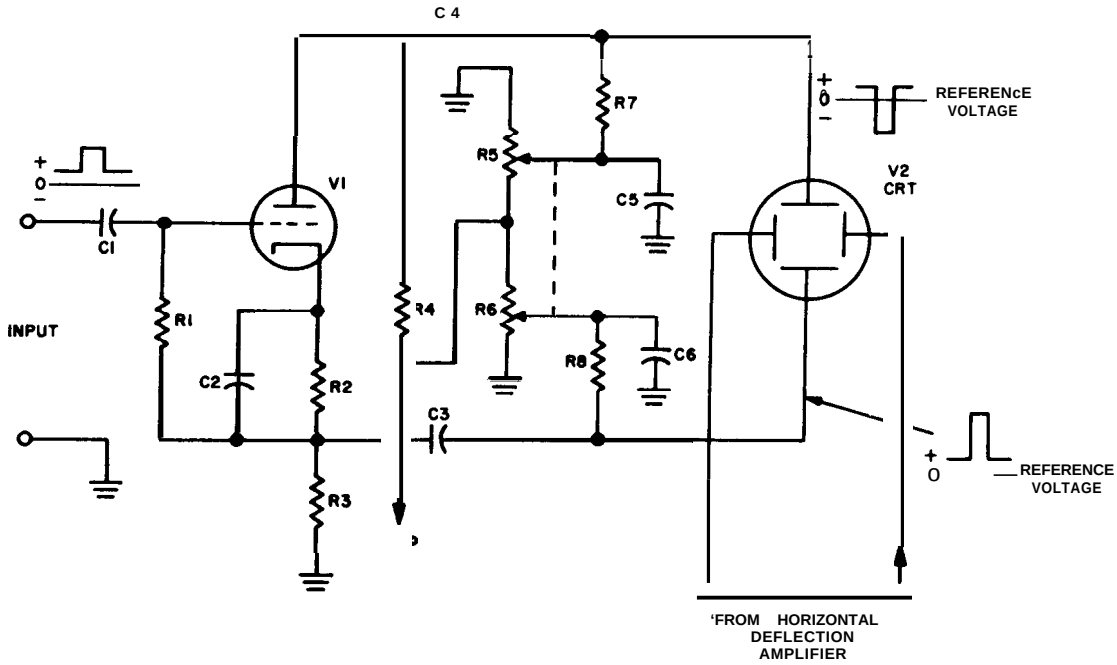
Gain of the amplifier depends on its intended application: it must be sufficient to produce a pattern of acceptable size, on the particular cathode-ray tube used, from the smallest (voltage) input signal required to be displayed on the screen.

Balance output (push-pull) is desirable–more so than in the horizontal-in order to reduce pattern distortion and beam defocusing. Since the input signal to the vertical deflection amplifier is generally much lower in amplitude than that of the horizontal input signal, the amount of gain required of the vertical amplifier is generally higher, and hence the possibility of distortion is also higher.

Circuit Analysis.

General. The circuit discussed here is a basic type of circuit and is given only for the purpose of discussion. More detailed discussion on actual circuits used as deflection amplifiers will be found in the two amplifier circuits to follow: Voltage Deflection Amplifier and Current Deflection Amplifier.

The following circuit is actually a simple paraphase amplifier, which is used to produce two output voltages, equal in amplitude and opposite in phase (polarity). Since 50 volts per inch is a common deflection sensitivity for cathode-ray tubes, and since the gain of the stage (Vi) is less than one, the amplitude of the input signal to this stage should be on the order of 50 volts. The input signal is applied through coupling capacitor Cl to the grid of the deflection amplifier tube, V1. The grid is returned to cathode through grid resistor R1. Plate voltage is applied through plate load resistor R4, and the cathode is biased by means of R2, which is bypassed by C2. The values of R3 and R4 are equal, and the same current passing through them will produce signals which are equal in amplitude but opposite in phase (polarity) at the plate and cathode. These two outputs, which provide push-pull deflection, are coupled through C3 and C4 respectively, to the vertical deflection plates of



Typical Deflection Amplifier Used for Vertical Deflection

cathode-ray tube V2. Equal deflection above and below a zero-voltage base line is provided by a centering control network consisting of dual control R5/R6, and resistors R7 and R8, which are bypassed by C5 and C6, respectively. Capacitors C5 and C6 insure that any electrons striking the deflection plates will be removed, to prevent a negative charge from building up. If a positive pulse of short time constant is applied at the input to the circuit, to C 1, the output at the plate of V1 will be an inverted, or negative pulse, which is shown at the top plate of cathode-ray tube V2 as a pulse below the reference voltage. The output at the cathode of V1 will be an upright, or positive pulse, which is shown at the lower plate of V2 as a pulse above the reference voltage.

Failure Analysis.

No Output. If a signal having an amplitude within the input limits of the deflection amplifier is applied to the input terminals, a defective tube is the most probable cause of a no-output condition. An open coupling capacitor Cl, a shorted grid resistor R1, an open cathode resistor R2 or R3, or an open plate resistor R4 would also be responsible for no output, as would also a power supply failure.

Reduced or Unstable Output. In the typical circuit illustrated, the failure of a component is more likely to cause a reduced, distorted, or unstable output, rather than no output whatsoever. A leaky coupling capacitor Cl or a change in value of any resistor would contribute to a reduced or unstable output. If cathode resistor R2 or R3 changed in value, the outputs from the plate and cathode would be shifted from the designed center (which may or may not be at ground potential, depending upon the designed application), and the output would be shifted with respect to the zero reference. If shifted too far, peak distortion may result. A similar condition would occur if resistor R5, R6, R7, or R8 became either open-circuited or changed in value, or if capacitor C3, C4, C5, or C6 became leaky. If capacitor C3 or C4 became open-circuited or if capacitor C5 or C6 became shorted, one half of the normal output signal would be removed from the cathode-ray tube, which would then display only the positive or the negative portion of the signal, depending upon the half of the circuit which continued to function.

VOLTAGE DEFLECTION AMPLIFIER (FOR ELECTRO-STATIC CRT) (ELECTRON TUBE)

Application.

The voltage deflection amplifier is used to amplify the input signals before they are applied (normally) to the vertical deflection plates of an electrostatic-deflection type of cathode-ray tube. It is also used to amplify the output signals of a sweep generator, before they are applied as a horizontal sweep voltage to the horizontal deflection plates of an electrostatic-deflection CRT.

Characteristics.

Horizontal Deflection Amplifier. Input impedance is high, thereby preventing any loading of the preceding horizontal generator circuit.

Input capacitance is low, thereby preventing the attenuation of high frequencies.

High-frequency response is good, within the design limits of the amplifier (which in many cases are more restricted than those of the vertical deflection amplifier).

Low-frequency response is good, but only in exceptional cases do the requirements demand response down to zero frequency (direct current).

Bandwidth depends on application design: usually covers a range of approximately 10 Hz to 100 kHz; special applications may require a range of 1 Hz to 500 kHz; other applications may require only a limited range, as in the switch-selected fixed sweeps used in radar deflection.

Output impedance is high, since no current need be supplied to the deflection plates of a CRT.

Gain depends on application design: as a rule it is relatively high, but not as high as that of a vertical deflection amplifier, because the input to the horizontal deflection amplifier is usually furnished by a sweep generator having an output level of appreciable value.

Balanced output, furnished by a push-pull type circuit, is desirable, in order to obtain a uniform deflection field, and avoid pattern distortion and defocusing effects inherent is single-ended output.

Vertical Deflection Amplifier. Input impedance is extremely high, thereby preventing any waveform distortion due to loading of the preceding output circuit supplying the signal to be displayed on the CRT. (Special applications may require a low value of input inpedance, which must then be matched to the source impedance of the input signal. Normally this would occur only when the deflection amplifier is permanently connected to a signal source. This would not be true in the case of a deflection amplifier used in a test oscilloscope, which must function with widely varying source impedances.)

Input capacitance is very low, thereby preventing the attenuation of the high-frequency components of the input signaL

High-frequency response is very good, generally better than that of the horizontal deflection amplifier.

Bandwidth depends on intended application; usual range is 10 Hz to 1 MHz. Test oscilloscopes of high quality may have a vertical amplifier bandwidth covering 2 Hz to 10 MHz. Other applications, such as oscilloscopes designed for use in teletype and audio work, may require a range which includes zero hertz (direct current), but they may require only a limited range in the higher frequencies.

Output impedance is high, since only a potential difference (no current) is required by the deflection plates of a cathode-ray tube.

Gain is usually high, and a gain control is usually included in the circuit, calibrated both in step and vernier values of voltage gain and/or decibels.

Balanced output (push-pull) is desirable-more so than in the horizontal deflection amplifier, because the gain required of the vertical deflection amplifier is usually much higher than that of the horizontal amplifier, in order to obtain a uniform deflection field and reduce the effects of beam defocusing and pattern distortion.

Circuit Analysis.

General. The most versatile voltage deflection amplifiers are those used in the horizontal and vertical deflection circuits of highquality test oscilloscopes. For this reason, the discussion that follows will be directed toward this application. In this way, circuitry peculiar to other applications will, in most cases, be included in this discussion as a matter of course.

A horizontal (voltage) deflection amplifier is designed to amplify the signals from a sweep generator, and apply the amplified (sawtooth waveform) signals to the horizontal deflection plates of an electrostatic deflection type of cathode-ray tube. The sawtooth sweep voltage is applied to the grid of the amplifier tube through a potentiometer, which affords control of the amplitude of the signal used as the horizontal time base. This control is normally front-panel mounted and captioned HORIZONTAL AMPLITUDE. In order to amplify a sawtooth waveform of voltage whose frequency may be (in a test oscilloscope) switch-selectable to a range which may include 10 Hz and 50 kHz as the low and high limits, respectively, the high frequency response must be maintained up to 350 kHz. The reason such high-frequency response is required is that, in order to reproduce a sawtooth waveform without appreciably distorting it, it is necessary to pass all frequencies up to the seventh harmonic of the fundamental frequency of the sawtooth wave. Thus, to pass a 50-kHz sawtooth wave, a minimum bandpass up to seven times this value is required.

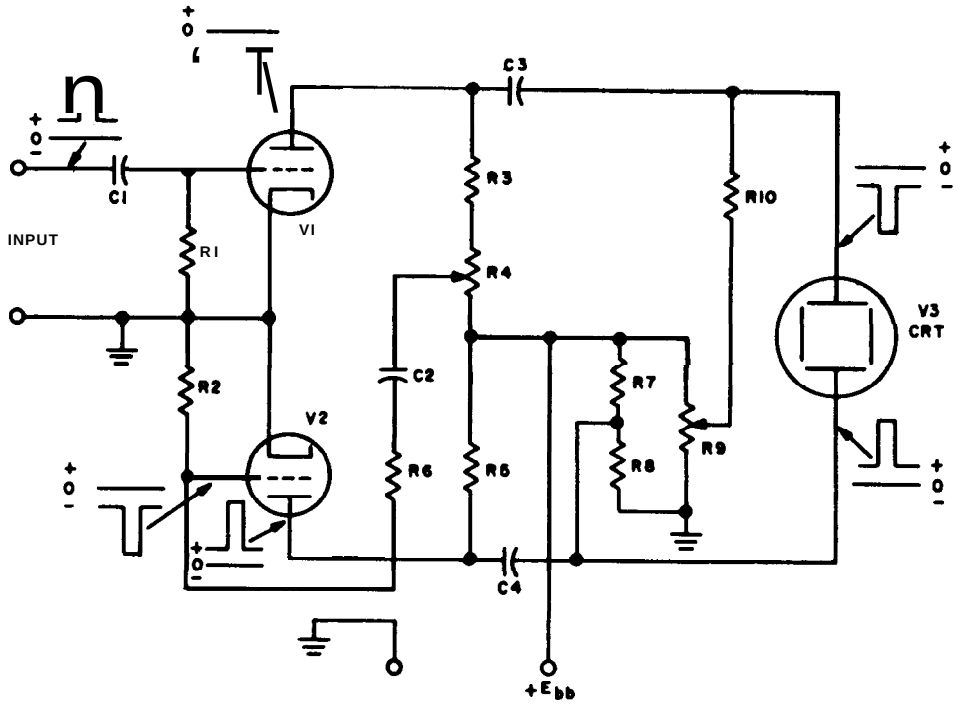
A vertical (voltage) deflection amplifier is designed to amplify the input signals - often extremely minute in value - which are to be displayed on the cathode-ray tube screen. The waveform of the input signal may vary from one extreme - a direct current, or zero frequency - to the other extreme - a square wave whose fundamental frequency in itself is relatively high. In order to pass a signal of zero frequency, a direct-coupled amplifier is the only choice. In order to pass a square wave with reasonable fidelity, a bandpass is required that includes the tenth odd harmonic of the fundamental frequency, which is a frequency of 21 times the fundamental. Therefore, the over-all bandpass required of the vertical amplifier has an extremely wide range. High-frequency compensation is usually included in the circuit, in order to extend the high-frequency response to the limits required. The gain is usually adjustable by means of both “coarse” and “fine” controls. The coarse adjustment, when provided, usually consists of a set of resistance-capacitance networks designed to have various degrees of attenuation. The networks of resistors and capacitors are used to maintain the attenuation of any one network constant over a wide range of frequencies. The fine adjustment of vertical gain is usually a potentiometer, located in the grid circuit of some stage of amplification other than the first. Here,

it is isolated from the critical constants of the attenuation networks (which are located in the first stage), and does not vary the input impedance presented by the circuit to the signal source.

In small and inexpensive vertical deflection amplifiers, a single output tube is sometimes used. The output signal is coupled directly from the plate of this tube to one deflection plate of the CRT, while the other deflection plate is grounded. This is an unbalanced output, and has the following disadvantage: Each time the ungrounded deflection plate goes positive, on a peak of signal voltage, the average potential of the two vertical deflection plates rises to a considerable value above that of the second anode. This causes the electrons in the beam to be accelerated to a higher velocity than that imparted to them by the second anode potential. As a result, the trace brightens on positive peaks of the signal, and the beam is not deflected as much by a given increment of signal voltage because of the higher velocity. Negative peaks have an opposite effect, in that they reduce the average potential of the deflection plates, decelerating the beam to a lower velocity. As a result, the trace is reduced in brilliance on the negative peaks, and the sensitivity is increased because the beam is deflected more than it should be by a given increment of signal voltage. These effects may be eliminated by the use of a balanced, or push-pull, type of output circuit.

In both vertical and horizontal deflection amplifiers of better design, balanced or push-pull deflection is always used. In this type of circuit, signals that are equal in amplitude and opposite in polarity are applied to both deflection plates, neither of which is grounded. The positive side of the high-voltage power supply, which is connected to the accelerating anode of the cathode-ray tube, is grounded. These connections produce a minimum difference of potential between the accelerating anode and the deflection plates. As a result, two advantages are realized: First, the effect of the accelerating anode potential in distorting the deflection field is minimized, because of the fact that as one deflection plate is charged to a potential which is positive with respect to the accelerating anode (which is at ground potential), the opposite deflection plate is simultaneously charged to a potential which is an equal amount negative with respect to the accelerating anode. Under these conditions, a line of equal potential midway between the two charged plates is maintained at the same potential (ground) as that of the accelerating anode. This results in a minimum of beam defocusing and pattern distortion. The second advantage of the positive-grounded connection of the high-voltage power supply is that no high-voltage insulation is required between the accelerating anode and the deflection plates and their associated circuitry. In this respect the problems common to high-voltage circuitry, such as corona and high-voltage breakdown, are eliminated from the region of the cathode-ray tube which includes the neck, the flared portion, and the face (screen), as well as from the output circuits of the deflection amplifiers which feed the signals to the deflection plates. The high (negative) voltage is contained within a small portion of the tube neck at the base, wherein are located the filament and cathode, and the first anode.

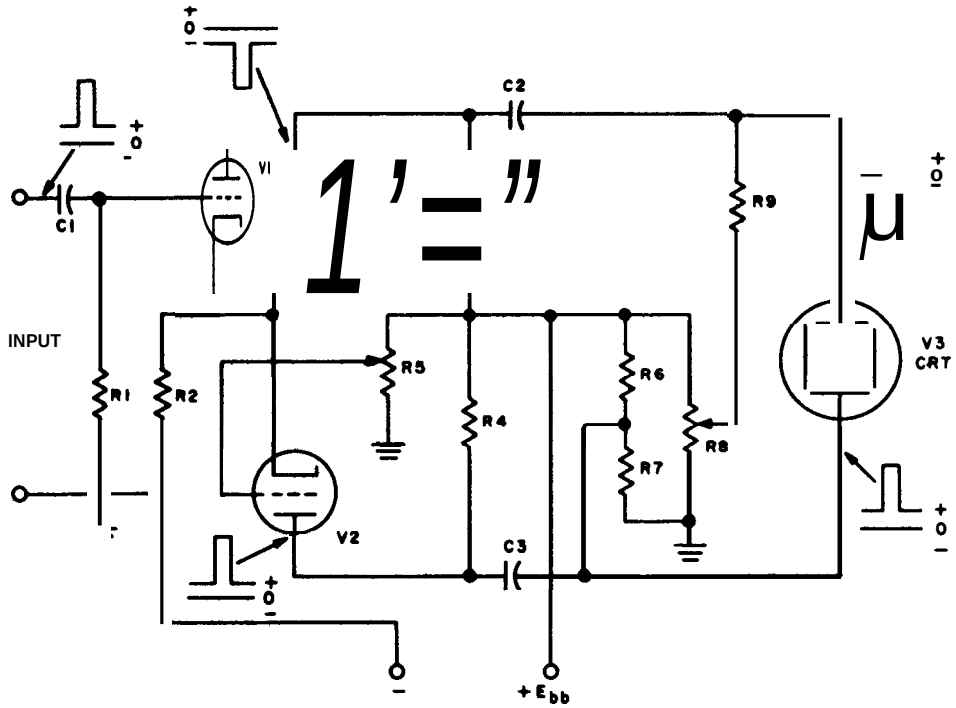
Circuit **operation.** The following schematics illustrate two common types of deflection amplifiers used for electrostatic deflection. The first shows a phase inverter used to obtain two output voltages, equal in amplitude and opposite in polarity, from a single-ended input signal. In this circuit, the input signal, which is shown as a positive pulse, is applied through a coupling capacitor, Cl to the grid of a triode amplifier, V1. The grid is returned to ground through grid resistor RI. The amplified output, which is a negative pulse due to phase inversion in the tube, is taken from the plate and applied, through coupling capacitor C3, to one of the vertical deflection plates of the cathode-ray tube, V3. The plate voltage is applied through plate load resistor R3 and potentiometer R4. The negative output puke at the plate of V1 also appears across R3 and R4, which act as a voltage divider. A reduced value of the negative output pulse is taken from a tap on the voltage divider by means of potentiometer R4 and applied, through coupling capacitor C2 and resistor R6, to the grid of the phase inverter tube, V2. Resistor R2 serves as the grid return for this tube. The output at the plate of V2 is a positive pulse, the amplitude of which is exactly equal to (although of opposite polairty) the amplitude of the output of V1, ***provided that*** potentiometer R4 is properly adjusted to furnish the correct value of signal input voltage to the grid of V2. This positive pulse output of V2 is coupled, through C4, to the other vertical deflection plate of the cathode-ray tube, V3. In this manner, equal and opposite signals are applied to the two deflection plates, to protide a balanced deflection.



Typical Phase Inverter Used as Voltage Deflection Amplifier

A shift circuit is usually included as part of a deflection amplifier for electrostatic deflection, by means of which the electron beam of the cathode-ray tube may be positioned in the exact center of the screen, or may be moved to any desired initial position under conditions of no input signal. Although the shift circuit is not, in a strict interpretation, actually part of the deflection amplifier (because the amplifier furnishes its output at the point of coupling to the CRT - at coupling capacitors C3 and C4 in the previous schematic), it is usually shown along with the amplifier circuitry in order to show the complete load circuit. In the illustration shown, the shift circuit is composed of equal resistors R7 and R8, isolation resistor R1O, and potentiometer R9. The bottom deflection plate of cathode-ray tube V3 is fixed at a potential half-way between +250 volts and ground, by the voltagedivider action of resistors R7 and R8. When the adjustable arm of potentiometer R9 is set exactly half-way between the two ends of its resistance, the voltage at this point - which is furnished through isolation resistor R1O to the top deflection plate - will be exactly equal to the voltage at the junction of R7 and R8. Hence, the fixed dc voltages applied to the top and bottom deflection plates will be equal, and the electron beam will be positioned midway between them. By adjusting the movable arm of potentiometer R9 away from its center position, the top plate of the CRT may be made positive or negative with respect to the bottom plate, thereby positioning the beam above or below the center position on the screen.

The second type of deflection amplifier used for electrostatic deflection is the paraphase amplifier, shown in the following illustration. In this type of circuit a balanced output is obtained from a single-ended input signal by means of common coupling in the cathode circuit of both tubes, which accounts for the circuit being known as a cathode-coupled paraphase amplifier. The input signal, again shown as a positive pulse, is applied through coupling capacitor Cl to the grid of triode amplifier VI, with the grid returned to ground through grid resistor RI. Cathode bias is obtained by means of cathode resistor R2,



Typical Paraphase Amplifier Used as Voltage Deflection Amplifier

which is common to both VI and V2. Since R2 is unbypassed, the input signal at the grid of VI also appears at the cathode, while the inverted signal appears at the plate as one output of the circuit. The signal at the cathode of VI is applied, through direct connection, to the cathode of V2. The grid of V2 is connected to a balance potentiometer which acts as a voltage divider between E_{bb} and ground, to furnish the proper bias so that the output signal of V2 can be adjusted to equal that of V1. The positive pulse at the cathode of V2 will increase the bias, decrease the plate current, and produce a positive output at the plate of V2. The output signal at the plate of V2 is reversed in polarity from the input signal, as in any ordinary vacuum-tube amplifier. But, because the input to V2 is the signal voltage developed across cathode resistor R2, and because this signal is applied to the cathode of V2, which has its grid returned to ground through R5 and is thereby at ground potential insofar as the signal is concerned, the output signal at the plate of V2 has the same polarity as the input signal at the cathode of V2 or the input signal at the grid of V1. In this way, the output signals from the plates of VI and V2, which are applied to the deflection plates of the CRT, are equal in amplitude but opposite in polarity (phase). Resistors R5, R6, and R7 and potentiometer R8 comprise a shift circuit which allows the electron beam to be positioned on the screen of the cathode-ray tube as desired, in the " same manner as described in the preceding typical phase inverter circuit.

The previous circuit operation and schematics have, for simplicity, omitted the additional compensation networks which are often included in specific applications. In order that deflection amplifiers do not restrict the bandwidth of the input signal, they must have wide frequency response, low distortion, and time delay proportional to frequency, similar to the characteristics of video amplifiers. Compensation circuits similar to those discussed under the paragraphs on Video Amplifier Circuits are used in

deflection amplifiers, depending upon the amplifier design and intended application.

Failure Analysis.

No Output. Assuming that a signal of proper amplitude (and polarity if the deflection amplifier is specifically designed for single-polarity pulse operation) is applied to the input terminals, a defective tube should first be suspected as the cause of a no-output condition. An open input coupling capacitor Cl, a shorted grid resistor R1, or an open common cathode resistor R2 (refer to paraphase amplifier circuit diagram), or a faihrte of the power supply would individually be responsible for no output. An open plate resistor on the input side of the circuit (R3 in the illustrations) would also result in no output. Components peculiar to a specific circuit may also be cause of circuit failure. As an example, referring to the second illustration on a typical paraphase amplifier, if plate resistor R4 became shorted, the high value of plate current that would flow through V2 would of course flow through the common cathode resistor, R2. As a result, both cathodes would be at a high positive potential. The grid of VI would therefore be highly negative with respect to its cathode, and might possibly be biased beyond cut off. No signal output would thereby be obtained.

Reduced or Unstable Output. In both of the typical circuits illustrated, a number of conditions could contribute to a reduced, distorted, or unstable output. The failure of out-of-phase amplifier tube V2, its plate resistor, or its output coupling capacitor; if open, would be responsible for an output of approximately one-half the normal amplitude. An open output coupling capacitor from the plate of VI would also result in an output signal of one-half normal amplitude. A change in the value of input grid resistor R1 would change the input impedance to the stage; this might affect the amplitude and possibly the waveform of the input signal. An open-circuited positioning potentiometer or its associated resistor (R9, R1O in typical phase inverter circuit; R7, R8 in typical paraphase amplifier circuit) would prevent the positioning of the waveform display on the screen of the CRT in the normal manner. An open resistor in the voltage divider connected across the positioning potentiometer (R7 or R8 in the typical phase inverter circuit; R5 or R6 in the typical paraphase amplifier circuit) would also be responsible for the failure of the positioning potentiometer ιo properly position the waveform display on the CRT screen.

CURRENT DEFLECTION AMPLIFIER (FOR ELECTROMAGNETIC CRT (ELECTRON TUBE)

Application.

The current deflection amplifier is used to amplify input signals before they are applied (normally) to the vertical deflection coils of the deflection yoke used with an electromagnetic-deflection type of cathode-ray tube. In addition, it is used to amplify the sweep signals which are used as a time base before they are applied (normally) to the horizontal deflection coils of the deflection yoke used with an electromagneticdeflection CRT.

Characteristics.

Horizontal Deflection Amplifier. Input impedance is high; loading of the preceding horizontal generator circuit is thereby prevented.

In put capacitance is low, attenuation of high frequencies is thereby prevented.

High-frequency response is very good: must be so to avoid the possibility of distorting the trapezoidal input waveform of voltage which is required to produce a sawtooth waveform of current through the horizontal deflection coils.

Low-frequency response is good, but does not include zero frequency.

Bandwidth depends on application design: may cover a range of 10 Hz to 100 kHz, but the range is usually more limited because the specific application normally requires only a few fixed sweep frequencies.

Output impedance is relatively low, and must be matched to the load (deflecting coil) for maximum transfer of current with minimum waveform distortion. This requirement acts to restrict the bandwidth.

Gain depends on application design: the current gain (power gain) is usually high, but the voltage gain may be low—even less than one.

Balanced output, furnished by a push-pull type circuit, is desirable, in order to obtain a uniform deflection filed. However, the principal applications of the electromagnetic deflection type of cathode-ray tube, namely, radar and television, do not require the precise duplication of the input waveform that is essential in the principal applications of the electrostatic deflection CRT, namely, waveform analysis and complex wave amplitude measurement.

Vertical Deflection Amplifier. Input impedance is normally extremely high, in order to prevent any

waveform distortion due to loading effects on the circuit supplying the input signal. However, since any particular application of an electromagnetic deflection type of cathode-ray tube normally operates with a permanently connected input circuit, the input impedance of the amplifier maybe of a fairly low value, which must be matched to the source impedance of the input signal.

Input capacitance is low, in order to prevent the attenuation of high frequencies.

High-frequency response is very good: must be so in order to respond to extremely sharp input pulses without introducing appreciable time delay.

Low-frequency response is good, but does not include zero frequency.

Bandwidth depends on application design: may cover a range of 10 Hz to 100 kHz, but the range may be more limited when only the leading edge and the length of an input pulse, and not the shape of the top of the pulse, is of consequence, as in pulse display applications (radar).

Output impedance is relatively low, and must be matched to the load (deflecting coil) for maximum current transfer with minimum waveform distortion.

Gain depends on application design: the current gain (power gain) is high, but the voltage gain maybe low.

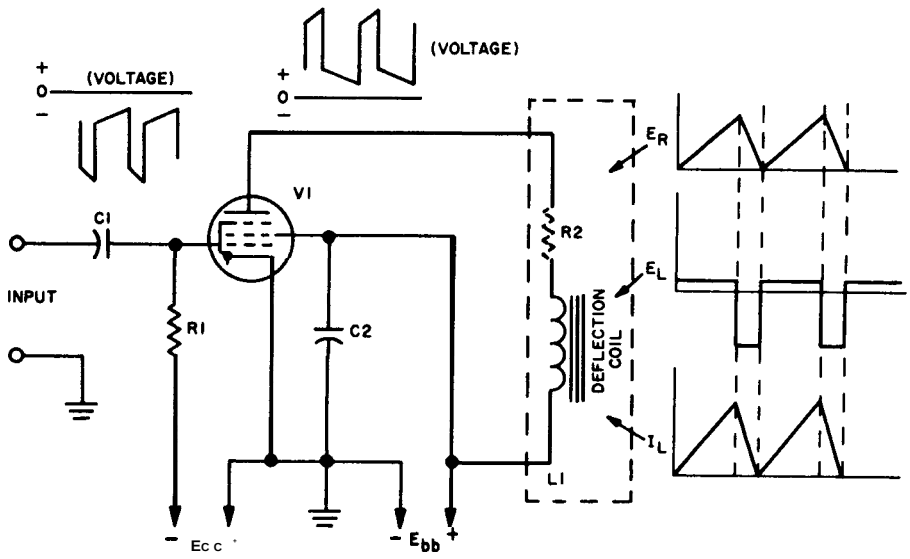
Balanced (push-pull) output is desirable, both from the standpoint of the high power output with minimum distortion required for magnetic deflection, and the need for an absolute minimum of beam defocusing when pinpoint radar target presentation is required.

Circuit Analysis.

Generel. The deflection of the electron beam in an electromagnetic deflection type of cathode-ray tube is proportional to the strength of the magnetic field set up within the tube, which is in turn proportional to the value of current passing through the deflection coil. Since it is desirable to deflect the electron beam linearly, the current through the coil must increase linearly with time. When the end of the sweep is reached, the electron beam must be returned to its starting point quickly. The current wave required for electromagnetic deflection must therefore be of sawtooth shape if the resultant sweep is to be linear. It should be observed that it is the ***current*** wave which must be of sawtooth shape for an electromagnetic tube, not the ***voltage*** wave as in an electrostatic tube.

The deflection coils, through which the deflection amplifier output current flows, consist of wire wound around either a non-magnetic core or an iron core. The wire used in the coil has, in addition to the desired inductance, some amount of resistance. As a result, the sawtooth current must flow through the equivalent of a series resistive-inductive (R-L) circuit. Since a square wave of voltage will produce a sawtooth wave of current in a pure inductance, whiIe a sawtooth wave of voltage will produce a sawtooth wave of current in a pure resistance, the combination of a square wave and a sawtooth wave of voltage is required to produce a sawtooth wave of current in a circuit containing both resistance and inductance. Such a combined waveform has the shape of a trapezoidal waveform of voltage. This, then, is the waveform which must be amplified by the current deflection amplifier.

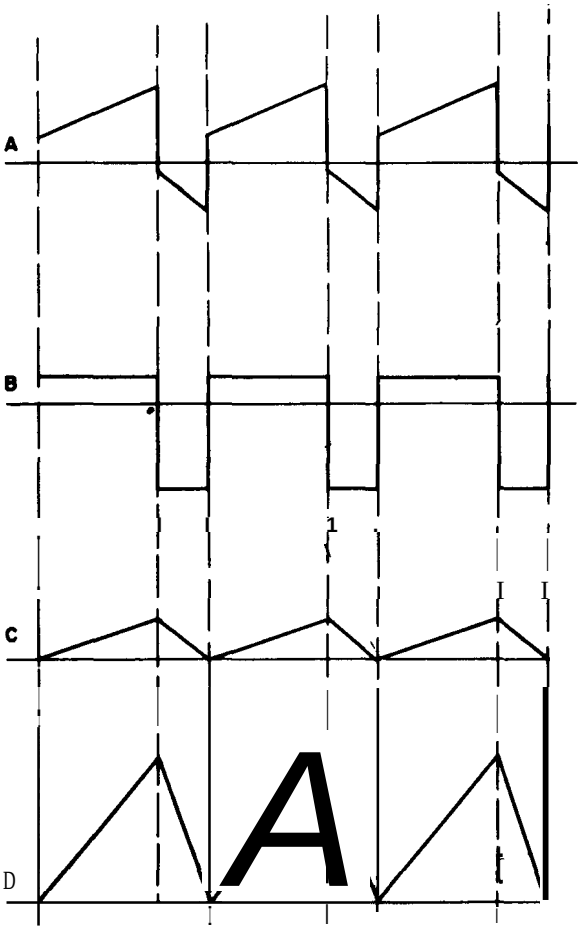
Circuit Operation. The accompanying schematic illustrates a simplified typical deflection amplifier for producing a horizontal time base using magnetic deflection. The input signal, which is a trapezoidal waveform of voltage as shown in the illustration, is applied through coupling capacitor C1 to the grid of pentode amplifier VI. The amplifier is operated as a Class A stage, with fixed bias applied from a negative power source. Sufficient bias is applied to the grid, through grid resistor R1, to prevent the grid from going positive with maximum signal input, The amplifier tube, Vl, is a pentode or a beam power type, in order to obtain the power amplification that is required to furnish sufficient current to the deflection coil. This coif may require between 50 to 100 milliamperes of current for maximum beam deflection. The output of VI is applied to the deflection coil, which in the illustration is presented by an inductance, L1, with a resistance, R2, in series with it, shown as a dotted resistance because it is actually a part of LI. The output voltage waveform at the plate of V1 is trapezoidal. when this waveform is applied to the series R-L circuit (deflection coil), the voltage waveform appearing across the resistance is resolved to a sawtooth shape, while that appearing across the inductance is resolved to a square-wave shape. The square wave of voltage across the inductance causes a sawtooth wave of current through it, which is the required waveform for producing a horizontal time base deflection on the screen of the cathode-ray tube.



Typical Current (Electromagnetic) Deflection Amplifier

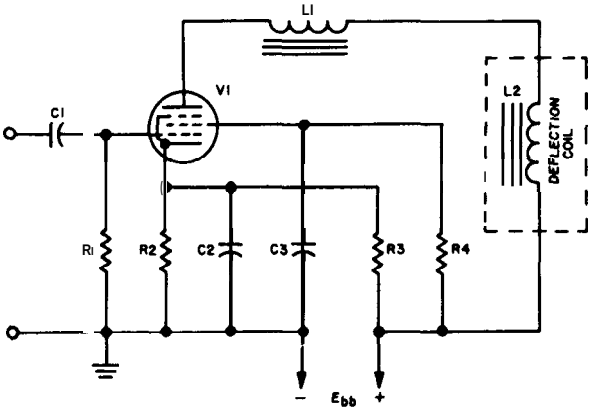
The development of the sawtooth current waveform from the trapezoidal voltage input waveform is shown in the following illustration. The trapezoidal voltage input waveform to the grid of amplifier VI is shown at A; differentiated voltage which appears across the inductance is shown at B; the integrated voltage which appears across the resistance (of the coil) is shown at C; the current through the deflection coil, which is the composite result of waveforms B plus C, is shown at D.

491-044 0-73- 35



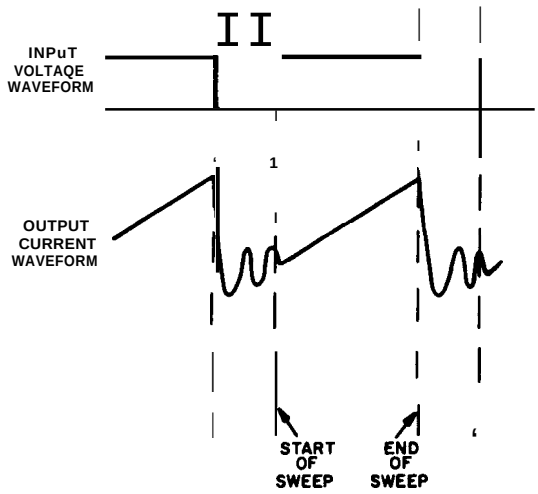
Development of Sawtooth Current Waveform in Deflation Coil from the Trapezoidal Voltage Waveform Input to Amplifier

A second circuit for producing a horizontal time base for magnetic deflection is shown in the following illustration. The input signal to this amplifier is a square wave, instead of the trapezoidal wave required in the previous circuit. This signal is applied, through coupling capacitor Cl, to the grid of a pentode or beam power amplifier, VI. The grid is returned to ground through resistor RI. The positive voltage applied to the cathode of VI, from the plate supply by means of the voltage-divider action of resistor R3 and cathode resistor R2, maintains V1 biased to cut-off in the absence of an input signal. When the first positive pulse of the input square wave reaches the grid, the tube conducts heavily. The resulting plate current, flowing through deflection coil L2 and inductor L1, rises exponentially toward a value which would be limited only by the resistance of the circuit. Before this limiting point is reached, however, conduction of the tube is suddenly interrupted by the negative-going end of the square-wave input pulse. In this way, only a relatively linear portion of the exponentially rising waveform is utilized. When the conduction of the tube is interrupted at the end of the positive square wave, V] is cut off, and the current decays rapidly to zero. This rapid decay is due to a change in the time constant of the circuit between the rise and fall of the current. During the rise of current, the circuit time constant (which is given as inductance divided by resistance, or L/R) is long, because of the large value of inductive reactance (due to the large inductance) and the small value of resistance in the circuit. The resistance is composed of cathode resistor R2 and the low value of plate resistance of V1. During the decay of current, the time constant is made short, as a result of the increase in the value of plate resistance when V1 stops conducting. With the shortened time constant, the current decays rapidly. The additional value of inductance in the circuit due to inductor L1 increases the time constant, to produce a slow build-up of current. Inductor L1 maybe effectively removed from the circuit, by shorting across it, when faster sweep deflection rates are required.



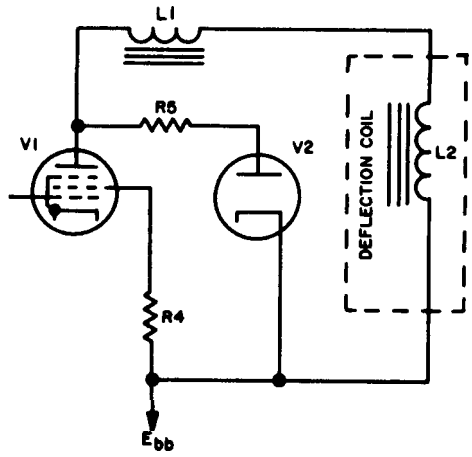
Current (Electromagnetic) Deflection Amplifier Utilizing Square-Wave Input

The sudden decay in current flowing in the deflection coils, when the tube stops conducting, causes a counter e.m.f. to be produced in the coil which opposes the current decay. In addition, the circuit may be shock-excited into oscillation by the sudden change in value of current. Although the oscillations gradually die out, they may continue into the following sweep, especially if the circuit Q is high. This condition may result in a nonlinear start of the build-up of current in the coil, and therefore a nonlinear sweep, as shown in the following illustration.



Undamped Oscillations in Deflection Coil Current

These oscillations may be eliminated, or damped out, by lowering the Q of the circuit by means of a resistor shunted across the coil. However, this wastes some of the deflection current; a more satisfactory method incorporates the use of a damping diode shunted across the deflection coil, as shown in the following illustration. In this circuit, diode V2 acts to damp out the oscillations in the following manner: When the current through V1 is increasing (during the rise of the sawtooth, current wave shown in the illustration above) to provide the sweep deflection, the voltage at the plate of VI is lower than the plate supply voltage by the amount of voltage drop in the deflection coil and inductor. The cathode of damping diode V2 is therefore more positive than its plate, and the diode will not conduct. When the current through V1 falls to zero (at the end of the sawtooth current wave illustrated), the voltage at the plate tends to rise above the plate supply voltage due to the fact that the counter e.m.f. generated by the inductance adds to the plate supply voltage. When this condition is reached, damping diode V2 conducts, and any oscillations are dissipated in resistor R5



Deflection Amplifier Output Circuit With Damping Diode Added

Balanced output (push-pull) circuits, when used, usually operate by means of a phase inverter circuit fed from a single-ended source, as described in the previous circuit on Voltage Deflection Amplifiers. In some cases in radar deflection circuitry, the two outputs obtained by means of a phase inverter are separately amplified by individual single-ended deflection amplifiers, and then applied to the two separate windings of a split-winding deflection yoke.

Failure Analysis.

No Output. Assuming that a signal of proper amplitude and waveform (square wave or trapezoidal wave, depending on circuit design) is applied to the input terminals, a defective tube would be the most likely cause of a no-output condition. If the tube is found capable of operation, an open input coupling capacitor Cl or open grid resistor RI, or open cathode or screen resistors, if used, may be the cause of no output. Since a currentdeflection amplifier is characterized by a relatively high value of plate-current flow, a common source of trouble is an open deflection coil. If the coil is open-circuited, and the circuit is similar to these previously shown under Circuit Operation, the application fo screen voltage to

the tube with no plate voltage present may result in a burned out tube or poor emission, because of excessive screen current. The same condition may prevail if the deflection coil is remotely located from the amplifier, and the interconnecting cable is inadvertently disconnected during operation. No output may also be due to failure of the plate-voltage supply.

Reduced or Unstable Output. A change in value of almost any of the circuit components, due to age or partial failure, may contribute to a reduced output. If the capacitance of input coupling capacitor Cl changed or the resistance of grid resistor RI changed, the output would be affected. If the cathode bypass capacitor (if one is used) became either open or shorted, the bias would be changed, resulting in either decreased output due to degeneration (if open) or distortion due to no bias (if shorted). If the circuit incorporates fixed cathode bias obtained through a voltage divider from the E_{bb} line, an open reSIStOr on the E_{bb} side of the cathode (R3 in the second circuit illustrated) would interrupt the fixed bias, and the circuit would operate with self-bias, which may produce distortion under high signal input conditions. A decrease in the voltage of the plate supply, due to faulty operation, would also be responsible for a reduced output.

4

PART 5-9. OPERATIONAL AMPLIFIERS

OPERATIONAL AMPLIFIERS

General.

The operational amplifier is a high-gain dc amplifier utilizing negative feedback to establish and control precise gain. An operational amplifier may be used to perform mathematical operations such as addition, subtraction, multiplication, and division, or to provide special waveforms or voltages. This type of amplifier is used especially for analog computation and instrumentation, and in special systems design. Analog computation differs from logic computation in the manner in which it is accomplished. The information applied to a digital computer is separated into and handled in discrete measurable steps (digits), whereas the information applied to an analog computer is usually slowly varying ac or dc voltages. For example, a sawtooth voltage could easily represent the acceleration of an airplane. The slope of the sawtooth could represent the magnitude of the acceleration; the starting level of the slope could represent the initial velocity, and the final level of the slope could represent the final velocity of the airplane. Thus, complex analog problems are solved by operational amplifiers, using resistive input and output networks and high-gain dc amplifiers.

Operational amplifiers are named for their function. For example, the summing amplifier produces an output voltage that is proportional or equal to the sum of the inputs. A difference amplifier acts as a subtracter, producing an output equal to the difference between the input voltages. Similarly, the exponential amplifier produces an exponential output, and the derivative amplifier produces the desired derivative. The logarithmic amplifier, in turn, produces a logarithmic output. Each of these mathematical types of operational amplifiers is fully discussed later in this section. The combining and coincidence amplifiers are considered as special nonmathematical operational circuits.

COMBINING AMPLIFIER (ELECTRON TUBE)

Application.

Combining amplifiers are used in transmitter modulation stages, or in combining circuits of television transmitters, where it is necessary to combine two or more signals to obtain an output proportional to each input.

Characteristics.

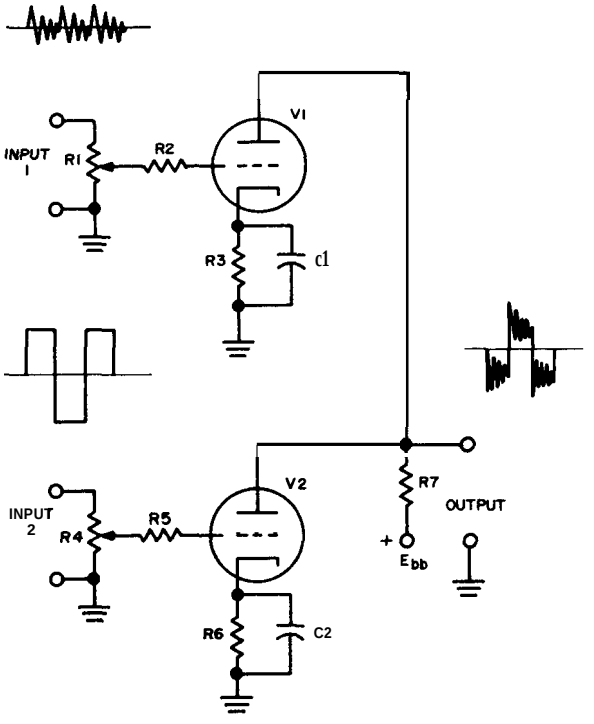
Uses a common plate load resistor.
Has two or more inputs.
Uses a separate amplifier for each input.
May be dc coupled or capacitively coupled.
Uses triode electron tubes.
Uses cathode bias.

Circuit Analysis.

General. The combining amplifier produces an output which is the result of two or more input signals not necessarily of the same shape, phase, or frequency. Each input signal is applied directly to the grid of a separate electron-tube amplifier through a resistive voltage-divider network. The amplified output of each tube is developed across a common plate-load resistor, resulting in an overall output which is the combination of all input signals.

Circuit Operation. A schematic of a typical combining circuit is shown in the accompanying illustration. Potentiometer RI and resistor R2 form a voltage driver which couples an input signal to the grid of triode V]. Potentiometer R4 and resistor R5 form a voltage divider which couples an input signal to the grid of triode V2. Resistor R3 is the cathode bias resistor for Vl, and capacitor Cl is the cathode bypass capacitor. Resistor R6 is the cathode bias resistor for triode V2 and capacitor C2 is the cathode

bypass capacitor. Resistor R7 is the common plate-load resistor used by both VI and V2.



Combining Amplifier

The amplitude of the input signal applied to the grid of V1 is determined by the setting of potentiometer R1, and the input signrd applied to V2 is, likewise, determined by the setting of potentiometer R4. By using R2 in series with the grid of VI, and R5 in series with the grid of V2, the grid circuits are effectively held at a high impedance, and the shunting effect of R1 and R4 on the respective grid input circuit is minimized. At the same time, overdriving of the grids is limited, since any grid current flow through R2 or R5 will develop an opposing negative bias and reduce the drive.

Normally both tubes are biased so that they are operating at approximately the same plate current. Thus, equal changes of grid voltage produce equal plate current variations and maintain a linear input-output relationship. When the grid of VI is driven in a positive direction, plate current will increase and produce a negative swing across load resistor R7. Since R7 is common to both tubes, if the grid of V2 is also driven positive at the same time as V1, the total plate current will be equivalent to the combination of both input signals at that instant. In this example, the circuit is acting as an adder. On the other hand, if one input is decreasing while the other input is increasing, the total plate current and voltage swing across R7 will represent the difference between the two signals.

Since the output voltage is developed by the separate plate currents of VI and V2 flowing through a common load resistor, the output waveform at any instant is the combination of the two input signals. Hence, applying a sawtooth waveform to one input, and a rectangular waveform to the other input, will produce an output waveform which contains both sawtooth and rectangular signal components, and will be the composite waveform produced by both signals. Because of the normal phase inversion or polarity change produced by the tube amplifier, the combined output will be out-of-phase with respect to the input. Where an output of the same phase or polarity as the input is desired, an additional stage of linear application will be required. The combining circuit is used when it is desired to combine the outputs of two separate channels to control a third channel.

Failure Analysis.

No Output. Loss of output can result from a defective plate supply voltage source, Ebb, or if resistor R7 is shorted or open. Loss of output can also occur if a failure exists in each of the individual amplifiers. Both triodes VI and V2 can be defective, both cathode bias resistors or both grid resistors can be open, or both input potentiometers maybe open.

Output voltage can not be developed if plate load resistor R7 is open or shorted. If the plate supply voltage source is defective, triodes V1 and V2 will not be supplied with either plate voltage or plate current to develop an output.

If plate load resistor R7 and the plate supply voltage source are not defective, there must be a defective component in both amplifier circuits. Consider first the circuitry associated with electron tube V 1; if the correct signal voltage is present at the grid of VI and no output is obtained from VI, cathode bias resistor R3 may be open, or tube V1 itself maybe defective. If potentiometer RI is defective, no sighai will appear at the grid of V 1 and no output will be obtained from this stage. By the same reasoning, if resistor R4 is

open, no signal will appear at the grid of V2, and no output will be obtained from V2.

An open grid resistor R5 or cathode resistor R6 will prevent an output signal from being obtained from V2. If the proper signals and proper voltages are available on the elements of V2, but no output is developed, the electron tube is probably defective.

Low or Distorted Output. A low or distorted output will be developed if the plate supply voltage is not the proper value, or if plate load resistor R7 is not the correct value. If either or both bypass capacitors C 1 and C2 are defective, or cathode resistors R3 or R6 are shorted, the output may be distorted. Defective electron tubes may also beat fault.

A lower than normal plate supply voltage or improper bias will cause the triodes to be operated over the nonlinear portion of their plate current-grid voltage characteristic curve. This will result in distortion of the output waveform. Shorted grid resistors R2 or R5 will allow a greater signal amplitude to appear at the grid of V1 or V2. This may drive the tube into saturation.

If one of the tubes is weaker than the other, a low output will be obtained, even though the voltages and parts of each amplifier stage test normal.

COMBINING AMPLIFIER (SEMICONDUCTOR)

Application.

Combining amplifiers are used to provide a single output which is equal to the combination of two or more input signals not necessarily of the same waveshape or frequency. The combining amplifier is used in transmitter modulator stages or in the combining circuits of television transmitters.

Characteristics.

Two transistor amplifiers are connected provide a common output.

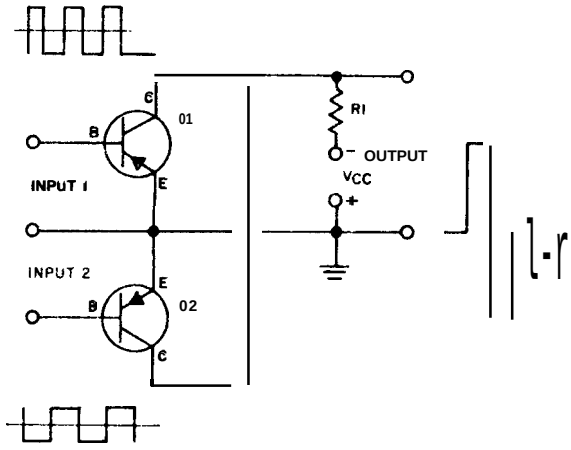
Output signal is developed across a common load resistor.

Two or more simultaneous inputs are necessary.

Circuit Analysis.

General. Two or more input signals not necessarily of the same shape, phase, or frequency, are combined to produce an output which is the result of these signals. Each input signal is applied directly to the base of individually grounded emitter PNP transistor amplifiers. The output of each amplifier is developed across a common collector resistor. The resulting output is then the combination of all input signals.

Circuit Operation. A typical schematic of a combining amplifier using the common-emitter arrangement is shown in the accompanying illustration. In the circuit, Q1 and Q2 are two identical PNP type transistors. The output impedance of the preceding stage is used to develop forward base bias for Q1 and Q2. The emitters of both transistors are grounded, and the collectors of both transistors are comected to the same end of common load resistor RI.

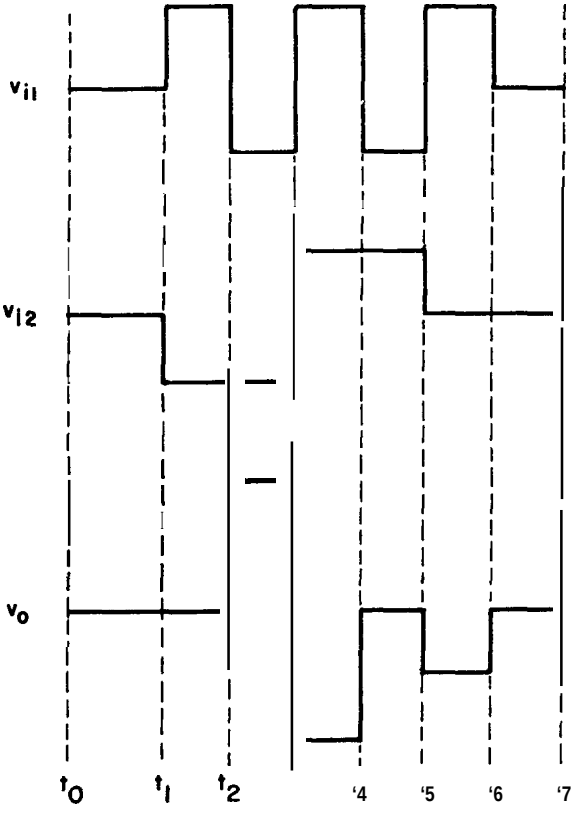


Combining Amplifier

Assume that a positive-going rectangular input waveform is applied to the base of Q1, and a negative rectangular input waveform of one half the frequency, but with the same amplitude as the input to Ql, is applied to the base of Q2. The output which is produced across the collector load resistor contains the amplified resultant voltages of the two waveforms.

For ease of circuit explanation refer to the accompanying input and output waveform chart. At time *O, both transistors have equal forward bias and no input voltage applied, and are in their quiescent or resting condition. At this time, the total of both collector currents produces a positive' voltage drop across common load resistor R1, and reduces the collector voltage applied to Q1 and Q2 to its normal resting value. At time '1, the positive-going leading edge of the pulse applied to the base of Q1 drives it

more positive and reduces the forward bias. The collector current of Q1 is correspondingly reduced, and the collector voltage tries to rise toward the negative supply value. At the same time, the negative leading edge of the input pulse applied to Q2 increases the forward bias, and the collector current of Q2 increases. Assuming equal amplitude inputs and matched transistors, the opposing changes in collector current through common collector resistor R1 balance each other out, so there is no effective change in current flow and voltage across RI. This condition occurs continuously from time t_1 to time '2. During this time, the output remains at its normal resting level as shown in the waveform chart.



Input and Output Waveform Relationships

At time '2, the input pulse on Q] reaches its trailing edge, driving the base of Q1 in a negative direction and increasing the forward bias. The collector current of Q1 now increases, and adds to the collector current drawn by Q2 which still has a negative pulse (forward bias) applied. With twice the normal collector current flowing through RI, the total collector voltage is decreased, and a positive-going output spike of voltage is produced. This positive output voltage continues for the duration of the negative portion of both input pulses from time '2 to time '3.

At time '3, both input pulses end and the trailing edges both drive the bases of Q 1 and Q2 positive, reducing the forward bias on both transistors. Consequently, the collector current of Q1 and Q2 flowing through R1 is reduced to twice the normal value, producing a negative-going output voltage swing as the collector voltage rises toward the supply value. This negative output voltage continues during the steady-state condition of the input pulses between times '3 and '4. At time '4, the trailing edge of Q1 input pulse drives the base of QI negative, increasing the forward bias. The collector current of Q1 increases, and the output voltage tends to rise in a positive direction as the collector voltage of Q1 decreases. However, the positive pulse applied to Q2 base still continues to keep the forward bias reduced, dropping the collector current of Q1. At this time, the increase of collector current through Q1 exactly balances out the decrease of collector current through Q2, and the opposing currents cancel so that no output is produced. Thus, the total output voltage returns to its normal resting value (the zero output level) between times '4 and '5 (the input voltages are again canceling each other in the output). At time t_5, the positive pulse applied to Q2 ends, and the trailing edge of the pulse drives Q2 base is a negative direction until the collector current of Q2 is returned to its normal resting value. At the same time, the leading edge of the input pulse applied ***to*** the base of Q] drives the base positive, reduces forward bias, and reduces Q2 collector current. During the interval from t_5 to t_6, Q2 collector current remains at the resting value, and Q 1 collector current is less than normal. Thus, the collector voltage of Q 1 increases negatively toward the supply value. Because Q2 is resting in its quiescent condition and only the current in Q 1 is reduced, the negative output voltage is only haIf the amplitude produced when both transistors are operating. At time t_6, the positive input pulse on Q1 base ends, and the negative trailing edge of the pulse increases the forward base bias and returns Q1 to its normal forward-biased condition. Hence, normal collector current of Q 1 occurs, and, since no

input pulse is applied to Q2, both transistors rest in the quiescent condition, effectively producing no output. At time '7, if the pulses are continued, the cycle of operation described above repeats.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low vrdues of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No Output. No output may be the result of defective supply voltage, a defective output resistor, or a defective transistor. With no collector voltage available for either transistor, no output can be produced. This lack of collector voltage may be the result of a faulty collector supply voltage source (V_{CC}), **or** a shorted or open collector resistor RI. If neither V_{cc} nor RI is defective, both QI and Q2 must be defective in order to produce no output.

Low and Distorted Output. Since there are only four components which make up this circuit, and two of them (R1 and V_{cc}) would not produce an output if either were defective, a low and distored output will result if either Q1 or Q2 is defective. In this case, the output of the good transistor alone would produce the total output voltage of the circuit, and no combining action would occur.

COINCIDENCE AMPLIFIER (ELECTRON TUBE)

Application.

The coincidence amplifier is mainly used in analog and digital computers. It is used to control the repetition frequency and pulse duration of a given signal by producing an output only when two simultaneous input signals are present.

Characteristics.

Requires a multigrid type of tube such as a pentode.

Simultaneous inputs are applied to the control grid and the suppressor grid.

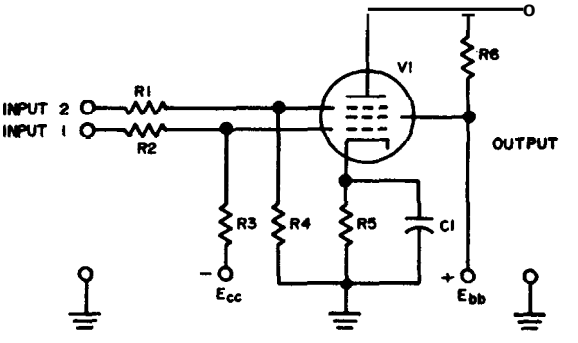
Tube is normally held at plate current cutoff by a large negative bias voltage.

A clipping circuit within the amplifier clamps the output to a constant amplitude.

Circuit Analysis.

General. The coincidence amplifier uses a pentode operated below plate current cutoff. An input signal applied to the control grid does not drive the tube above cutoff unless another signal is applied to the suppressor grid at the same time. When both signals are present, the tube conducts and the output is held at a constant level by a clipping circuit within the amplifier. In effect, the coincidence amplifier functions as a gated amplifier, which only operates when switched on by simultaneous input signals.

Circuit Operation. The schematic of a coincidence amplifier is shown in the accompanying illustration. Input signals are applied to the suppressor and control grids of pentode VI through resistors RI and R2. Resistor R5 is the cathode-biasing resistor, and capacitor Cl is the cathode bypass capacitor.



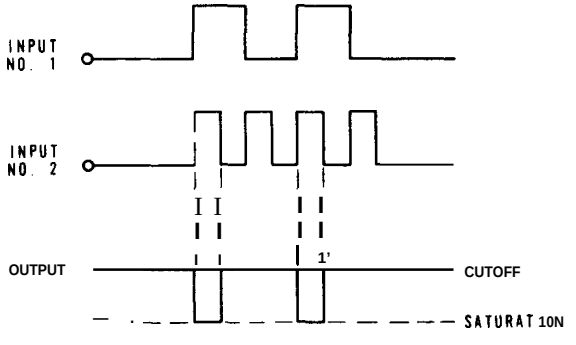
coincidence Amplifier

Resistor R4 is a clamping resistor, which limits the output to a certain level. The highly negative bias voltage (E_{cc}) is applied to the control grid of VI through isolating resistor R3. The screen grid and plate of V1 are furnished with positive dc supply voltage from a common source. Plate load resistor R6 drops the plate voltage to a lower positive value than the screen grid supply voltage. The output voltage is obtained between the plate of VI and ground, developed by plate current flow through R6.

The primary input signal (input-1) is applied to the control grid of V1 through resistor R2. This voltage can not by itself raise the tube grid out of the cutoff

region. The output voltage thus remains at a value slightly less the plate supply voltage. The second input signal (input-2) provides a large positive gating potential on the suppressor grid and overcomes the fixed negative grid bias. When the primary input signal occurs at the same time that the second input signal is applied to the suppressor grid, the pentode conducts.

As shown in the following illustration, an output will be present only at those times when both input no. 1 and input no. 2 are positive at the same time (in coincidence). As the conduction and plate current through R6 increases, the plate voltage decreases by the drop across R6. Plate current is prevented from increasing above a certain level by a suppressor grid-to-cathode feedback voltage. This voltage is developed across resistor R4 when the peak input to the suppressor is large enough to cause the suppressor grid to draw current. (Electron flow from the cathode to the suppressor grid of V1 and ground through R4 develops a negative voltage, which opposes the applied suppressor signal voltage.) The flow of suppressor current also causes the cathode to become more positive, thus increasing the cathode bias voltage and retarding tube conduction. The amplitude of the plate output voltages is then held constant by the combined effect of the retarding suppressor and cathode bias voltages, regardless of the amplitude of the input pulses.



Failure Analysis.

No Output. Lack of filament supply, screen grid or plate supply voltage, a defective electron tube, an open input or output circuit, as well as improper bias, can produce a no-output condition.

A lack of plate voltage, measured between plate and ground, can be caused by open plate load resistor R6. In this case, the screen grid will also glow red, due to an overload, since the electron flow is attracted to the screen. If there is no plate or screen voltage, the plate supply voltage source is probably defective.

When no output exists, but there is a higher than normal plate voltage, plate load resistor R6 may be shorted or tube V1 may be defective.

An open cathode circuit will result if cathode resistor R5 is open. Check the resistance of R5. No filament voltage will also cause a loss of output. This condition can result from a defective filament supply source or defective tube.

An open control gain or screen grid resistor (RI or R2) will prevent a signal from being applied to the supressor grid or control grid. Check RI and R2.

If none of the components is open or shorted and voltages present on the elements of the electron tube are of the proper value, pentode V1 is probably defective.

Low or Distorted Output. Defective grid, bias or plate supply resistors, or an open or shorted cathode capacitor Cl can cause low or distorted output voltage.

An improper voltage on the control grid of V1 indicates that control grid resistor R2 may be open, or that biasing resistor R3 may be open or shorted. A shorted suppressor grid resistor, RI, or an open or shorted clamping resistor, R4, will be indicated by improper voltage on the suppressor grid of V]. If RI were shorted, only the output would be lowered, but if R4 were shorted, the output would not be clamped at a specific level, and would depend on the input level.

The cathode VI may measure an incorrect potential because cathode biasing resistor R5 is defective, or because cathode bypass capacitor C 1 is open or shorted. A shorted bypass capacitor is indicated by

no voltage at the cathode. An open cathode resistor will usually indicate above normal voltage, since the meter multiplier will act as the cathode resistor.

DERIVATIVE AMPLIFIER (ELECTRON TUBE)

Application.

The derivative or differentiation amplifier is used in analog computers and control circuits to develop an output voltage which varies negatively as the derivative of the amplified input voltage.

Characteristics.

Has a low input and low output impedance.

Uses a capacitive input network.

Uses negative feedback.

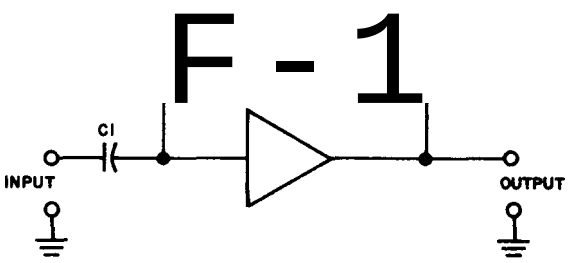
Operation of the amplifier is based on resistance-capacitance time constant relationship.

Output is 180° out of phase with input.

Circuit Analysis.

General. The derivative amplifier develops an output which is the differentiated value of the input voltage. This output is developed by the relationship between the input capacitor and a feedback resistor of a triode operational amplifier. The r-c time constant, which determines the exponential decrease of current, is the product of the capacitor and the feedback resistor. The exponentially varying current flows through the capacitor, the triode, and the feedback resistor. This current value times the feedback resistor value equals the output voltage value at any given time. The output voltage, then, varies exponentially as the current varies.

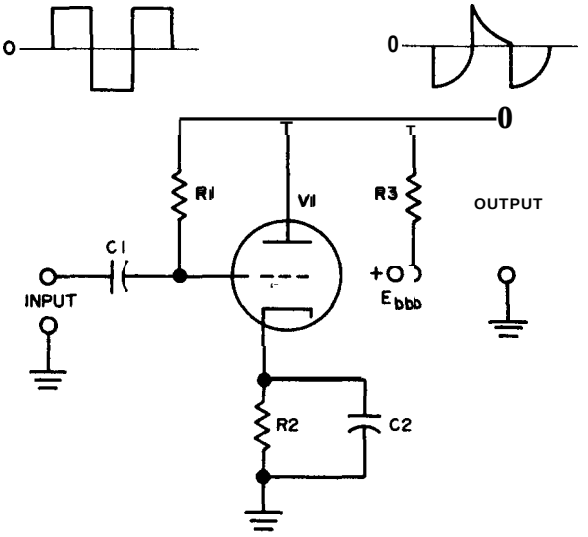
Circuit Operation. The one-line diagram of a derivative amplifier is shown in the accompanying illustration. It shows a derivative amplifier in simplified form. The triangle represents the basic operational amplifier circuitry, so that only a capacitive input and a resistive feedback network are needed to complete the functional diagram of the derivative amplifier. This type of diagram makes it easy to recognize the circuit function, particularly in complex illustrations where many operational amplifiers are used.



Derivative Amplifier

The schematic of a derivative amplifier is shown in the accompanying illustration. Capacitor Cl is an input capacitor which couples the input signal to the grid of triode V1.

Together with feedback resistor R1, C 1 forms an R-C time constant network which determines the output waveform at any given time. Resistor R2 and bypass capacitor Cl form the cathode-biasing network for triode VI. Resistor R3 is the plate load resistor from which the output is taken.



Derivate Amplifier Schematic Diagram

When a positive-going pulse input signal is applied to the grid of VI through capacitor Cl, the grid of V1 is driven positive. This causes maximum plate current flow, which develops a maximum negative output, and the current through feedback resistor R1 is also at a maximum. The large feedback current through R1 produces a voltage drop across RI, which slightly decreases the total input voltage. Capacitor Cl charges at a rate determined by the time constant of Cl and R1. The voltage applied to the grid of VI then decreases at the rate that Cl charges. Plate conduction is decreased by an amount proportional to the decrease in grid signal voltage, and the positive-going output voltage increase is proportional to the decrease in plate current. The resulting output voltage varies directly with the charge on capacitor C 1. This output voltage is the negative derivative of the positive input voltage. The charging of Cl during the flat top portion of the input signal continues until the input signal abruptly switches polarity. The negative-going input signal now causes the charge on capacitor Cl to discharge abruptly. The full negative input voltage swing now is applied to the grid of VI and triode V1 is driven into cutoff. The internal resistance of V1 is now greater than the resistance of R1, permitting the capacitive discharge to flow directly through RI to the output. At this point, the positive output vohage reaches a maximum positive value. Once discharged, capacitor C 1 again charges through resistor R1 at a rate equal to the value of capacitor C 1 times resistor RI. As the capacitor charges in a positive direction, the grid of V1 becomes more positive, and rises above cutoff. This causes plate current to flow, and produces a decreased plate output voltage (negative swing), at the rate that capacitor C 1 charges. The decreasing positive output voltage represents the negative derivative of the negative input signal.

Failure Analysis.

No Output. A defective electron tube, an open input or output circuit, an open biasing network, or a defective plate supply voltage can result in loss of output voltage.

The input signal can not be applied to the grid of V1 if capacitor Cl is open. If cathode-biasing resistor R2 is open-circuited, the output and tube current flow will be prevented. An open plate load resistor, R3, will prevent plate voltage from being applied to the plate of VI. Similarly, if R3 were short circuited, no output voltage variations could be developed. With a defective plate supply voltage source, no voltage would be available for the plate of V1. If no output occurs, and the proper potentials appear at the electron tube elements, electron tube V1 is probably defective. 4

Low or Distorted Output. A shorted input, a defective feedback network, a defective triode V1, or a diminished plate supply voltage value can cause the output to be low or distorted.

A diminished plate supply voltage will cause low plate voltage and the output to be lower than normal. If capacitor Cl is shorted, no charging action will occur, resulting in an output which is not the derivative of the input. A shorted or open feedback resistor R1 will cause the same effect as a shorted input capacitor. If cathode biasing resistor R2 is defective, V1 will be improperly biased and a lower, or higher, than normal plate current will produce an improper output.

If cathode bias capacitor C2 is shorted, it will produce an abnormally large and distorted output. An open capacitor will produce degenerative feedback, and a reduced output will occur.

DERIVATIVE AMPLIFIER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

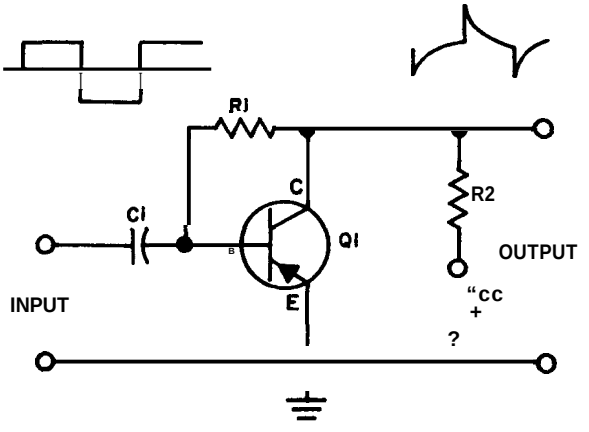
Essentially the same characteristics as electron tube version, except it uses a transistor instead of an electron tube.

Circuit Analysis.

General. An output which is the differentiated value of the input voltage is generated by the derivative amplifier. The relationship between the input capacitor and feedback resistor of a PNP transistor operational amplifier develops the differentiated output. The r-c time constant, which determines the exponential decrease of current, is formed by the product of the input capacitor and feedback resistor. The exponentially varying current flows through the capacitor, the transistor, and the feedback resistor. The product of the current and the ohmic valve of the feedback resistor equals the output voltage value at any given time. The output voltage, then, varies exponentially as the capacitor current varies. 4

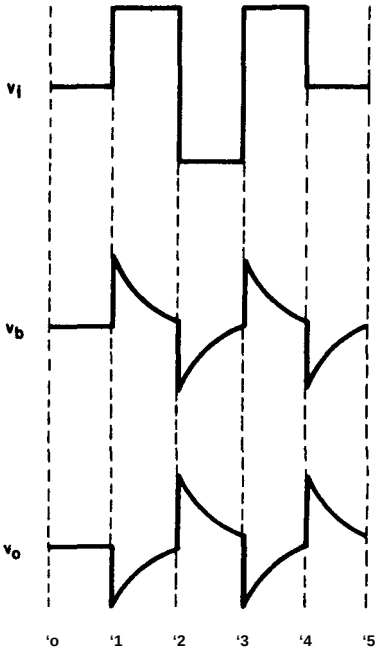
Circuit Operation. The one line diagram for the semiconductor version of the derivative amplifier is the same as the electron tube version, and therefore is not shown here.

The schematic of a derivative amplifier is shown in the accompanying illustration. Capacitor Cl couples the input signal to the base of transistor Q1. Capacitor C 1 and resistor R1 form an r-c network which determines the output waveform at any given time. Resistor R1 also provides base bias to transistor Q1. Resistor R2 is the collector loadresistor.



Derivative Amplifier

Assuming a square wave signal is applied to the input, and a positive-going input pulse is applied to the base of Q1 through Cl, the transistor forward bias is decreased. Emitter and collector currents are decreased because of the decreased forward bias. The collector current decrease produces a more negative voltage at the collector of Q1 as the collector voltage rises toward the supply value (time t 1 on the waveform chart).



Waveform Chart

Simultaneously, feedback current flows through resistor RI from collector to base, producing a voltage drop across R1, which slightly reduces negative collector voltage fed back to the base, which simultaneously reduces the input voltage. Capactor Cl charges at a rate determined by the time constant of Cl times R1. The input voltage at the base of Q1 decreases at the rate that Cl charges (during time '1 to '2). This charging action increases the forward bias of Q1, creating increased emitter to collector current. As the collector current is increased toward its quiescent value at '2, the voltage at the collector becomes less negative (more positive) at the same rate. The resulting positive-going voltages swing varies directly

with the charge on C 1. The negative output voltage spike produced from '1 to '2 is the inverted derivative of the applied positive input voltage. The charging of Cl, during the flat-top portion of the input signal during time t_1 to t_2 produces the curved trailing edge of the negative output signal, and continues until the input signal changes polarity at time t2. The negative-going trailing edge of the input signal causes Cl to discharge abruptly. The full negative input voltage is now applied to the base of Q1 at time t2. This produces a large increase in forward bias, which increases the emitter to collector current. The increase of collector current results in a less negative (more positive) voltage at the collector of Q1 (developed by the larger IR drop across collector resistor R2). A feedback current also flows through RI from collector to base, and develops a feedback voltage which detracts slightly from the input voltage. Capacitor Cl again charges at the rate determined by Cl times RI during time '2 to '3. The charge is now in a positive direction and the voltage at the base of Q1 again increases during time t2 to '3 at the rate that Cl charges. This decreases the forward bias of Ql, creating decreased emitter to collector current. As the collector current is decreased, the voltage at the collector rises towards the supply value and becomes more negative at the same rate, since there is less current flowing through collector resistor R2. The resulting output voltage during time '2 to '3 varies directly with the charge on Cl. This output voltage is the inverted derivative of the applied negative input. Again C 1 charges during the flat portion of the input signal '2 to '3). When the signal changes polarity at time '3, Cl is immediately discharged and the same action occurs as described above for the first positive-going input pulse at time '5.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity, since a forward bias through any of the transistor junctions will cause a flase low-resistance reading.

No **Output.** An open input, a defective collector load, a defective collector supply, or a defective transistor can cause a lack of output to occur.

If capacitor Cl is open, no input will be applied to the base, resulting in no putput variations. An open or shorted resistor R2, or a defective collector supply voltage source will prevent voltage from being available at the collector of Q1. If none of these components is found defective, transistor Q1 is probably defective.

Low or Distorted Output. The output may be low or distorted if the input is shorted the feedback resistor is open or shorted, the collector supply is defective, or transistor Q1 is defective.

With input capacitor Cl shorted, no charging time constant can be developed, and the output becomes - an inverted form of the input voltage. Likewise, with resistor R1 open, no time constant is developed by which Cl can charge. If R1 is shorted, the transistor effectively becomes a diode and the output is not influenced by the input. A low or high collector supply voltage, produced by a defective collector supply source, results in a distorted output. If none of these faulty conditions exists, but there is a low or distorted output, Q1 is probably defective.

DIFFERENTIAL AMPLIFIER (ELECTRON TUBE)

Application.

The differential amplifier is used in control and analog circuits to provide an output which represents the difference between two input voltages.

Characteristics.

Uses dual triodes with a common cathode resistor.

Degenerative feedback is used.

Output is taken from between the plates instead of between plate and ground.

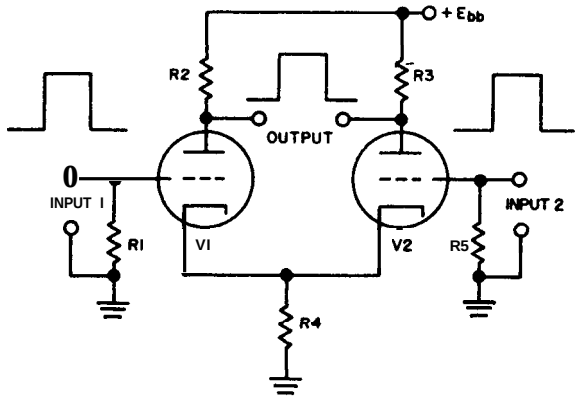
Symmetrical grid and plate circuits are used.

Circuit Analysis.

General. The differential amplifier (sometimes referred to as a difference amplifier) uses two triodes connected to a common cathode resistor. Plate current flow through the triodes develops a common cathode bias. Since the plate and grid circuits of each tube are symmetrical, equal grid input voltages produce equal plate output voltages. Since the output is taken between the plates of the two tubes, there is no potential difference and, effectively, no output. Hence, the output is the effective difference between

the two input signals. Unequal input voltages produce unequal plate voltages. The output voltage is now the difference between the input signals. If opposite polarity input signals are applied, the output will represent the algebraic difference between the input signals.

Circuit Operation. The schematic of a typical difference amplifier is shown in the accompanying illustration.



Differential Amplifier

Resistors RI and R5 are the respective grid return resistors for V 1 and V2, while R2 and R3 are the respective plate resistors. Cathode resistor R4 is unby - passed, and provides an instantaneous bias which varies with the signal, providing degenerative feedback. The output is taken between the plates of VI and V2.

For ease of circuit explanation, the operation of each tube will be discussed separately and then the two will be combined. When examined individually, the effect of two simple amplifiers with degenerative "feedback in the cathode will be clearly understood. Thus, when V1 grid is driven in a positive direction, increased plate current flows through R2 and produces a negative voltage drop or output. At the same time, the flow of current through cathode resistor R4 develops a cathode bias which determines the grid operating point, plate current flow, and effective amplification factor. The larger the input signal, the greater is the bias developed across the cathode resistor. Thus, a degenerative form of feedback is developed which reduces the range of amplification, helps to make the operation more linear, and reduces the effects of changes in variation of gain with different tubes. When a negative input signal is applied to VI grid, plate current flow through R2 is reduced. Consequently, the output voltage increases and produces a positive output swing. At the same time, the cathode bias voltage developed across R4 is less.

If we now consider the operation of V2, it can be seen that it operates identically, except that when the input is applied to the grid of V2, plate current increases or decreases through plate resistor R3. For identical input signals, equal outputs of the same polarity are developed across both plate resistors.

Consider, now, the combined operation of both tubes through the common cathode connection. When the grids of VI and V2 are both driven equally in a positive direction, equal plate currents flow through R2 and R3, developing equal plate voltage drops. Since the output is taken between both plates, there is no potential difference and zero output. This represents complete subtraction of both input signals. With both plate currents flowing through cathode resistor R4, the grid to cathode potentials are practically identical and the tube currents are balanced.

On the other hand, when one input signal is larger than the other input signal, different plate currents flow through the plate resistors. Similarly, the cathode current flow is less and the total effective bias is reduced. Since the grids are returned to ground through grid resistors R1 and R5, the effective grid-cathode voltage is also changed. If V 1 is the more heavily driven tube, the plate current of V2 is reduced, while Vi's plate current through R2 is increased. Hence, the voltage drops across R2 and R3 no longer are equal, and an output voltage will appear between the plates of V1 and V2. This output is proportional to the difference between the two input signals.

When opposite polarity input signals are applied to the grids of the tubes, the plate outputs are also opposite in polarity, and the effect is similar to normal push-pull amplifier operation. In this instance, the output represents the algebraic difference between the input signals. It should be realized that, because of the degenerative feedback afforded by the unbypassed cathode resistor, maximum tube gain is not obtained. Hence, push-pull inputs are not normally applied to the difference amplifier, except where the effect of the difference between two different polarity input signals is desired to control another

circuit, motor, relays, or to produce a direct meter indication.

Failure Analysis.

No Output. An open input or output circuit, lack of supply voltage, an open cathode circuit, or a defective tube can cause a loss of output. Since the output is taken between the plate circuits of two tubes, both tubes or circuits must be inoperative to cause a loss of output; otherwise, there will be some kind of output from one of the circuits. Normally, an open cathode bias resistor will prevent an output from either tube, and lack of plate supply voltage due to a blown fuse or defective supply will also inactivate both circuits. If there is supply voltage, but no plate voltage on both tubes VI and V2, plate load resistors R2 and R3 are probably defective. If both grid resistors Rl and R5 are open, or no input signals are applied, there will probably be a loss of output. In the special case where VI and V2 grids are connected across a common load resistor, open RI or R5 grid resistors may not prevent an output. If all resistors are satisfactory and plate voltage is present on both tubes, the tubes may be at fault. In the case where equal input signals are simultaneously supplied, the circuit will be zero-balanced, and although operating normally, no output will be obtained.

Low Output. A low plate or supply voltage, a small difference between input sigmls, too high a cathode bias, or defective tubes can produce a low output. If the plate supply voltage is normal, but the plate voltage on either or both tubes is not normal (with no grid input applied) plate resistor R2 or R3 may have changed value, or the tube showing abnormal plate voltage may be defective. If the plate voltage of both tubes with no input signal is low, or high, cathode bias resistor R4 may have changed value. If the plate voltage of one tube is lower than that of the other tube, with equal grid input voltages, either the grid or plate resistors are changed in value, or one of the tubes is drawing more plate current than the other. Compare the resistance values of RI and R4, and R2 and R3, as well as the plate currents of VI and V2.

Distorted Output. An output which does not vary in accordance with the difference between the input signals is distorted. Usually such a result occurs when only one of the amplifier circuits is operating properly. In such case, it will be necessasy to check each circuit individually for proper resistance and voltage values, and for defective tubes.

DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

Emitters are coupled together.

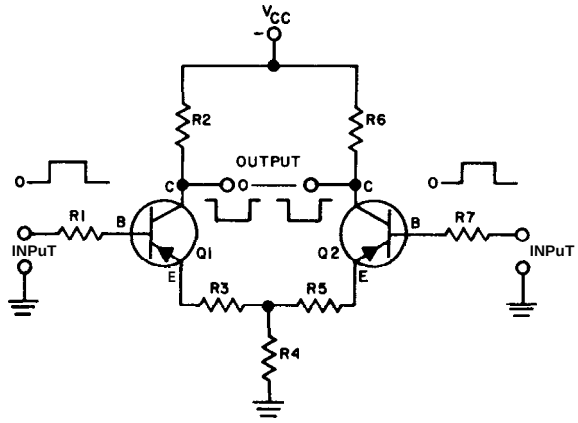
Output is obtained between the collectors of the transistors rather than between the collector and ground.

Symmetrical base and collector circuits are used.

Circuit Amlysis.

General. The differential amplifier uses two transistors connected to a common stabilizing resistor through separate emitter resistors. Current flow through both transistors develops a common bias. Since the collector and base circuits of each transistor are symmetrical, equal input signals produce equal collector output voltages. Since the output is taken between the collectors of the two transistors, with equal input signals, there is no potential difference, and effectively no output. Hence, the output is the difference between two input signals. Unequal input signal voltages produce unequal collector voltages. The output voltage is now the difference between the two collector voltages and represents the difference between the input signals. If opposite polarity input signals are applied, the output represents the algebraic difference (or mathematical sum) between input signals.

Circuit Operation. The schematic of a typical transistordifferential amplifier is shown in the accompanying illustration. Resistors RI and R7 are equivalent base input resistors. Resistors R3 and R5 are equivalent emitter resistors. Resistors R3 and R5 in conjunction with common emitter resistor R4 help to establish equal bias voltage for Q1 and Q2. Resistors R2 and R6 are equivalent collector load resistors, which are connected to a common collector supply voltage source.



Differential Amplifier

This Circuit is, in effect, two grounded emitter amplifiers using degenerative feedback in the emitter circuit. For ease of explanation, one amplifier will be discussed and then the combined action of both amplifiers will discussed. When a positive-going voltage is applied to the base of Qi, the forward bias is reduced. The decreased forward bias between the emitter and base of Q1 reduces emitter-to-collector current flow. Consequently, collector current flow through collector load resistor R2 is also reduced. The voltage drop across the collector load resistor is thereby reduced, and the voltage at the collector rises toward the negative collector supply voltage. When a negative-going voltage is applied to the base of Q1, forward bias is increased. The increased forward bias and base of Q1 increases the emitter-to+ ollector current flow and the collector current through R2. The voltage drop across R2 now increases and makes the collector of Q1 more positive and develops a positive output swing.

Since the amplifier consisting of Q2, R5, R6 and R7 is identical to the amplifier just discussed, with the same input pulses applied to the base, operation is identical. When equal amplitude positive pulses are applied to the bases of both transistors, equal negative voltage drops are produced at the collectors of both transistors. Hence, no output is produced in this case, since the output is the difference between the two collector voltages. When a positive pulse is applied to the base of Q1 and a negative pulse is applied to the base of Q2, a negative voltage is produced on the collector of Q1 and a positive voltage is produced on the collector of Q2. The output is now the algebraic difference between these voltages or the mathematical sum of these voltages. By the same reasoning, when a negative pulse is applied to the base of QI and a positive pulse is applied to the base of Q2, a positive voltage is produced on the collector of Q1 and a negative voltage is produced on the collector of Q2. The output again is the algebraic difference between these voltages, or the mathematical sum of these voltages.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier shunting resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful, also, to observe proper polarity when checking continuity or making resistance measurements since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A lack of output can result from an open common cathode circuit, a defective plate supply voltage source, or a defective component in both amplifiers.

With resistor R4 open, current is prevented from flowing through any part of the circuit. If collector SUpply voltage source V_{cc} is defective, no voltage is supplied to the collector of either transistor.

An output cannot be produced by either amplifier if the input resistor (Rl or R7) is open, the collector load (R2 or R6) is defective, the emitter bias resistor (R3 or R5) is open, or if the transistor (Ql or Q2) is defective.

When the input resistor (Rl or R7) is open, the input signal can not be applied to the base of the transitor. If the collector load resistor (R2 or R6) is open, no collector voltage will appear on Q1 or Q2. An open emitter resistor (R3 or R5) prevents current flow through the amplifier containing this resistor. If proper voltages are present on the electrodes of the transistor, and the collector voltage does not respond to the signal voltage variations, transistor Q1 or Q2 is probably defective.

Low or Distorted Output. A shorted input, a shorted emitter resistance, a defective collector supply voltage, or a defective transistor may cause, the output to be low or distorted.

If resistors R1, R7 or both R1 and R7 are shorted, the signal voltage applied to the base of Q1 and/or Q2

491-044 0- 73 - 36

will not be attenuated, the base bias will be less, and the output will probably be distorted. If resistor R3, R4, or R5 is shorted, the emitter biasing of transistors Q1 or Q2 will be incorrect and a low or distorted output will occur. If the collector supply voltage source is defective the output voltage will be either higher or lower than the required voltage. If none of these conditions exists and the output is low or distorted, either transistor Q1 or Q2 may be defective.

BALANCED DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

The balanced differential amplifier is used in CRT deflection circuits and in instrumentation and control circuitry where a balanced input and output are required.

Characteristics.

Produces an output which is in proportion to the difference between two inputs.

Output and input are balanced with respect to ground.

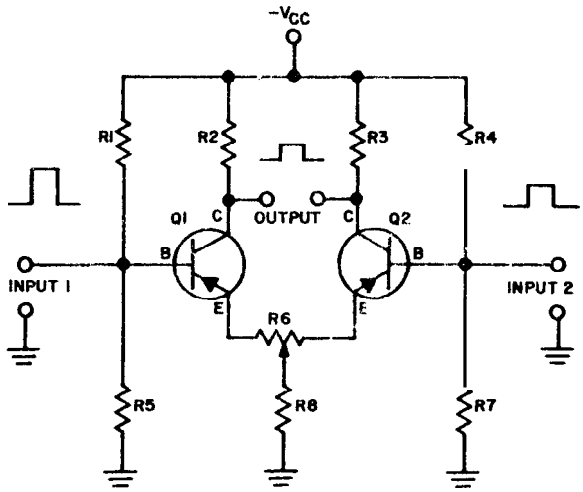
Output is taken between the collector elements instead of from collector to ground.

May be used as an ac or dc amplifier.

Circuit Analysis.

General. The balanced differential amplifier uses two similar amplifier circuits arranged to be driven by separate base inputs, and the emitters are coupled together through a common emitter-resistor. Identical input signals produce identical output signals. Since the output is taken between the two output loads, instead of to ground, there is no potential difference between identical outputs. Thus, an output exists only when there is difference between input signals. Consequently, common noise inputs tend to cancel each other so that the signal-to-noise ratio is usurdly improved by the differential amplifier.

Circuit Operation. A schematic diagram of a balanced differential amplifier is shown in the accompanying schematic diagram.



Balanced Differential Amplifier

Fixed base bias is applied to Q1 by bias voltage divider R1 and R5 connected between the negative supply and ground. Resistor R4 together with R7 forms an identical base bias voltage divider for Q2. Resistor R2 is the collector resistor for Ql, and R3 is the collector resistor for Q2; both collector resistors are also the load resistors across which the output is developed. Potentiometer R6 couples the emitter of Q1 to Q2, with the ground return being made through a common-emitter resistor, R8. Potentiometer R6 also permits adjusting Q 1 and Q2 for zero balance, and R8 also provides emitter temperature stabilization. Any change in transistor current-flow due to temperature effect produces an opposing bias across R8 which returns the current flow to normal. Emitter stabilization is thus obtained.

Both Q1 and Q2 are symmetrical common-emitter - amplifier circuits. When a forward bias is applied to the base of Ql, increased collector current flows through collector load resistor R2, reduces the applied collector voltage to a more positive vrdue, and produces a positive output voltage swing. At the same time that collector current increases, emitter current also increases. The voltage drop produced by current flow through emitter resistors R6 and R8 reduces forward bias slightly, and provides a slight amount of

degenerative feedback which improves output linearity. Since R6 is connected to the emitters of Q1 and Q2, any change appearing on QI emitter also appears on Q2. Hence, R6 can be adjusted with equal driving input signals to produce equal conduction through each transistor. This provides an effective zero-balance arrangement to compensate for slight production variations in transistors.

Transistor Q2 operates similarly to Q1. Thus, an increase of forward bias on the base of Q2 produces an increased collector current flow through collector resistor R3, and a positive-going output voltage. With equal amplitude input voltages applied to the base of Q1 and Q2, equal output voltages are produced. Since the output is taken between the collector resistors, instead of to ground, equal output voltages produce no difference of potential between them, and there is no effective output across the output terminals. When one input is larger than the other, an output is produced which is the difference between the two collector outputs.

When the forward bias on either Q1 or Q2 is reduced, less collector current flows through R2 and R3, and the collector voltage increases toward the supply value, producing a negative-going output swing. Again, for equal inputs, no output is produced. For different amplitude signals, the output is proportional to the difference between the applied input signals.

When signals of opposite polarity are applied, the output polarities are opposite, since the collector current of one transistor increases while that of the other transistor decreases. Thus, push-pull operation is obtained, and the output represents the sum, or algebraic difference between the two input signals.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** An open input, output, emitter circuit, or defective transistors, as well as a loss of supply voltage can produce a no-output condition. In most instances, both circuits must be affected, since if only one of the circuits is operative, some kind of output will be obtained. Lack of supply voltage will cause both circuits to be inoperative. An open emitter resistor, R8, will also prevent both circuits from operating. Two input signals of equal polarity and amplitude will also cause lack of output indication, but in this instance the circuit is operating normally. Where the bias, emitter, and collector voltages appear normal, but there is still no output with unequal input signals, the possibility exists that both transistors Q1 and Q2 are defective.

Low Output. Lower than normal bias, emitter, collector, or supply voltages can cause a loss of output. With a normal supply voltage, low bias can be caused by a change in the value of bias voltage-divider resistors R1 and R5, or R4 and R7. Low collector voltage can be caused by a change in collector resistor values of R2 or R3, or by a change of characteristics in either transistor Q1 and Q2. If emitter resistor R6 or R8 increase in value, a low output will also occur. There is also the possibility that an unbalance caused by a change in values in the parts of one amplifier can be compensated for by readjustment of zero balance potentiometer R6. In most cases, a resistance analysis of the individual parts will indicate the defective component.

Distorted Output. An output which does not vary proportionally with the difference between input signals can be considered as operating in a distorted mode. In most instances of this type, one of the amplifiers will be operating normally while the other amplifier is defective. If the individual outputs are observed against ground with the same input signal applied, the unequal output may be easily determined. Do not neglect the possibility that zero balance control R6 is incorrectly adjusted, since unequal outputs will occur if the circuit is not balanced properly.

SINGLE-ENDED OUTPUT DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

The single-ended output differential amplifier is used in control circuitry and data handling equipment where the difference between two input signals is used to control an output which is not balanced to ground.

Characteristics.

Uses two transistor amplifiers with a common emitter-coupling resistor.

Two inputs are required to produce an output proportional to their difference.

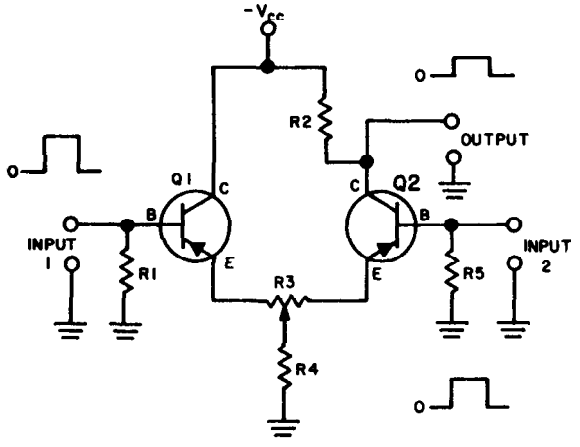
The output is unbalanced with respect to ground.

May be used as a dc or an ac amplifier.

Circuit Analysis.

General. The single-ended output differential amplifier can be considered as an emitter-follower amplifier driving a common-base output amplifier. One input controls the emitter-follower amplifier, which is direct connected to the emitter of the common-base amplifier. The output is thus controlled by the emitter bias. Simultaneously, an input is applied to the base of the output amplifier which also controls the output. When the inputs are of different polarity, the output to ground represents the algebraic difference between the two signals. When the inputs are of the same polarity, the output represents the mathematical difference between these signals. Inputs of equal amplitude and polarity effectively cancel and prevent any change of circuit operation, producing on effective zero output. For unequal amplitude inputs, the larger signal controls operation.

Circuit Operation. The schematic of a typical single-ended output differential amplifier is shown in the accompanying illustration.



Single-Ended Output Differential Amplifier

Resistor R1 is the base input and bias resistor for Q1. Potentiometer R3 is the common emitter-coupling resistor and zero-balance control for Q1 and Q2, with R4 acting as the emitter stabilizing resistor. Resistor R2 is the collector load and output resistor for Q2, and R5 is the base input and biasing resistor. The output is taken from the collector of Q2, and the separate inputs are applied to the base of Q1 and Q2.

Since there is no collector resistor for Q1, the collector bias supply filter capacitor effectively grounds the collector for ac. The output is taken from the emitter of Q1 and applied through R3 to the emitter of Q2; therefore, transistor Q1 can be considered an emitter-follower circuit. Likewise, since the inputs of Q2 are between emitter and base of QI, and between base and emitter for Q2, transistor Q2 can be considered a common-base amplifier. For ease of circuit explanation, each stage is considered separately and their operation combined in a common output.

in the schematic, Q1 and Q2 are fixed-biased by a separate emitter bias supply, so that the base of both transistors are normally forward-biased and the collectors are reverse-biased. When a positive input signal is applied through input-1 to the base of QI, the forward bias is reduced; thus, the emitter current is reduced. As the emitter current reduces, the output voltage across R4 and R3 increases positively. Thus, a positive increase in emitter voltage is applied directly through R3 to the emitter of Q2, and the emitter current of Q2 tends to increase. When the emitter current of Q2 increases, the collector current also increases, and a positive-going voltage drop is produced across collector resistor R2 of Q2, producing a positive output. However, at the same time that the emitter of Q2 is driven positive, input 2 (which is also positive) is simultaneously applied to the base of Q2. Normally, “this will decrease the forward bias on Q2 and cause the collector voltage to rise toward the source and produce a negative output. Since a positive input to the emitter of Q2 effectively cancels the positive input to the base of Q2, the total resultant forward (or decreased) bias depends upon the relative amplitudes of the input voltages. If input 1 predominates, a positive output is produced. If input 2 predominates, a negative output is produced. In either case, the relative output is proportional to the difference between the two input voltages. When both inputs are of the same amplitude, the negative

and positive drops acfoss R2 are equal, and no output results. When inputs of opposite polarity are applied, they bias Q2 in the same direction, so the output actually is the sum of the two signals, or the algebraic difference. Emitter-coupling resistor R3 is a potentiometer, and permits R4 to be connected as a voltage divider to produce an emitter input to Q2 which is equal in amplitude to the base input. Hence, by applying equal input signals and adjusting R3, the output voltage from Q2 may be balanced to zero.

Other circuit variations may be found in other technical manuals, such as using fixed or voltage divider base bias, or even self bias. The circuit arrangement is always such that the output developed by Q1 opposes the input applied to Q2, and results in the difference between the input signals producing the output.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low value of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe the proper polarity when checking continuity with the ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** Open input circuits, open emitter circuits, open output circuits or defective transistors can cause loss of output. If base resistors R1 and R5 open, the base to emitter circuit will be offered a high impedance path through the input signal source, and operation will probably be blocked. If either R3 or R4 opens, the emitter circuits of the transistors will be incomplete and no bias voltage will be measured between emitter and ground. If R2 opens, there will be no collector load for Q2 and no output can be developed. If the emitter, collector, and base voltages are normal, but still no output is obtained, transistors Q1 and Q2 are defective. If no collector voltage appears on both transistors, the supply source is at fault.

Low Output. If any of the resistors change in value, if the supply source is low, or improper bias is applied, or if one or both transistors are not normal, the output will be lower than normal. If the voltage on Q2 collector is normal, and both R2 and the supply source voltage are normal, but the collector voltage of Q2 is low, improper bias can be the cause. Check R3 and R4 and the emitter supply voltage. If RI or R5 changes in value, the input signal amplitudes will be affected, and an improper output will be obtained. Similarly, if Q1 or Q2 characteristics change, an improper output will be obtained.

Distorted Output. If the output of Q2 varies other than as the difference between the input signals, one or both transistor circuits are operating improperly, and distortion is occurring. The output of Q1 should produce a waveform identical in shape and polarity to input-1 and of slightly less amplitude. The output of Q2 should always be proportional to the difference between the waveform on the emitter of Q2 and input-2.

BALANCED SUPER-ALPHA DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

The balanced super-alpha differential amplifier is used in analog computers and control circuitry where higher gain than that obtained by the conventional balanced differential amplifier is required.

Characteristics.

Uses super-alpha circuit to provide high gain.

Circuit is balanced with respect to ground.

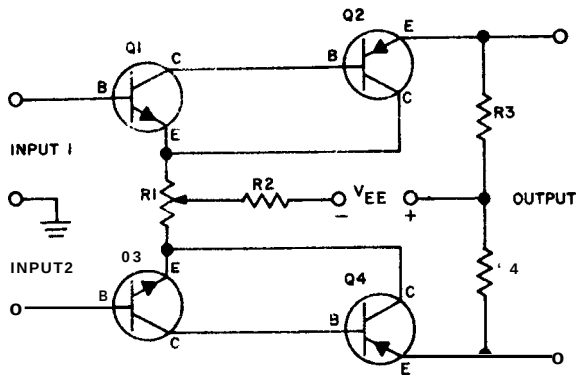
Output is taken between emitters instead of to ground.

Either self- or fixed-bias can be used.

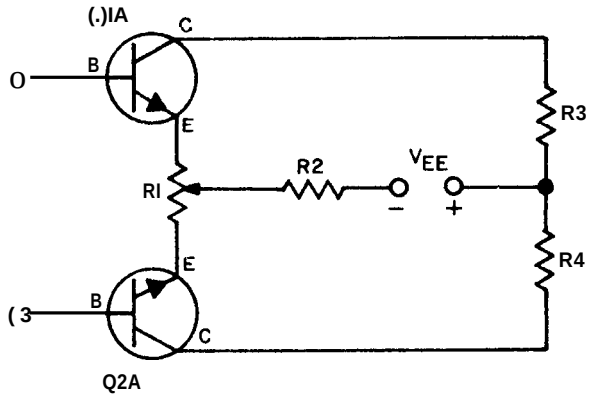
Circuit Analysis.

General. The super-alpha differential amplifier uses two NPN and two PNP transistors. Through use of the complementary transistors, the same power source may be used for both stages and a super-alpha circuit can be employed. The super-alpha circuit connection uses two direct-coupled transistors in a feedback circuit which is equivalent to a single transistor with superhigh gain. This gain is usually so high that it can never be equalled by a single transistor. Both input and output circuits are blanced, and identical outputs are obtained. Since the output is taken between the emitters instead of to ground, equal outputs effectively cancel; an output is only obtained when the input signals are different in amplitude, resulting in an amplifier which responds only to the difference between the input signals.

Circuit Operation. The accompanying schematic illustrates a typical balanced super-alpha differential amplifier.



Super-Alpha Differential Amplifier



Simplified Super-Alpha Circuit

Resistor RI is the emitter-coupling resistor for transistors Q1 and Q3, while R2 is the common emitter-stabilizing resistor. Resistor RI also provides a zero-balance arrangement for the circuit. Transistors Q1 and Q3 are the complementary input amplifiers, while Q2 and Q4 are the complementary output amplifiers. Resistors R3 and R4 from the emitter and output loads for Q2 and Q4, respectively.

Since the emitters of Q1 and Q3 are connected to a negative source, forward+x-nitter bias is produced for these NPN transistors. Since the collectors of Q2 and Q4 are connected to the same negative source, the collectors are reverse-biased, as is usual for PNP transistors.

Basic operation can be more easily understood if the super-alpha circuit is simplified to a single NPN transistor as shown in the accompanying illustration. In this case Q1 and Q2 are replaced with single NPN transistor QIA, while Q2 and Q4 are also replaced with a single NPN transistor, Q2A. Even though simplified, current flow is the same as in the original circuit, and because of this the emitter and collector elements are drawn reversed. Hence, when a positive input signal is applied to NPN transistor QIA, the forward bias on the NPN transistor is increased, a larger emitter current flows through R2 and R1, and back through the collector of QIA and load R3 to the supply. Similarly, when a negative input is applied to the base of Q2A, an increased emitter current flows through R2 and R1, and through the emitter to the collector of Q2A and R4 to the supply source. Thus, negative-going voltage drops are produced across R3 and R4, and the output taken between the collectors of QIA and Q2A is zero (for equal input amplitudes) when R1 is set for zero balance with no inputs. For unequal inputs, the output is the difference between the collector voltages, which is proportional to the difference between the inputs.

Now consider the original super-alpha circuit, remembering that current flow is in the same direction, but that the output emitter and collector elements are reversed in a PNP configuration. When a positive input is applied to the base of Q1, the emitter and collector current of Q1 increases. Current flow is through R2, R1, and the emitter and collector of Q1 to the base of Q2. An increased current flow into the base of Q2 increases the emitter and collector current of Q2, and an increased current flows from the emitter to the collector of Q2 and through emitter-load resistor R3 to the supply. Thus, a negative-going voltage is produced by Q2. In a similar manner, when a positive input is applied to the base of Q3, the emitter and collector current of Q3 increases, and current flows through R2, RI, and from the emitter to the collector of Q3. Since the collector of Q3 is connected to the base of Q4, an increased base current flows. As a result, the emitter and collector current of Q4 increases and an increased current flows through Q4 and back through R4 to the supply source. Thus, a negative-going output voltage is developed across the output of Q4. With equal amplitude inputs, equal negative outputs are developed, and no difference in potential exists across the output when the circuit currents are balanced.

When the input to Q1 or Q2 is changed to a negative input, the reverse action occurs; the PNP

transistor currents are reduced, and the drop across the output load is in a positive direction. Again, with equal inputs and outputs, there is no potential difference across the output and effectively no output occurs. Unequal inputs produce an output proportional to the difference between the input signals.

Since the input emitters of QI and Q3 are connected together through RI, it is also possible to apply a single input to Q3 and ground the input to Q1. In this special case, the emitter of Q3 will have an opposing signal applied and a balanced output will still be obtained. If, however, the output is taken against ground, the output of Q4 will be in-phase with the input, while the output of Q2 to ground is out-of-phase with the input. When different polarity inputs are applied, the output will act as a push-pull amplifier and the sum of the input, or algebraic difference, will produce the output.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No Output. Lack of supply voltage, open emitter resistors, or collector resistors, as well as defective transistors can cause a loss of output. If there is no supply voltage, if R2 is open, or if both transistors Q1, Q3, or Q2, Q4 are defective, no output can occur. If potentiometer R1 is open on only one side, or if only Q1 or Q2, or Q3 or Q4 is open, or if output resistor R3 or R4 is open, a partial output will occur. It is necessary for both R3 and R4, Q1 and Q3, or Q2 and Q4, or both sides of RI to be open to produce no output, since both circuits must be rendered inoperative simultaneously for no output to occur.

Low or Distorted Output. If the supply source is low, if any transistor changes characteristics, if improper bias exists, or if R2, R3, or R4 changes in value, a low or distorted output can occur. If the supply source measures low, low bias and output current will produce a low output. If one half of the circuit operates properly and the other half does not, a distorted and low output will probably occur. A change in the value of currents drawn by the transistors will produce different voltage drops across R1, R2, R3 and R4, and produce unequal output. If the currents decrease, or the resistor values decrease, a low output will occur. If the currents increase, or the resistor values increase, a higher than normal output will probably occur. Where the waveforms appear normal at the inputs, and the outputs are distorted but voltages appear to be within tolerance, the transistors are probably at fault. A resistance check will usually indicate if any parts are defective.

DIRECT-COUPLED CASCADED DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

The direct-coupled cascaded differential amplifier is used in computers, cathode-ray tube circuits, and in control circuits where a low-drift and high-gain dc amplifier is required.

Characteristics.

Direct coupling is used.

Both amplifiers are balanced with respect to ground.

Output is taken from between the collectors instead of to ground.

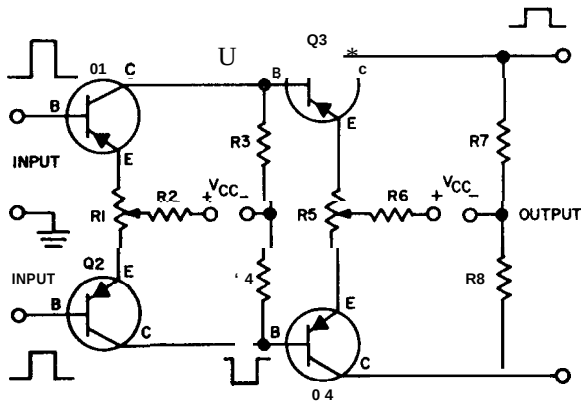
Fixed bias is employed.

Circuit Analysis.

General. The direct-coupled cascaded differential amplifier uses two differential amplifier connected in series, that is, the collector output of the input stage is directly connected to drive the base of the output stage. Both input and output stages can also be direct-coupled to the input or output loads, if desired. Since the differential amplifier is balanced, and inherently stabilized by a common-emitter resistor against temperature effects, it has very little drift (output level does not change with temperature). Therefore, with a minimum of drift, direct coupling is used to obtain a relatively stable high-gain amplifier. When an input signal is applied to both input stages, it either increases or decreases the base bias of the output stage. Consequently, either a negative or a positive output swing is developed across the output load. Since both outputs are of the same polarity when similar inputs are applied, the output is produced by the difference between the two input signals. Equal amplitude imputs will produce equal outputs, and there will be no potential difference between them. Thus, the effective output will be zero

if the circuit is correctly balanced. With unequal polarity inputs applied, the circuits will operate as push-pull amplifiers and produce the algebraic difference or sum of the input signals. Since each stage inverts the input and two stages are used, the output will always be the same polarity as the input.

Circuit Operation. The schematic of a typical cascaded direct-coupled differential amplifier is shown in the accompanying illustration.



Cascaded Direct-Coupled Differential Amplifier

Resistor RI couples the emitters of input transistors Q 1 and Q2 together, and R2 is an emitter-stabilizing resistor which is common to both input stages. Resistors R3 and R4 are the collector resistors and loads for Q1 and Q2, respectively. They also act as the base input resistors for Q3 and Q4. Potentiometer R5 couples the emitter of Q3 and Q4, and acts as a zero-balance control for the output circuit. Resistor R6 is an emitter-stabilizing resistor which is common to both Q3 and Q4. Resistors R7 and R8 are the collector and load resistors for output transistors Q3 and Q4 respectively. The inputs are applied to the base of Q1 and Q2, while the output is taken between the collectors of Q3 and Q4.

Normally, Q1 and Q2 are base-biased by the input circuit, or by voltage divider bias (not shown in the schematic). The bias is such that equal input swings are possible without biasing the transistors to cutoff (Class A operation). Transistors Q1 and Q3 operate as conventional common+ mitter amplifiers. The direct coupling between the collector of Q 1 and the base of Q3 places a reverse collector bias on Q1 and a forward base bias on Q3. Operation normally is such that the reverse leakage collector current of Q1 and the collector resistor value produce a bias which places Q3 at the desired operating point. If necessary, separate bias can be applied to the emitter to obtain the desired operating point. When a positive input is applied to the base of Q1, forward bias is reduced and less collector current flows. The collector voltage on Q1 then increases and a larger negative bias is applied to the base of Q3, producing an increased forward bias. Consequently, Q3 collector current increases, and the increased current flow through collector resistor R7 decreases the collector voltage. Thus, a positive-going output voltage swing is created, and the output is in phase with the input.

In a similar manner, when a positive signal is applied to the base of Q2, reduced collector current flows through R4 and the collector voltage on Q2 increases. This negative increase of voltage is applied to the base of transistor Q4, and causes an increased collector current flow through R8. Hence, the output of Q4 is positive-going, and is in phase with the input. Since the output is taken across the collectors, equal output swings of equal polarity will produce an effective zero output. As log as the output swings are different, there will be a proportionate output which varies as the difference between the outputs. Since a difference in outputs can only be produced (in a balanced circuit) if there is a difference between the input signals, any output represents the difference between the input signals. By connecting the emitters of Q1 and Q2 together with potentiometer R 1, emitter-stabilizing resistor R2, which is common to both stages, provides the same temperature compensation for each transistor. Also, the different resistance paths through R1 to both emitters cause an emitter bias to be produced, which compensates for any differences in emitter current resulting from production variations. Thus, RI is adjusted for zero-balance with no input signal applied, so that approximately equal output currents are developed by equal input signals. Potentiometer R5 connects the emitters of Q3 and Q4 together and operates similarity to zero-balance the output stage, while resistor R6 operates as the common stabilizing emitter-resistor for Q3 and Q4. With both input and output circuits properly zero-balanced, equal outputs are always developed for equal inputs.

In normal design, transistors Q3 and Q4 are usually power-type transistors. Thus, with conventional driving transistors used for Q1 and Q2, a high-current gain can be realized from cascaded direct-coupled stages, and a large output is developed.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No Output. Lack of supply voltage, an open input or output circuit, or defective transistors can result in a loss of output. If emitter-stabilizing resistor R2 or R8 opens, the associated amplifier circuits will not operate. If collector resistors R3 and R4, or R7 and R8 are open, no collector voltage will appear on the collectors of Q1 and Q2, or Q3 and Q4, respectively, and no output will occur. Note that both resistors must be open, or alternate resistors in cascaded stages must be open, to cause a complete loss of output. Likewise, if the transistors are defective, it is necessary that one in each channel be defective; otherwise, a single unbalanced output could occur.

Low or Distorted Output. If the supply voltage is low, if improper bias exists, if the collector resistors change in value, or the emitter resistors change, a low output or a distorted output can occur. If the transistor characteristics change, of if the circuit is not zero-balanced, a low and distorted output can occur. If emitter coupling resistors RI and R5 open, the circuits cannot be zero-balanced and the output will be somewhat distorted. If collector resistors R3, R4, R7 or R8 change in value sufficiently that zero balance cannot be obtained, unsymmetrical outputs will be obtained, and a low or distorted output will occur.

DIRECT-COUPLED CASCADED, COMPLEMENTARY-SYMMETRY DIFFERENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

Same application as direct-coupled cascaded differential amplifier.

Characteristics.

Same characteristics as direct-coupled cascaded differential amplifier.

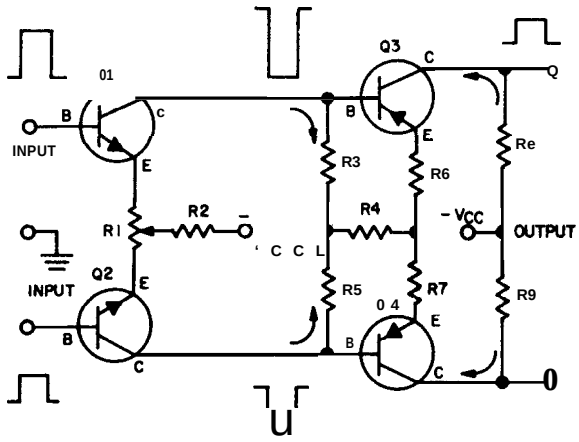
Circuit Analysis.

General. The direct-coupled cascaded, complementary-symmetry differential amplifier uses two complementary-symmetry differential amplifiers connected in series (cascaded). The output of the input amplifier is directly connected to drive the base of the output amplifier. Both input and output stages can also be direct coupled to the input or output loads, if desired. Since the differential amplifier is balanced, and inherently stabilized by a common emitter resistor against temperature effects, this type of amplifier has very little drift (the output level does not change with temperature). When minimum drift exists, direct coupling can be used to obtain a relatively stable high-gain amplifier. By using cascaded complementary-symmetry stages, the small amount of drift which normally exists is reduced still further, and extremely higher than normal gain may be obtained.

When an imput signal is applied to both input stages, it either increases or decreases the base bias of the output stages. Consequently, either a negative or a positive output swing is developed across the output

load. With similar input polarity signals applied, similar output signals are produced. Since the output is taken between the collectors, equal outputs produce no potential difference between them, and for equal inputs there is effectively no output. With unequal inputs, the output represents the difference between the input signals. When the input signals are of opposite polarity, the output operates as a push-pull amplifier and produces different outputs. The result is the sum or algebraic difference between the input signals. Since each stage inverts the input, and two stages are used, the output is always of the same polarity as the input.

Circuit Operation. The schematic of a typical cascaded complementary-symmetry differential amplifier is shown in the accompanying illustration.



Cascaded Direct-Coupled Complementary-Symmetry Differential Amplifier

Potentiometer RI couples the emitters of NPN input resistors Q1 and Q2 together, and R2 is an emitter stabilizing resistor common to both input stages. By adjusting the emitter bias applied through RI and R2, the output may be adjusted for zero balance (with no input signals applied) to ensure that both stages are properly balanced. Resistors R3 and R5 are the collector resistors and loads for Q1 and Q2, respectively. They also act as base input resistors for PNP transistors Q3 and Q4. Resistors R6 and R7 couple the emitters of Q3 and Q4, and act as balancing and stabilizing resistors. Resistor R4 is an emitter bias and stabilizing resistor which is common to both Q3 and Q4. Resistors R8 and R9 are the collector and load resistors for output transistors Q3 and Q4, respectively. The inputs are applied to the bases of Q1 and Q2, while the output is taken between the collectors of Q3 and Q4. Normally Q1 and Q2 are base-biased by the input circuit, or by a voltage divider bias (not shown on the schematic). The bias is such that equal input swings are possible (class A operation). Transistors Q1 and Q3 operate as conventional cascaded common-emitter amplifiers. Transistor Q1 is an NPN type, while Q3 is a PNP type. The direct coupling between the collector of Q1 and the base of Q3 places a reverse collector bias on Ql, and indirectly, a forward bias on the base of Q3. As connected, the emitter of Q3 is forward-biased through R4 and R6 from the same supply which biases the collector of Q 1 and the base of Q3. Collector resistor R3 for Q1 is larger in value than emitter resistors R4 and R6 combined. Thus, the drop through R3 by normal (quiescent) collector current flow throu-gh Q1 produces a steady negative voltage drop, so that the base of Q3 is always more negative than the emitter. The emitter is more positive than either the base or collector of Q3, since the collector of Q3 is reverse-biased. Thus, Q3 base is effectively forward-biased by the direct coupling circuit, even though a positive voltage exists on the collector of Q1 and the base of Q3. That is, the base of Q3 is less positive (more negative) than the emitter of Q3, and the operating bias is effectively a negative (forward bias) voltage with respect to its emitter. Design is such that the stage operates at the center of its linear Class A range, so that equal positive or negative bias swings are possible without creating excessive distortion.

When a positive input signal is applied to the base of Q1, the forward bias is increased and more collector current flows through R3, driving the base of Q3 negatively and increasing the forward bias on Q3. Hence, the collector current of Q3 increases and the voltage drop produced across the collector resistor R8 is positive-going, producing a positive output (less negative voltage) at the collector.

In a similar manner, when a positive input signal is applied to the base of Q2, forward bias is increased, and the increased collector current flow through R5 produces a negative-going voltage at the base of Q4, and increases the forward bias. With an increased forward bias on Q4, an increased collector current flows through R9, reduces the collector voltage, and produces a positive-going output swing. Since the output

of the total circuit is taken between the collectors, equal amplitude output swings of the same polarity produce an effective zero output. If the output voltage swings are different in amplitudes, there will exist a proportionate output which varies as the difference between the output of Q3 and Q4. A difference in outputs can only be produced in a balanced circuit when there is a difference between the input signals. Since the emitters of Q1 and Q2 are connected together by potentiometer R1, emitter stabilizing resistor R2, which is common to both stages, provides the same temperature compensation for each transistor. By varying the position of R2 along potentiometer RI, different resistance paths are provided through R1 to each emitter, and allow an emitter bias to be produced which compensates for any differences in emitter currents caused by production variations. Thus, R1 is adjusted for zero balance (no output with no input signal applied), so that approximately equal output currents are developed by equal input signals. Resistors R6 and R7 connect the emitters of Q3 and Q4 together, and are temperature-stabilized through common emitter resistor R4, which operates similarly to R2. Since resistors R3 and R5 are equal, as are R6 and R7, and R8 and R9, only the single zero-balance potentiometer RI is needed for proper adjustment of circuit balance.

When negative inputs are applied to Q1 and Q2, the collector-current flow through R3 and R5 is reduced by the decreased forward bias, and the collector voltage of Q1 and Q2 becomes positive-going, rising toward the source value. In turn, the base bias of Q3 and Q4 is reduced, and less collector current flows through resistors R8 and R9. Thus, the collectors of Q3 and Q4 rise toward the negative source voltage, and produce an effective negative-going output. Again, for equal inputs, equal outputs are produced, and there is no effective difference in potential between them. Hence, the total output is effectively zero. For different amplitude signals, the output is again proportional to the input and the polarity is reversed.

Failure Analysis.

Generel. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional ohmmeters. Be careful, also, to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** Lack of supply voltage, an open input or output circuit, or defective transistors can result in a loss of output. If emitter-stabilizing resistor R2 or R4 is open, the associated amplifier circuits will not operate. If collector resistors R3 and R5, or R8 and R9 are open, no collector voltage will appear on the collectors of Q1 and Q2, or Q3 and Q4, respectively, and no output will occur. Note that both resistors of balanced stages must be open, or alternate resistors of cascaded stages must be open, to cause a complete loss of output. Likewise, if the transistors are defective, it is necessary that one in each channel be defective, otherwise, a single unbalanced output could occur.

Low or Distorted Output. If the supply voltage is low, if improper bias exists, if the collector resistors change in value, or the emitter resistors change, a low output or a distorted output could occur. If the transistor characteristics change in value, or if the circuit is not zero-balanced, a low or distorted output could occur. If emitter resistors R1, R6, or R7 open, or change to a high value, the circuits cannot be zero-balanced and the output will be somewhat distorted. If collector resistors R3, R5, R8 or R9 change in value sufficiently that zero-balance cannot be obtained, unsymmetrical outputs will occur, and a low or distorted output will result.

EXPONENTIAL AMPLIFIER (ELECTRON TUBE)

Application.

The exponential amplifier is used in analog computers and cathode-ray tube circuits to develop an output voltage proportional to the desired exponential of input voltage.

Characteristics.

Uses a variable-mu pentode.

Unbypassed cathode resistor is used to provide degenerative feedback.

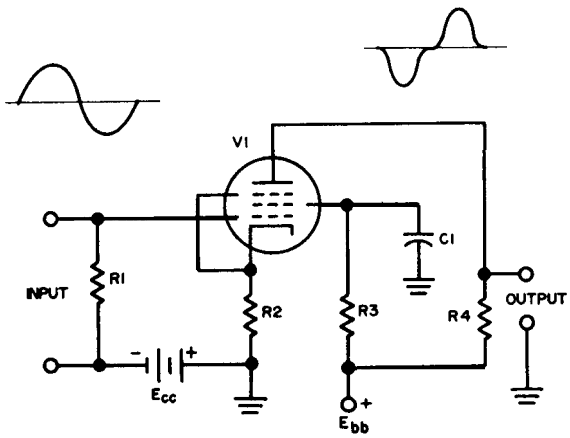
The tube is operated at a non-linear portion of the plate current-grid voltage characteristic curve.

The desired multiple of the input (exponent) to which the output is raised is determined by plate and cathode resistance, and plate voltage.

Circuit Analysis.

General. The exponential amplifier produces an output signal equivalent to an exponentially increased (squared, cubed, etc ...) input signal. This is accomplished by operating only over a selected portion of the tube plate current-grid voltage characteristic curve. The plate current (and output voltage) is, made to vary proportionally with the grid voltage raised to between the 2/2 power and the 2.5/2 power. The desired exponent by which the input is to be raised is obtained by the proper selection of plate load resistance, cathode resistance, and plate voltage for a specific value of internal tube plate resistance.

Circuit Operation. The schematic of a typical exponential amplifier is shown in the accompanying illustration.



Exponential Amplifier

The input is applied across grid resistor RI. This resistor is also used to apply fixed bias from a separate bias supply voltage (Ecc); self-bias is also supplied by unbypassed cathode resistor R2. Electron tube V1 is a variable-mu pentode. Resistor R3 is the screen grid voltage-dropping resistor. Capacitor Cl is the screen grid bypass capacitor. Resistor R4 is the plate load resistor.

The cathode resistance, R2, plate supply voltage, Ebb, plate load resistor R4, and the internal resistance of electron tube V1 are chosen to provide an amplified output which varies as the square of the input voltage. By operating variable-mu pentode VI along a nonlinear portion of the grid voltage-plate current characteristic curve, the desired exponential relationship between input and output is obtained.

When a positive-going sine wave is applied across resistor R1 to the grid of V1, it effectively decreases the fixed negative bias voltage, and produces increased plate conduction of VI. The plate current rate increase is slight for a small applied grid voltage, and is not proportional to the signal voltage increase. When a positive l-volt signal is applied, conduction is directly proportional to the input; when the signal increases above 1-volt, the conduction rate becomes proportional to the product of the signal voltage value squared. The increased rate of conduction is enhanced by negative feedback voltage developed at the cathode of V1 through unbypassed resistor R2. The increased plate current of V1 caused by the reduced bias produces a proportional reduction in plate and output voltage.

As the sine wave decreases it causes the grid bias voltage effectively to increase. Plate conduction then decreases at the same rate it increased, until the signal voltage reaches zero. Here the conduction rate of VI is at a quiescent (static) value. When the input signal voltage swings negative, the plate conduction also decreases at a rate proportional to the square of the input signal voltage. The output voltage developed across plate resistor R4 then increases at a rate proportional to the increase of plate current.

Failure Analysis.

No Output. A loss of output voltage may be caused by an open output circuit, a defective tube, an open cathode resistor, or lack of plate supply voltage.

If plate load resistor R4 is open, no output voltage can be developed since no plate voltage will be applied to VI. A defective plate supply voltage source has the same effect. An open cathode resistor, R2, will produce an open output circuit. If the proper voltages are present on the elements of V1 and there is no output, tube VI is probably defective.

Low or Distorted Output. A defective input, a defective cathode circuit, a defective screen circuit, or defective supply voltages can result in an output which is low or distorted.

If resistor R1 is defective, improper bias voltage will be applied to the grid of V1, thus providing the incorrect amount of plate conduction for a given signal. A shorted cathode bias resistor, R2, or a defective bias supply voltage Ecc will produce the same effect. If screen resistor R3 is defective, improper

screen voltage will be applied to the screen grid of VI. A defective supply voltage source, Ebb, will cause low plate and screen voltages. A defective screen bypass capacitor, Cl, will cause output voltage variations to be coupled back to the screen grid of V1, resulting in a distorted output. If none of these conditions exists and proper potentials exist at the elements of V1, the tube is probably defective.

EXPONENTIAL AMPLIFIER (SEMICONDUCTOR)

Application.

The exponential amplifier is used to develop an output voltage proportional to the desired exponential of input voltage. The amplifier is used in analog computers and control circuits.

Characteristics.

Uses common-emitter transistor amplifier configuration.

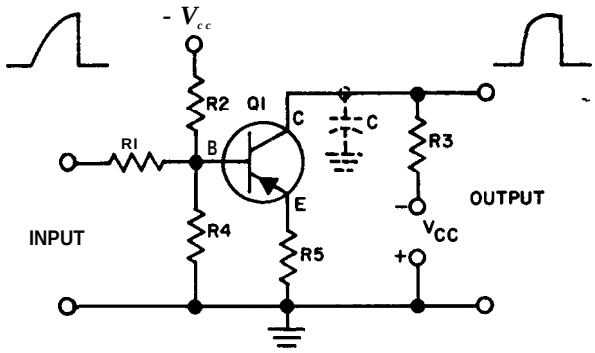
Uses emitter stabilization for temperature compensation.

Transistor is selected to give an exponential response.

Circuit Analysis.

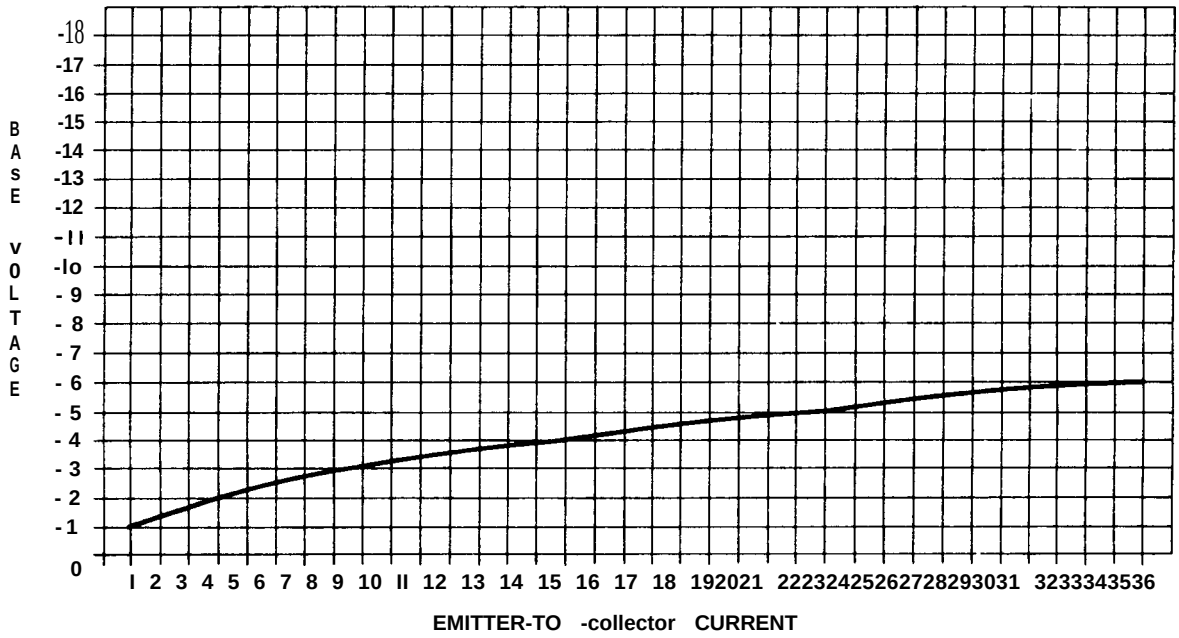
General. A transistorized exponential amplifier uses a circuit configuration which is essentially the same as a basic transistor amplifier. The distinction between the two types of amplifiers is with the transistor, and, the biasing potentials used. The exponential amplifier uses a transistor and bias combination that produces a collector current variation which is the input voltage raised by a desired exponential. The collector current variation, in turn, produces similar collector and output voltage variations.

Circuit Operation. The circuit of a typical transistorized exponential amplifier is shown in the corresponding illustration. Resistor RI is a series base resistor. It attenuates the input signal before being applied to the base and reduces base current. Resistors R2 and R4 form a fixed-bias voltage divider for the base of Q1. Resistor R5 is an emitter stabilization resistor, and resistor R3 is the collector load resistor.



Exponential Amplifier

The positive portion of an imput waveform is applied to the input, where it is attenuated by resistor R1 before being applied to the base of Q1. The positive-going input voltage decreases the forward bias of C 1. A decrease in base bias causes a decrease in emitter-to-collector current, which, in this case, is proportional to the square of the input signal variation. This is shown in the accompanying illustration of the "Transistor Transfer Characteristic Curve". The decreasing collector current of Q1 causes the IR drop across resistor R3 to decrease at the same rate. The collector, and output voltage then decrease toward the negative collector supply voltage.



Transistor Transfer Characteristic Curve

As the input waveform passes its positive peak and begins its negative swing, the negative-going input voltage (after being attenuated by Rl) is applied to the base of Q1. The forward bias of the transistor is increased by the negative-going input. An increase in bias causes an increase in emitter-to-collector current, which is proportional to the square of the input signal variation. The exponentially increasing collector current of Q1 causes the IR drop across R3 to increase at the same rate. In some circuit variations, a capacitor is placed from the collector to ground to produce an exponential charging waveform.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeter. Be careful to observe proper polarity when checking continuity, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No Output. There will be no output voltage if the input is open, the collector load is defective, the bias resistor is open, the collector supply source is defective, or transistor Q1 is defective.

An open base resistor, Rl, prevents output signal variations from being developed. If R3 were open, no collector supply voltage would be applied to the collector of Q1. No collector supply voltage would be present on Q1 if the collector supply voltage source V_{CC} were defective. An open emitter resistor, R5, prevents any current from flowing in the circuit. If none of these components is defective, and there is no output, transistor Q1 is defective.

Low or Distorted Output. The output becomes low or distorted if the input is shorted, the bias resistor is shorted, the collector supply sources is defective, or if the transistor is defective.

If base input resistor R1 is shorted, the input signals will not be attenuated and a distorted output will occur. A shorted emitter resistor, R5, will slightly lower the output and no temperature compensation

will be produced. A defective collector supply source, V_{CC} may provide a higher or lower collector supply voltage than is necessary. If none of these components is defective and the output is low or distorted, transistor Q1 is probably defective.

INTEGRATING AMPLIFIER (ELECTRON TUBE)

Application.

The integrating operational amplifier is used in analog computer and control circuitry to develop an output voltage that is the integral of the input voltage.

Characteristics.

Uses a resistive input network.

Uses a capacitive feedback.

Uses a triode electron tube.

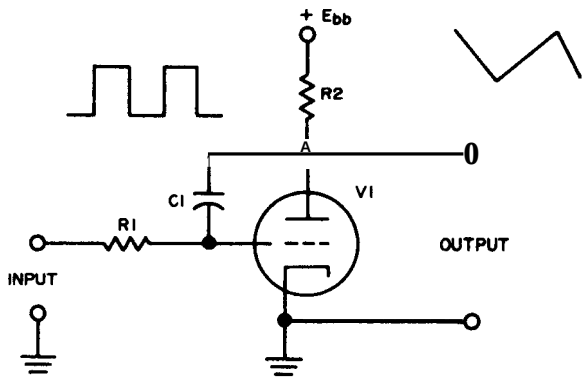
A square-wave input produces a triangular output waveform.

Usually operated near zero bias.

Circuit Analysis.

General. This intergrating operational amplifier, sometimes referred to as a "Miller" integrator, uses a resistive input network and capacitive feedback to produce the integrating effect. The capacitive feedback is essential to circuit operation. The output is developed by the charge and discharge of the capacitive feedback network during the pulse width and the time between pulses of a square wave input. The capacitor also makes the output more linear by controlling plate voltage variations with corresponding smaller and opposite grid voltage (feedback) variations. The output always represents the integral of the input.

Circuit Operation. The schematic of a typical integrating amplifier is shown in the accompanying illustration. Resistor RI is the grid resistor for electron tube V1. Capacitor Cl is the feedback capacitor, and resistor R2 is the plate load resistor.

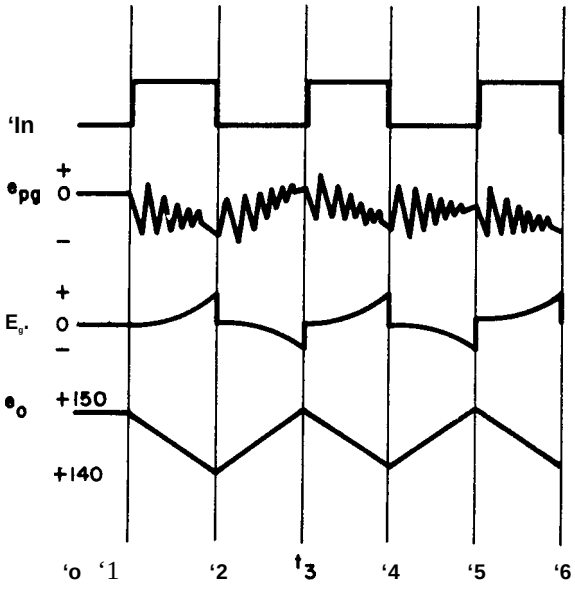


Integrating Amplifier

When a positive-going square wave is applied to the grid of Vl, it causes increased plate conduction. A corresponding plate voltage decrease (negative swing) is developed across R2. This decrease in voltage (negative swing) is coupled back to the grid through Cl. The sum of this voltage and the square wave input pulse results in a decreased grid signal for the moment.

For ease of understanding, refer to the accompanying waveform chart, which shows the grid and plate waveforms and their relationship slightly exaggerated for the purpose of illustration. At time t. there is not input, approximately zero bias is applied, and the average plate voltage is 150 volts with no output voltage existing. At time T_1, the positive-going leading edge of the input signal produces a positive grid bias, which drives the plate into heavy conduction and produces a negative feedback voltage spike. This feedback voltage is applied from plate to grid through Cl and is shown as e_{pg} on the chart. The negative feedback cancels a portion of the positive input signal, and the grid signal is instantaneously reduced to a small value. As a result, plate current decreases and develops a positive feedback voltage, which drives the grid further positive and increases

plate current. The corresponding negative plate feedback signal again cancels a portion of the square wave input, which is constantly applied at full amplitude, for the duration of the input pulse. During time t_1 to t_2, feedback capacitor Cl is constantly being charged by the effect of negative feedback voltage and the positive input voltage. The addition of these two voltages produces an effectively positive linear grid signal. The positive grid voltage would normally rise exponentially with the charge, as long as the input amplitude remained constant. Since the feedback voltage is constantly affecting the input voltage, the charge occurs nearly linearly. The effect is to produce an average plate current which constantly increases to a maximum at time t_2, when the trailing edge of the input signal appears. At the same time, the voltage constantly drops, reaching a minimum at 140 volts. Thus, there is a 10-volt negative triangular voltage produced.



Grid and Plate Waveforms

When the negative trailing edge appears at the input (at t_2), the grid is instantly driven negative, and a large positive plate feedback pulse is created by the decreased plate current. This positive feedback causes an increase in plate current, which produces a negative feedback voltage swing. The negative swing applied to the grid through Cl reduces the positive voltage on the capacitor, and discharges it a slight amount. Plate current is again decreased, and a positive swing is fed back to the grid. Thus, instead of decreasing exponentially between times t_2 and t_3, the grid charge voltage on Cl is reduced linearly. As the positive grid bias is reduced to zero between pulses by the discharge of Cl, the plate voltage constantly rises. At time t_2, it again reaches its starting value of 150 volts, the leading edge of the next input pulse arrives, and now drives the grid in a positive direction. From time t_3 to t_4 the cycle of action described above occurs again. The square wave input thus creates a 10-volt triangular output, and represents the integral of the input signal. By selecting the proper time constants and applied voltages, the output voltage and waveshape may be varied for the desired design characteristics. For this reason, the integrator circuit is sometimes used with a switching tube and amplifier to provide a linear sawtooth sweep voltage.

Failure Analysis.

No Output. A defective plate supply source, a defective plate resistance, an open input or a defective electron tube can cause a loss of output.

If no voltage is present on the plate of V1, either the plate supply voltage source or plate load resistor R2 is defective. Check R2 for proper value. If resistor R1 is open, no input will be applied to the grid of V1 and thus no output will be obtained. If all voltages on the electrodes of V1 are proper and no output exists, tube V1 is probably defective.

Low or Distorted Output. The output of this circuit can be made low or distorted by a shorted grid resistor, R1, a defective feedback capacitor, Cl, a defective tube, Vl, or a defective plate supply voltage source.

If resistor R1 is shorted, the correct charging time constant of Cl will not be obtained, and the output will be something other than the integral of the input. Likewise, if feedback capacitor Cl is open, no charging action will occur, and the output will more closely resemble the input. If Cl were shorted, no charging action would occur and in addition V1 would be connected between grid and plate, acting as a diode. This would produce an output waveform independent of the input voltage. The output will become distorted if the plate supply voltage source provides voltage higher or lower than the desired plate supply voltage. If proper voltages are supplied to all the elements of

491-044 0-73- 37

VI, and the component parts of this circuit are normal, triode VI is probably defective.

INTEGRATING AMPLIFIER (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

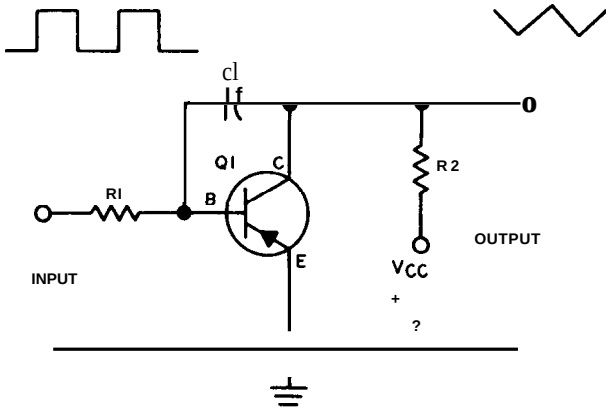
Same characteristics as electron tube version except it uses transistor with self-bias.

Circuit Analysis.

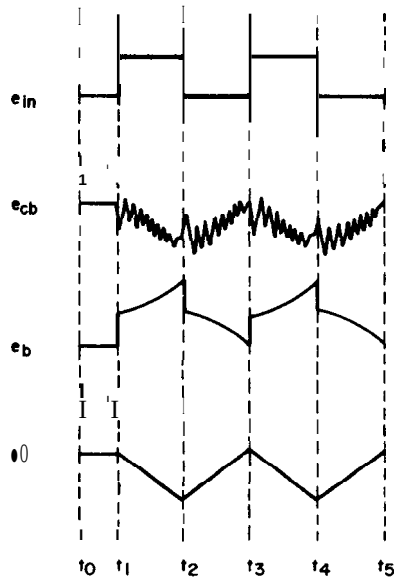
General. An integrating operational amplifier uses a resistive input network and capacitive feedback to produce the integrating effect. The output is developed by the charge and discharge of the capacitive feedback network during the pulse width and the time between pulses of a square-wave input. The capacitor also makes the output more linear by applying feedback to the base to control collector voltage variations. The output always represents the integral of the input voltage.

Circuit Operation. The schematic of a typical integrating amplifier is shown in the accompanying illustration. Resistor R1 is the base input resistor. Capacitor Cl is the feedback capacitor connected between the collector and base of transistor Q1. Resistor R2 is the collector load resistor.

The accompanying waveform chart shows the relationship of collector, base, and capacitor feedback waveforms. At time t. there is no input and the collector voltage rests at some negative value. At time t_1 a positive-going square wave is applied to the base of Q1, causing a decrease in forward bias. The collector voltage increases negatively and approaches the collector supply voltage, since the current through the collector load resistor is decreased. The negative-going change in collector voltage is capacitively coupled back to the base by Cl. This feedback voltage is designated as e_{cb} in the waveform illustration. The base voltage is now lower than the applied input voltage by the amount of the feedback voltage. The forward bias is then increased by this amount resulting in a slight emitter and collector current increase, and a slight drop in voltage across R2 to some more positive value. This positive change in voltage is coupled through Cl to the base of Q1, where it cancels some of the effect of the previously negative-going feedback. The current is decreased slightly between the emitter and collector, and collector voltage again approaches the collector supply voltage, but not nearly as much as it did with the original signal application. This effect continues during the signal pulse



Integrating Amplifier



Base and Collector Waveforms

between t_1 and t_2, but becomes less significant with each feedback pulse. This sawtooth effect is exaggerated in the e_{cb} waveform illustration. During time t_1 to t_2 capacitor Cl is charged by the effect of the negative feedback and the positive input voltage. The addition of these two voltages produces an effectively linear positive base signal. The positive base voltage will normally rise exponentially with the capacitor charge, as long as the input amplitude remains constant. Since the feedback voltage is constantly affecting the input voltage, the charging action occurs nearly linearly. The effect is to produce an average emitter and collector current which constantly decreases to a maximum at time t_2, when the trailing edge of the input signal appears. At the same time, the collector voltage constantly approaches the negative collector supply voltage. Thus, a nearly linear decreasing negative output is produced.

At time t_2, the base is instantly driven negative by the negative trailing edge of the input signal. The forward bias is now increased, and produces a larger emitter and collector current, causing greater current flow through R2. The collector current flowing through R2 produces a larger voltage drop across R2, and a more positive (less negative) voltage on the collector of Q1. The increased positive collector voltage is fed back to the base, and causes a decrease in emitter and collector current, producing a negative collector voltage swing. This negative swing is fed back to the base through Cl and reduces the positive voltage on the capacitor, discharging it a slight amount. Emitter and collector current is again increased, and a positive swing is again fed back to the base. Thus, instead of decreasing exponentially between time t_2 and t_3, the base charge voltage on Cl is reduced linearly. As the forward bias is increased between pulses by the discharge of Cl, the collector voltage constantly rises. At time t_3, it again reaches its initial value, the leading edge of the next input pulse arrives, and applies a positive-going voltage to the base of Q1. From time t_3 to t_4 the cycle of action described above occurs again. The square-wave input thus creates a triangular output, which is the integral of the square-wave input. The output voltage and wave shape may be changed somewhat be selecting the proper time constant and changing the input voltage shape and duration.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional voh-ohmeters. Be careful also to observe proper polarity when checking continuity, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** An output cannot be produced if the collector supply is defective, or transistor Q1 is defective.

If collector load resistor R2 is defective, input variations will not produce output variations. If resistor RI is open, no signal can be applied to the base of Q1. No collector voltage will be available if collector supply voltage source V_{cc} is defective. If none of these components is defective and there is no output, transistor Q1 is probably defective.

Low or Distorted Output. A low or distorted output may be the result of a shorted base resistor, a defective feedback network, a defective collector supply, or a defective transistor, Q1.

A shorted base resistor will change the r-c time constant so that the base boltage of Q 1 will no longer vary linearly and cause an abrupt decrease in output. If feedback capacitor Cl is open, no collector to base feedback will occur and the output variations will duplicate the input variations. If this capacitor (Cl) was shorted the collector and base of Q1 will be tied together, causing Q1 to act as a diode. A defective collector supply voltage source may cause the collector voltage to be higher or lower than the required voltage. If none of the previously mentioned components is found defective and the output is low or distorted, transistor Q1 is defective.

LOGARITHMIC AMPLIFIER (ELECTRON TUBE)

Application.

The logarithmic amplifier is used in analog computers and cathode-ray tube circuits to produce an output voltage which varies as the logarithm of the input voltage.

Characteristics.

Circuit uses two electron tubes; a variable-mu pentode and a constant-current pentode.

Plate of the constant-current pentode is connected directly to the cathode of the variable-mu pentode.

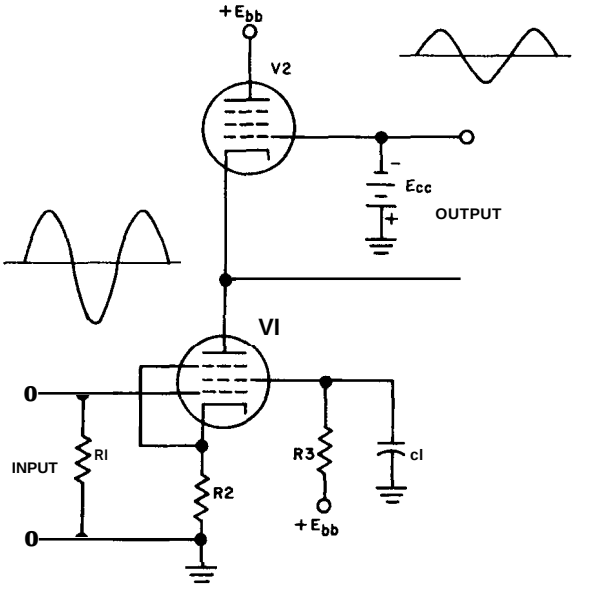
Control grid of the variable-mu pentode is maintained at a constant potential by fixed bias.

Output voltage is taken between the cathode and control grid of the variable-mu pentode.

Circuit Analysis.

General. The logarithmic amplifier uses two pentodes in a circuit configuration where the plate of a constant-current pentode is directly connected to the cathode of a variable-mu pentode. The variable-mu pentode has a natural logarithmic relationship from the input to the output, where the output voltage and plate current are normally proportional to the natural logarith base e raised to a power equal to the input voltage. In this circuit, however, the output is taken from between the cathode and grid instead of the plate, and the input is applied directly to the cathode. Regardless of the output connection, the output voltage stiU varies proportionally to the tube plate current, and the plate current varies logarithmically with the cathode input voltage. The input voltage applied to the cathode is the plate voltage of the constant-current tube, which varies directly in relation to the signal voltage applied to the grid of the constant-current tube. Thus, the final output voltage varies in relation to the natural logarithm $(\log_e)$ of the input voltage.

Circuit Operation. The schematic of a typical logarithmic amplifier is shown in the accompanying illustration. The input signals is applied across resistor R1 to the grid of Vl, a constant-current, sharp cutoff pentode. Resistors R1 and R2 develop a bias potential between the grid of Vl, and the cathode. Resistor R3 is a screen grid voltage-dropping resistor, and capacitor C 1 is the screen grid bypass capacitor. Electron tube V2 is a variable-mu pentode, which has a constant control grid voltage (E_{cc}) applied.



Logarithmic Amplifier

When the positive-going portion of a sinusoidally varying input voltage is applied across resistor RI to the control grid of Vl, it produces a corresponding increase in plate current conduction. Plate voltage is reduced as plate current increases. The reduced plate voltage causes a reduction in the voltage applied to the cathode of V2. This reduced cathode voltage is equivalent to a decrease in the grid voltage of V2, although the grid voltage is maintained at a fixed negative bias value by a separate supply. As a result, the plate conduction of V2 is increased and the plate voltage of V2 is decreased proportionally. Tube V2 is operated along the nonlinear portion of the (grid voltage-plate voltage) transfer characteristic curve of the variable-mu pentode. The resultant plate voltage

decrease causes the grid-to-cathode bias voltage to be decreased by an amount equal to the natural logarithm of the plate voltage. A bias decrease produces a more positive grid-to-cathode voltage, which is the output voltage. Since the input voltage variations cause corresponding variations in the plate currents and plate voltage of V1 and V2, the relation between the input signal and plate voltage of V2 is linear. However, the grid-to-cathode voltage (output voltage) varies at a rate equal to the natural logarithm of the plate voltage of V2. The positive-going output voltage is then proportional to the natural logarith of the positive-going input signal.

As the negative-going portion of the signal is applied to the grid of VI, the conduction of V1 is decreased and the plate voltage is increased. The increased plate voltage of V1 results in increased voltage applied at the cathode V2. The higher cathode voltage causes a decreased plate current and a proportional increase in plate voltage of V2. The plate voltage increase causes the grid-to-cathode voltage of V2 to become more negative by an amount equal to the natural logarithm of the plate voltage. The negative-going input voltage then causes a negative-going output proportional to the logarithm of the input signal.

Failure Analysis.

No Output. An open cathode resistor, a defective pentode VI or V2, or a defective plate supply voltage source can result in a loss of output.

Cathode resistor R2, if open, will prevent any current flow in the circuit. If pentode V1 were defective, no voltage would be applied to the cathode of V2 and thus, no voltage would appear at the output. If the proper voltages appear on the elements of V1 and there is no output, V1 is defective. If the proper voltages are present on the elements of V2 and there is no voltage on the plate of V1, pentode V2 is defective. No voltage on the plate of V2 (and the screen grid of VI) indicates that plate supply voltage source E_{bb} is defective.

Low Output. Low Output can result from low plate supply voltage, low V2 grid bias, or from a defective screen voltage-dropping resistor.

Low plate supply voltage causes the conduction of V1 and V2 to be lower than desirable and makes a lower voltage appear at the cathode of V2. Low bias voltage on the control grid of V2 also Iowers the potential existing between the grid and cathode of V2. If screen grid dropping resistor R3 is open, or larger than it should be, the conduction of V1 will not be sufficient to produce a normal output.

Distorted Output. If grid resistor RI is defective, cathode resistor R2 is shorted, bypass capacitor C 1 is defective, or pentodes VI or V2 are defective, the output voltage may be distorted.

A shorted or open grid resistor Rl, or shorted cathode resistor R2, produces a reduced bias on V1 and causes VI to be operated on a different portion of the pentode characteristic curve. This, in turn, causes the output to vary improperly with an input signal. An open screen grid bypass capacitor Cl will allow the screen grid voltage to vary with signal current variations in the plate circuit and produce distortion in V1. If none of these conditions exists and proper voltages are available on the elements of VI, pentode VI is probably defective. If the plate supply voltage of V1 is incorrect and the voltages on the elements of V2 are correct, pentode V2 is probably defective.

LOGARITHMIC AMPLIFIER (SEMICONDUCTOR)

Application.

The logarithmic amplifier produces an output which is proportional to the logarithm of the input. The logarithmic amplifier is used in analog computers and cathode-ray circuits.

Characteristics.

The logarithmic amplifier consists of three stages– a dc amplifier, an emitter follower, and a logarithmic circuit.

Two crystal diodes produce an output proportional to the logarithm of the applied signal.

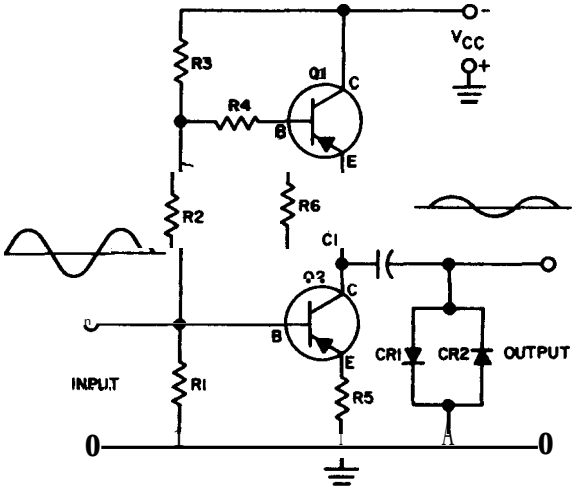
The amplifier provides low-voltage gain.

Circuit Analysis.

General. This amplifier is especially useful in controlling and maintaining the output of an exponentially increasing input to a linear output. The amplifier, however, can be used to produce an output which is the logarithm of any input. The operation of this circuit is based on the inherent characteristic of silicon semi-conductor diodes to" develop a current which is the logarithm of the signal applied to these diodes. The driving circuit for the diodes consists of an operational amplifier and an emitter-follower circuit connected in series with the collector and supply source. The operatiomd amplifier increases signal

strength so that the logarithmic compression of the signal by the diode will not reduce the output to the point where it is unusable. The emitter-follower circuit maintains a high output impedance for the operational amplifier and prevents any load changes from greatly affecting the output impedance of the operational amplifier.

Circuit Operation. The schematic of a typical transistor logarithmic amplifier is shown in the accompanying illustration. In the circuit, resistors Rl, R2, and R3 provide voltage divider base bias voltage for transistor Q1. Resistors R2 and R4 also attenuate the input voltage before applying it to the base of transistor Q1. Transistor Q1 and emitter resistor R6 corm prise a series load for transistor Q2. Capacitor Cl couples the output of transistor Q1 to the logarithmic output network consisting of the parallel diode combination of CR1 and CR2.



Logarithmic Amplifier

As the positive portion of a sinusoidally varying signal is applied to the input, the bases of both Q1 and Q2 are driven positive. The base of Q1 is driven to a less positive potential than the base of Q2, since the input voltage is attenuated by resistors R2 and R4. The positive-going input voltage decreases the forward bias of both transistors, and the emitter-to-collector current of both transistors decreases. As a result of decreased collector current, the collector voltage of Q2 attempts to increase (rise negatively). Since the collector voltage of Q1 remains at the negative collector supply voltage value, the decreased emitter current increases the internal resistance of Q2 and causes the emitter of Q1 to become more positive. The voltage at the collector of Q2 then decreases. This, in effect, helps to decrease the total collector voltage swing of Q2 without lowering the supply impedance. The reduced collector current of Q2, however, tends to allow more current to be shunted around Q1 through CR2 without decreasing the supply impedance. The output voltage produced across CR2 is proportional to the natural logarithm of the current flowing through CR2.

As the sine wave reaches its positive peak and swings negative, the input voltage applied to the bases of Q1 and Q2 goes negative. Thus, the forward bias of both transistors increases, and the forward bias of Q1 is somewhat less than the forward bias of Q2 as a result of the attenuation provided by resistors R2 and R4. The current flowing from emitter to collector of each transistor now increases. The current increase of Q2 would normally be much greater than the current increase of Q1. The collector voltage of Q2 becomes more positive by the increased voltage drop across resistor R6. However, the internal impedance of Q1 is lowered, reducing the drop across Ql, and the effective supply voltage at the input to R6 increases. Thus, the collector voltage swing of Q2 is reduced. The collector output voltage swing is coupled through capacitor Cl to the diodes, and since it is positive-going, CR1 now conducts and CR2 ceases to conduct. The output voltage produced across CRI is proportional to the natural logarithm of the current flowing through it.

Semiconductor diodes provide a good logarithmic range when the current flowing through the diode is larger than the saturation current of the diode. The output voltage is then proportional to the natural logarithm of the quantity formed by the instantaneous forward current through the diode (iF) plus the saturation current value (Is), divided by the saturation current. This quantity is added to the diode voltage drop which is the product of the current through the diode (iF) and the actual resistance of the diode (Rd). This proportionality is expressed mathematically as:

$$V_{\cdot} = \log_e \frac{(iF + Is)}{Is} + iF\,Rd$$

Hence a logarithmic output is produced.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of a conventional volt-ohmmeter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** An output may not be produced if the collector supply is defective, if either transistor is defective, if the collector load resistor, or emitter bias resistor is open, if the coupling capacitor if open, or if both diodes are defective.

A defective collector supply source (V_{CC}) prevents any voltage from being available on the collectors of either transistor. If either transistor Q1 or Q2 is defective, no current carI flow in the circuit. Likewise, current cannot flow in the circuit if the collector load resistor of Q2 (R6) or emitter bias resistor (R5) is open. An open coupling capacitor, C 1 prevents current from flowing through either diode. If there is no output developed and if none of the previously mentioned components is defective, both diodes CR1 and CR2 are probably defective.

Low or Distorted Output. A low or distorted output may be produced if any of the biasing resistors is defective, the coupling capacitor Cl is shorted, either diode is defective, or if the collector supply voltage source is defective.

If any of the bias resistors Rl, R2, R3, R4 is shorted, the bias voltage available for Q1 and Q2 is incorrect. If resistor R2 or R4 is open, the input signal will not be applied to Q1. A shorted coupling capacitor Cl allows the dc voltage on the coIlector of Q2 to be applied to the crystrd diodes. If either diode CR1 or CR2 is defective, a logarithmic output will only be produced for one half of the input signal. A low supply voltage will prevent the correct supply voltage from being applied to either collector and produce a Iower than normal output.

SUMMING AMPLIFIER (ELECTRON TUBE)

Application.

The summing amplifier is an operational amplifier used in analog computer circuitry to develop an output voltage which is the sum of two or more input voltages of the same polarity and phase.

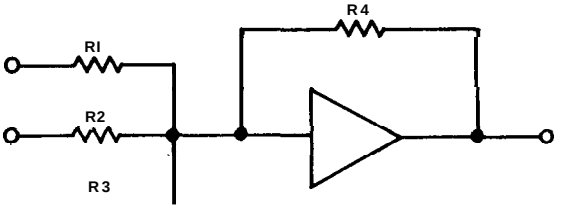
Characteristics.

High stabilized gain.
Negative feedback is employed.
Fixed or self bias maybe employed.
Input and output networks are resistive.
Amplifier stages are directly coupled.

Circuit Analysis.

General. A summing amplifier is a direct-coupled amplifier with high stabilized gain. It produces an output voltage that is equal or proportional to the sum of the applied input voltages, which are usually of the same phase and polarity. The input voltages are applied to the grid of an electron tube through equal input resistors forming a summing network. The corn bined input voltages are inverted and amplified by the tube. A portion of this voltage is fed back to the input of the amplifier through a resistive feedback network. This feedback voltage stabilizes the output and maintains a relatively constant gain.

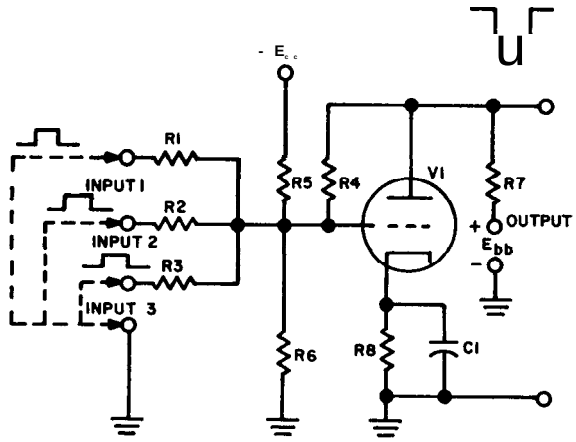
Circuit Operation. The accompanying illustration shows a summing amplifier in symbolic one-line form. Using this type of circuit representation, the amplifier is indicated by an isosceles triangle. The base of the triangle represents the input of the amplifier and the vertex represents the output of the amplifier. Resistors RI, R2, and R3 form the summing network which provides the input signal to the input of the amplifier. Resistor R4 forms the feedback network for the amplifier. The one-line type of diagram may use a vacuum tube, transistor, or integrated circuit as the amplifier. The symbolic representation is used to show the relation among the input, the output, the feedback network, and the amplifier in simplified form.



Summing Amplifier Circuit Representation

In the following schematic diagram, the operational amplifier uses triode VI, Resistors RI, R2,

R3, and R6 form a resistive summing network which provides the input signal to the grid of V1. Resistor R8 is a cathode bias resistor bypassed by capacitor C 1. Resistor R7 is the plate load resistor from which the output voltage is obtained. Resistor R4 is the feedback resistor which returns a portion of the output voltage to the input to prevent distortion and drift. Fixed negative bias voltage is applied through grid-isolating and voltage-dropping resistor R5. Resistor R6 forms a bias bleeder network with R5 to stabilize the fixed bias voltage on the grid of VI and completes the summing network path to ground.



Summing Amplifier Circuit

Voltages of the same polarity and phase are applied to each input simultaneously. The total value of the added input voltages appears at the grid of VI, and produces an increased plate current, which is proportional to the summed input voltage. The plate (and output) voltage decreases in relation to the plate current increase, creating a negative voltage swing. A portion of this negative plate voltage swing is returned to the grid of V1 through feedback resistor R4. This ensures that any distortion or drift existing in the input signal at the grid is canceled by feedback 180° out of phase with the input. The positive plate voltage fed back to the grid of V1 through R4 requires that a fized negative bias voltage be applied to the grid to prevent the grid from going positive and driving V1 to saturation. A negative voltage source supplies the added bias to the grid of VI through resistor R5. Resistor R6 prevents a grid-current initiated voltage drop across R5 from changing the bias voltage at the grid of V1.

When the input voltage swings in a negative direction or reduces, the plate current also decreases. The decrease in plate current causes the plate (output) voltage to rise toward the supply value, creating a positive swing. A portion of the increasing plate voltage swing is fed back to the grid to cancel again any input signal distortion or drift.

The summing amplifier depends upon the feedback network to provide a constant gain despite any variation in tube characteristics. Although a high gain is produced by the tube, the feedback connection reduces the overall gain obtained by the amount of feedback. When an input voltage is applied to either Rl, R2, or R3 it will cause a current to flow through the respective resistor and a voltage wiU be applied to the grid of VI. When this input signal increases, the first small change in voltage is amplified by V1 and appears in the output circuit. In turn, a portion of this output voltage is fed back through R4, and being out of phase with the input, decreases the total input voltage at the grid. The decrease in input is amplified and fed back again to increase the amplitude of the input voltage. This process continues until the amplifier reaches a point of stable operation. If the input resistance is equal to the feedback resistance, the output voltage is equal to the input voltage, except that the output polarity is reversed (provided that an odd number of stages is used). Hence, if the input voltage is doubled, the output voltage will double. The amount of feedback used determines whether or not the output signal will be equal to, greather than, or less than the actual value of input voltage. So, depending upon design, the summing amplifier may not actually. amplify the total signal, but it will produce an output which does represent the sum of the applied input voltages.

Failure Analysis.

No Output. Lack of plate voltage, a defective tube, an open input circuit, or lack of input signal can cause a loss of output. If plate load resistor R7 is open, no voltage will appear on the plate of V1. An open cathode resistor, R8, will prevent the tube from operating. Excessive bias caused by a shorted R5 can produce plate current cutoff and no output. Conversely, if R5 is open, a high positive bias voltage will be fed back from the plate of V1 to the grid and

cause heavy plate current flow. In this case, the final value of plate current will be determined by cathode resistor R8, the plate voltage of VI will be extremely low, and a large voltage drop will occur across plate load resistor R7, In this instance, although an apparent output will be obtained, it will be constant, and the circuit will no longer act as an adder. If bias and plate voltages measure normal and input voltage is present on the grid of Vl, but there is no output, the tube is probably defective. For the input circuit to be open, resistors R1, R2, and R3 must simultaneously be open. Check for the proper resistance value and continuity.

Low Output. A low output is an inaccurate output, and can be caused by a defective input circuit, improper bias and plate voltages, as well as a defective tube. Check Rl, R2, R3, and R6 for continuity and resistance. Measure the cathode, grid, and plate voltages with no input applied. No cathode voltage indicates the possibility that capacitor Cl is shorted or V1 is defective. Improper grid bias voltage indicates that R4, R5, or R6 are defective, or that the bias supply is at fault. Improper plate voltage indicates that R4, R7, or V1 can be defective.

Distorted Output. In the summing amplifier, am inaccurate output can be considered as a distorted output. Usually a change in feedback resistor R4, or a change in the values of input resistors R1, R2, or R3 are the cause, or the tube is defective. Check the values of the resistors to make certain that they are normal. Also check the bias and plate voltage sources to make certain that the external circuits are not at fault.

SUMMING AMPLIFIER (SEMICONDUCTOR)

Application.

The summing amplifier produces an output voltage which is the sum of two or more input voltages of the same polarity and phase. The summing amplifier is primarily used in analog computers, and in control and instrumentation circuitry.

Characteristics.

A number of input signals are applied to produce a single output.

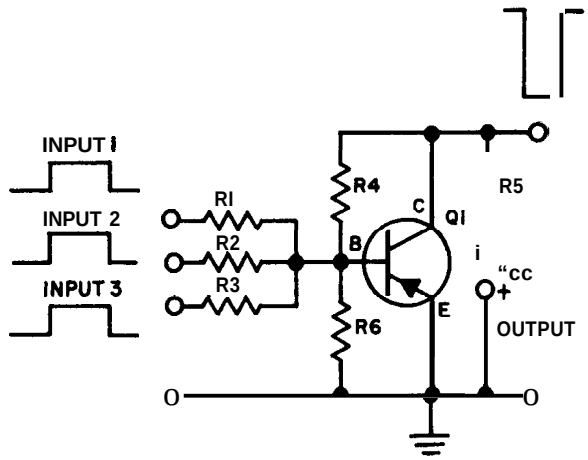
Resistive input summing networks are used.

Negative feedback is used.

Circuit Analysis.

General. A summing amplifier uses a direct-coupled amplifier with high stabilized gain. It produces an output voltage that is proportional to the sum of the applied input voltages. Each input voltage has the same phase and polarity as the other input. The input voltages are applied to the base of a transistor through a summing network. The combined signals are inverted and amplified across a common load resistor. A portion of this output voltage is fed back to the base of the transistor as negative feedback. The feedback voltage stabilizes the output and maintains a relatively constant gain.

Circuit Operation. The schematic diagram of a typicrd transistorized summing amplifier is shown in the accompanying illustration. Resistor Rl, R2, and R3 together with R6, form a resistive summing network, which provides the total input signal to the base of transistor Q1. Resistor R4 is the collector-to-base feedback resistor and together with R6 supplies base bias to Q1. Resistor R5 is the collector load resistor.



Summing Amplifier

Separate positive signal voltages of the same phase and frequency are applied to resistors Rl, R2, and R3. The total sum of these voltages appears across R6 (which completes the path to ground) at the base of Ql, and reduces the normal forward bias of the transistor. The emitter and collector currents are thereby reduced, allowing the collector voltage to rise and

approach the negative supply voltage value. A portion of this negative voltage swing is returned to the base of Q1 through feedback resistor R4. This negative feedback voltage cancels any distortion or drift existing in the combined input voltage since it is 180° out of phase with the input signal.

When the input voltage swings negative, the combined voltages at the base of Q1 develop an increased forward bias. As a result, the emitter and collector currents increase. The increased collector current flow through resistor R5 causes an increased voltage drop across the load. The collector of Q1 is thus driven to a less negative potential (more positive). A portion of this positive collector voltage swing is fedback to the base of Q1 through R4 where it again cancels any input signal distortion or drift. The output voltage taken between collector and ground is the amplified output which is proportional to the sum of all of the inputs.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A lack of output may result if all inputs are open, the collector load is defective, the collector supply is defective, or if transistor Q1 is defective or improperly biased.

If input resistors, Rl, R2, and R3 are all open, no input voltage can be applied to the base of Q1. An open collector load resistor, R5, will prevent any collector supply voltage from appearing at the collector of Q1. If the collector supply voltage source, V_{cc} is defective, no voltage will appear at the collector of Q1. If none of these components is found to be defective and there is no output, transistor Q1 is probably defective; or R4 may be open, causing loss of forward bias.

Low or Distorted Output. The output of the summing amplifier is low or distorted if any of the inputs is defective, if the feedback network is defective, if the collector supply is defective, or the transistor is defective.

If one or two of the input resistors are open, only the signals applied to the remaining input resistors will be applied to the base of Q1 across R6. If any or all of these resistors are shorted, the input signals will not be properly summed before being applied to the base of Q1. If feedback resistor R4 is open, any distortion of the input signal will not be corrected before being applied to the base. Transistor Q1 will act as a diode if resistor R4 becomes shorted. The input variations will then be rectified and appear as an average steady output voltage. The collector voltage may be higher or lower than the required voltage, If collector supply voltage source V_{cc} is defective. If the components are not found to be defective with abnormal output, transistor Q1 is probably defective.

RING-BRIDGE AMPLIFIER (SEMICONDUCTOR)

Application.

The ring-bridge amplifier is used to detect and amplify a double-sideband suppressed-carrier signal or a single-sideband signal.

Characteristics.

Requires a ring-bridge detector and a transistor amplifier.

Two stages are needed to provide the dual function of this circuit.

Transformer coupling is used between stages, but the output stage is direct-coupled to the load.

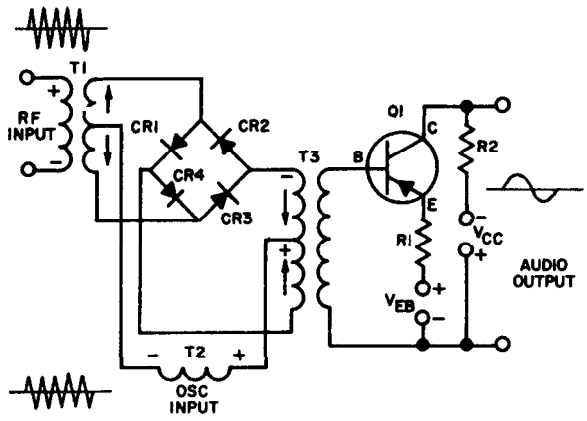
A reference oscillator input is required to produce an output.

Circuit Analysis.

General. The ring-bridge amplifier is a two-state circuit consisting of a ring-type rectifier or detector, transformer-coupled into a dc operational amplifier circuit. The ring-type detector appears in the form of a bridge rectifier, from which the circuit name is derived. A reference oscillator provides a simulated carrier which is transformer-coupled between the center taps of the input and output transformers of the detector bridge, so that an in-phase signal may be coupled to each pair of diodes. No output is obtained as long as the simulated carrier signal alone is applied, since in the balanced bridge circuit equal conduction between opposite diodes occurs, and equal current flowing in opposite directions in the two halves of the same transformer effectively cancels any output. The applied sideband input signal beats with the simulated carrier, and results in the addition to and subtraction

of the input signal from the oscillator signal, causing each diode to conduct alternately on opposite half cycles. The output produced by the bridge diodes is coupled through the output transformer of the detector to the input of the second stage, where the detected signal is inverted and amplified.

Circuit Operation. A typical ring-bridge amplifier schematic is shown in the accompanying illustration. Transformer T1 is the r-f (or subcarrier) input transformer while T2 is the reference oscillator transformer. Transformer T2 is connected between the center taps of T1 and T3. Transformer T3 is the output transformer of the detector stage. Diodes CR1 and CR3 form one group of bridge rectifiers and CR2 and CR4 form the other group. The diode pairs conduct simultaneously for in-phase signals and alternately for push-pull signals. Resistor R1 is an emitter stabilization resistor for Q1. Resistor R2 is the collector load resistor of Q1. The collector supply voltage is V_{CC} and V_{EB} is a separate emitter bias voltage source.



Ring-Bridga Amplifier

When no input signal is applied, except the reference signal from the oscillator, the center tap of T3 is driven positive, and the center tap of T1 is driven negative. Diodes CR2 and CR4 conduct because of the positive voltage applied to the anodes. Electron flow is from the negative terminal of T2 through the lower half of T1 secondary and the cathode to anode of CR4, back through the lower half of T3 primary to the positive terminal of T2. Current also flows through the top half of the secondary of T1 to the junction of CR2 and CR1. Diode CR2 is forward-biased and conducts, causing current to flow through the top of T3 primary winding back to the positive end of T2. Because of the equal and opposite currents flowing through each half of the secondary of'Tl and the primary of T3, the transformer windings cancel, preventing any voltage from being induced into either the primary of T1 or the secondary of T3. As a result, no input is applied to the operational amplifier and no output is produced. When the polarity on the secondary of T2 reverses, a similar situation arises with diodes CR1 and CR3 conducting. In this case, current flows from the center tap of T3 to the cathodes of CR1 and CR3, and to the plates of CR2 and CR4. CR1 and CR3 conduct, causing equal currents to flow through opposite ends of T 1 to the center tap. The currents through both halves of the primary of T3 are **equal,** but opposite in polarity, which again causes the opposing induction fields set up in T3 to cancel, resulting in no output from the detector and no output from the amplifier.

Since the reference oscillator amplitude is stronger than that of the incoming r-f sideband signals, the polarity of the reference oscillator on the diodes controls conduction. Assume that a push-pull r-f signal is applied to the input of Tl, developing a voltage across the secondary of T1 which is negative at the top and positive at the bottom. The reference oscillator also assumed to be applying a signal which normally keeps diodes CR2 and CR4 conducting; when both signals add instantaneously, CR2 then conducts more and CR4 conducts less, developing unequal currents flowing from each end of T3 to the center tap. In this case, a greater current flows from the top of T3 to the center tap as a result of the greater conduction of **CR2.** At the same time, less current flows from the bottom of T3 to the center tap as a result of the lesser conduction of CR4. The result of these unbalanced currents is that the top of T3 becomes more negative with respect to the bottom of T3. The induced voltage in the secondary of T3 is positive at the top of the winding with respect to the bottom. Since the top of the secondary of T3 is connected directly to the base of Ql, the positive input voltage reduces the forward bias of Q1. Q1 conducts less as a result of this reduced forward bias. The smaller emitter-to-coflector current of QI results in less collector currently flowing through R2, producing a smaller IR drop across R2. The smaller IR drop across

R2 causes the voltage on the collector of Q1 to rise toward the collector supply voltage value.

The result of a positive-going input signal riding on a reference carrier input is a negative-going output, which is amplified. The reference carrier is automatically canceled so that it does not appear in the output.

A negative-going input signal riding on a reference carrier input produces the opposite action. Thus, diode CR4 conducts more, while diode CR2 conducts less.

The potential across the primary of T3 now reverses, inducing a voltage across the secondary of T3 which is 180° out of phase with the primary voltage. Hence, a negative voltage is now applied to the base of Q1, producing a greater forward bias; consequently, the greater emitter-to-collector current produces a greater IR drop across R2, and a positive-going collector and output voltage. Again, the reference carrier signal is automatically removed by the canceling action in T3, previously described.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of conventional volt-ohmmeters. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a faIse low-resistance reading.

No **Output.** The output may be lacking if transformer T1 and T3 is defective, if the collector load resistor is defective, if the emitter stabilizing resistor is open, if the bias voltage source is open, if the collector supply source is defective, if any of the four diodes is defective, or if transistor Q1 is defective.

If transformer T1 is completely open or completely shorted, the input signal will not be coupled to the detector circuit and no input will be applied to the amplifier circuit. If transformer T3 is completely open or completely shorted, the detected signal can not be applied to the amplifier. A shorted or open collector load resistor, R2 prevents any sup ply voltage from being applied to the collector of Q1. Collector voltage is prevented from being applied to the collector also, if collector supply voltage source V_{cc} is defective. If emitter stabilization resistor R1 is open, the transistor amplifier circuit sees an open emitter circuit and no current will flow through Q1. An open emitter to base bias voltage source, V_{EB}, will also prevent current flow in the amplifier circuit. If diodes CR1, CR2, CR3, and CR4 are defective, no potentird difference can be developed across T3, and thus no input will be applied to the base of Q1. If one of these components is defective, and there still is no output developed, transistor Q1 is probably at fault.

Low or Distorted Output. A low or distorted output can result from a defective reference carrier oscillator transformer T2, a defective diode, a defective transformer T1 or T3, a defective collector supply voltage source, a defective emitter bias source voltage, or a defective transistor.

If reference carrier oscillator transformer T2 is defective, the reference carrier signal will be absent and prevent the detector bridge from being properly balanced. If any of the diodes in the bridge is shorted or open, proper current will not flow through the diode and the proper potential difference will not be developed across the primary of T3. If either transformer T1 or T3 is partially shorted, improper voltage will be applied to the detector bridge circuit or to the amplifier circuit. A defective emitter bias source will cause improper bias to be developed and produce distortion. If collector supply source V_{cc} is defective, improper voltage will be applied to the collector of Q1. If these components are not found to be defective and a low or distorted output is developed, transistor Q1 is probably defective.

SECTION 6
OSCILLATORS

PART 6-1. ELECTRONIC

ARMSTRONG (TICKLER-COIL) OSCILLATOR (ELECTRON TUBE)

Application.

The Armstrong oscillator is used to produce a sine-wave output of constant amplitude and fairly constant frequency within the r-f range. The circuit is generally used as a local oscillator in receivers, as a single source in signal generators, and as a variable-frequency oscillator over the medium- and high-frequency ranges.

Characteristics.

Utilizes an L-C tuned grid circuit to establish the frequency of oscillation. Feedback is accomplished by mutual inductive coupling between the tickler coil and the L-C tuned grid circuit.

Operates Class C with automatic self-bias.

Frequency stability is fair.

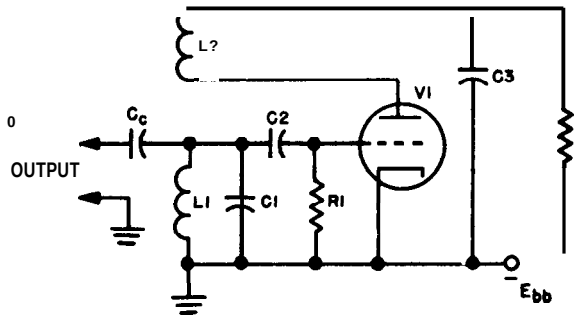
Output amplitude is relatively constant.

Circuit Analysis.

General. Oscillations of a tuned circuit will tend to die out at an exponential rate and will finally cease, unless energy is replaced at regular intervals. For oscillations to be sustained, sufficient energy must be supplied to overcome circuit losses. The use of an electron tube as an amplifier provides the additional energy necessary to sustain oscillations. The energy applied to the tuned circuit must be of the correct phase relationship to aid the initial oscillations and of sufficient amplitude to overcome circuit losses in the tuned circuit.

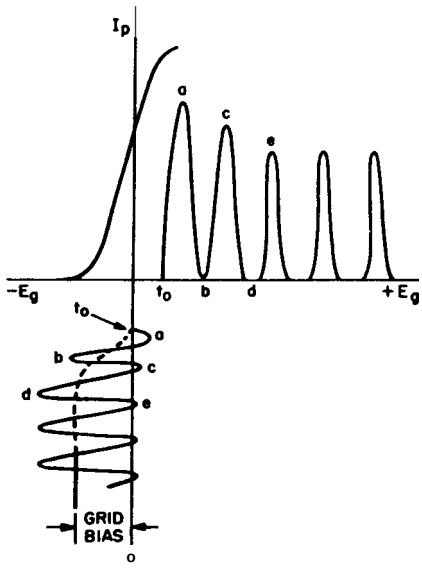
The circuit used to provide this type of feedback is called a ***regenerative circuit, and*** the ***energy*** supplied is called ***positive feedback.*** In the accompanying circuit schematic the tuned L-C circuit is designated as L1, C 1; the tickler (feedback) coil is designated as L2.

Circuit Operation. The accompanying circuit schematic illustrates a triode electron tube in an L-C Armstrong oscillator circuit. Inductance L1 and capacitor Cl form the resonant grid circuit. Inductance L2 is the plate, or tickler, coil and is mutually coupled to L1, to couple a feedback voltage to inductance L1 by transformer action. Capacitor C2 and resistor R1 form an R-C circuit which is used to develop the operating bias. Capacitor C3 functions as an r-f bypass to place the B+ terminal of tickler coil L2 at signal ground potential. Resistor R2 isolates the B+ line from the r-f signal and also serves to reduce the input voltage applied to the oscillator circuit. Capacitor C_c is the output coupling capacitor.



L-C Armstrong (Tickler-Coil) Oscillator

For the follOwing discussion of circuit operation, refer to the accompanying illustration of oscillator grid-signal voltage and plate-current waveforms.



Theoretical Grid-Voltage and Plate-Current Waveforms

Initially, the tube is at zero bias (t. on waveform illustration) to permit the circuit to be self-starting. When input power is applied to the circuit, the tube conducts because of the lack of operating bias. As the plate current increases through tickler coil L2, an expanding magnetic field is built up around the tickler coil. This expanding field causes an increasing voltage to be induced in inductance L1 of the tuned circuit, and this voltage is of such polarity that the grid of V1 is made positive with respect to the cathode. The positive grid condition increases the flow of plate current, which further increases the field about tickler coil L2; consequently, the voltage induced in inductance L1 increases and the grid is drawn further in the positive direction. This process continues until saturation is reached, at which time no further increase in plate current can take place (point *a* on waveforms).

During the period of time that a charging voltage is induced in inductance L1, capacitor C 1 changes to maximum; also, capacitor C2 receives a charge as the result of grid-current flow through the low internal cathode-to-grid resistance of the tube.

When the plate current reaches saturation, a steady (unchanging) magnetic field is produced about tickler coil L2, and, as a result, a voltage is no longer induced in inductance L1. With no induced voltage present, capacitor Cl begins to discharge through inductance Ll, and capacitor C2 begins to discharge through resistor R1 (and Ll). The positive voltage on the grid of V1 decreases as capacitor C1 discharges through inductance L1, and this decrease in the grid voltage causes the plate current to decrease below the saturation value. The decrease in plate current through tickler coil L2 causes the magnetic field about the tickler coil to decrease and start to collapse, and thus causes an increasing voltage to be induced in inductance L1. However, the polarity of the induced voltage is reversed from that originally inducted in L1 when the magnetic field about tickler coil L2 was expanding. Hence, the induced voltage causes the grid of V1 to be driven negative with respect to the cathode, and the plate current is further decreased, causing the magnetic field about tickler coil L2 to collapse completely. As this occurs, the grid of V1 becomes increasingly negative until a voltage is reached which prevents any further decrease in plate current (point *b* on waveforms). (The voltage induced in L1 during this time also aids the discharge of Cl.)

At this instant, capacitor C2 starts to discharge through resistor RI (and Ll), decreasing slightly the negative potential existing between the grid and cathode of VI. Also, capacitor C 1 discharges through inductance LI, producing an expanding magnetic field about inductance L1; when capacitor Cl is completely discharged, the magnetic field begins to collapse. The collapsing magnetic field about inductance L1 again produces a voltage across the inductance which charges capacitor Cl and also drives the grid of V1 in a positive direction. As the grid of VI becomes positive with respect to the cathode, plate current begins to flow through tickler coil L2. The magnetic field produced about tickler coil L2 again increases and induces a voltage in inductance Ll, which drives the grid still further into the positive condition. Grid current again flows through the internal cathode-to-grid resistance of the tube to produce a negative charge on capacitor C2. Plate current again rises to maximum, at which time no further increase in plate current can take place (point c on waveforms).

The entire process repeats as described above, with the bias voltage continuing to build up across capacitor C2 until a steady value of Class C bias, effectively across resistor RI, is reached. The interchange of

energy at the resonant-frequency rate between inductance L1 and capacitor Cl of the tank circuit maintains the oscillations during the period of time that plate current is cut off and no energy is supplied to the tuned circuit through the tickler-coil feedback circuit.

As oscillations build up, the maximum signal across the resonant circuit becomes increasingly greater. Note that the grid-leak-and-capacitor combination, R1 and C2, is used to develop the operating bias, to permit Class C operation of the tube. When the circuit is placed in operation, a stable operating point is quickly reached where the positive signal peaks are of sufficient amplitude to cause grid current to flow and to charge the grid capacitor, C2. Momentarily, when the signal is less positive, grid current ceases to flow, and capacitor C2 discharges slowly through grid-leak resistor R1. Since the value of R1 is large, only a small amount of charge is lost by capacitor C2 before the signal again is sufficiently positive to cause the grid to again draw current. As a result of this automatic charge-discharge action, an average value of negative bias, approximately the value to which capacitor C2 is being charged, is developed across R1, between the grid and cathode. Whenever the signal amplitude tends to increase, additional grid current flows through the internal cathode-to-grid resistance of the tube, and, therefore, capacitor C2 is charged to a higher value. Consequently, the bias voltage also increases, and the resulting effect is to decrease the gain of the tube. As the gain of the tube decreases, the output-signal level also decreases and returns to approximately its original amplitude. Similarly, when the signal amplitude tends to decrease, there is a decrease in bias voltage and an accompanying increase in the gain of the tube. As the gain of the tube increases, the output-signal level also increases and returns to its original amplitude. Thus, through the regulating action of grid-leak bias, the circuit operation is stabilized, and the amplitude of the output is held essentially constant.

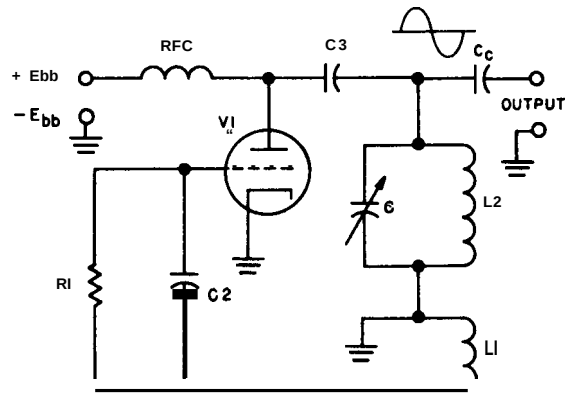
The oscillator output frequency is determined primarily by the values of inductance L1 and capacitance Cl at resonance

$$(f. = \frac{1}{2\pi\sqrt{LC}}),$$

although interelectrode capacitances of the electron tube and distributed capacitances and inductances of the circuit also have an effect upon the oscillator frequency. In most circuits a variable capacitor is used to change the frequency; however a variable inductance can be used with a fixed capacitor to accomplish the same purpose.

The oscillator output, which is taken from the tuned circuit, is generally capacitively coupled (Cc) to the associated load circuit; however, inductive coupling may also be used with the output coupling coil being mutually coupled to Ll near its ground end.

Tuned-Plate Version. The proceeding circuit description covered the basic Armstrong circuit, in which the tank coil is in the grid circuit (tuned grid) and the tickler coil is in the plate circuit. Another circuit version in which these conditions are reversed in called the tuned-plate circuit. In this circuit, the tank is in the plate circuit and the tickler (feedback) coil is in the grid circuit. The operation of this oscillator is identical to that of the tuned-grid circuit, except for limitations imposed by coupling between the plate and grid. This coupling limits the range of oscillation in the tuned-grid version, but not in the tuned-plate version. Actually, the tuned-plated oscillator is considered less susceptible to frequency changes caused by power supply voltage changes than the tuned-grid oscillator. The schematic of the tuned-plate circuit is shown in the following illustration.



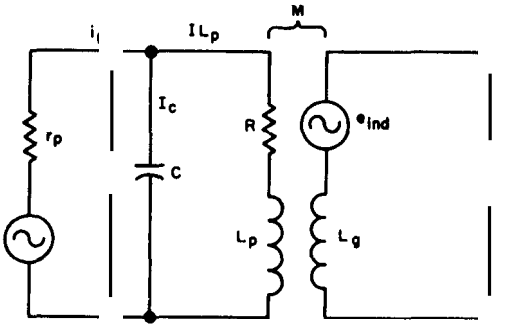
Tuned-Plate Armstrong Oscillator

The parts in the tuned-plate oscillator are labeled the same as in the illustration of the tuned-grid oscillator, for comparison. The differences are the use of shunt plate feed in the tuned-plate circuit instead of

what is essentially series plate feed in the tuned-grid circuit and the use of series grid-leak bias instead of. shunt grid-leak bias. Actually, the use of shunt or series feed does not change the method of operation; it merely illustrates possible circuit variations. Grid-leak components R1 and C2 operate in the same manner as described for the tuned-grid version, and C3 is a plate blocking and coupling capacitor instead of an r-f bypass. Note that plate dropping resistor R2 is replaced by radio-frequency choke RFC, which keeps the r-f from being shunted to ground via the power supply falter capacitors. When the circuit is energized, the flow of plate current produces tank circuit variations through L2, and an in-phase voltage is fed back through grid (tickler) coil L1 to sustain feedback exactly as described under L-C circuit operation for the tuned-grid circuit previously discussed. The grid leak formed by RI and C2 controls the amplitude and grid bias.

Detailad Analysis. Since the oscillator is considered to be a Class C amplifier with a feedback loop, a rigorous mathematics analysis is complex because the circuit operation is inherently non-linear. The analysis can be greatly simplified by using the equivalent plate circuit, together with a few assumptions. This method of amlysis is helped in determining the conditions necessary to produce sustained oscillations and in determining the basic frequency of oscillation. With this approach, it is customary to neglect the flow of grid current, but to bear in mind that its effect must be considered and the final results modified to take the grid current into account. Actually, losses due to grid current can be treated as an equivalent loss in the tuned circuit.

The ac equivalent circuit for the tuned plate oscillator is shown in the following illustration. Assuming that the currents are sinusoidal and neglecting grid current flow, Kirchhoff's laws and Thevenin's theorem can be applied to this circuit to obtain the limiting parameters that determine oscillation and frequency.



Tuned Plate Equivalent Circuit

Mathematics analysis of the equivalent circuit for the tuned-plate oscillator shows that the critical value of coupling is:

$$M = \frac{L_p + CRr_p}{\mu} \qquad (1)$$

which gives the minimum value that M can have and still allow the circuit to oscillate. To satisfy this condition, M must be posaible and:

$$g_m = \frac{RC}{M} + \frac{L_p}{M r_p} \qquad (2)$$

Thus, the coupling between grid and plate coils must exceed the minimum value indicated in equation (l), and must have the sign to produce a positive grid voltage component when I_{L_p} is increasing (this is the condition required for regenerative feedback). The frequency of oscillation is determined by:

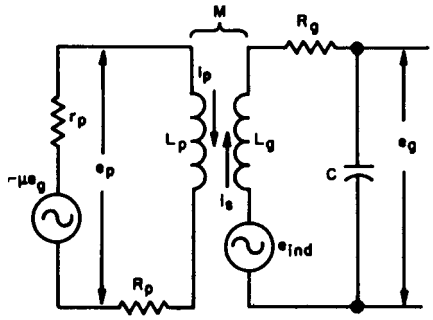
$$\omega = \sqrt{\frac{R + r_p}{L_p C r_p}} = \omega_o \sqrt{1 + \frac{R}{r_p}} \text{ or } f = \frac{1}{2\pi\sqrt{LC}} \cdot \sqrt{\frac{R + r_p}{r_p}}$$

It is evident from (3) that the frequency of oscillation is affected to some extent by the resistance of the load, as well as the plate resistance of the tube. With r_p >> R to provide better frequency stability (which condition normally exists), we can say that for all practical purposes, or

$$f = \frac{1}{2\pi\sqrt{LC}},$$

where C includes all of the stray and distributed capacitance that tunes L_p.

A similar analysis of the tuned-grid circuit can also be made by using the following equivalent circuit.



Tuned-Grid Equivalent Circuit

In this instance it can be demonstrated that the requirement for oscillation is:

$$g_m = \frac{RC}{M} + \frac{M}{L_p r_p} \qquad (4)$$

Since the quantity M appears in the denominator of one term and in the numerator of the other, the value of g_m is large for both high and low values of M, with a minimum value existing somewhere between. This is to say that in the tuned-plate circuit, while there is a critical value of coupling below which oscillation will not occur, there is no limit to the maximum value of coupling; although plate current and output may be reduced as a consequence, oscillation will still occur. For the tuned-grid circuit there exists both a lower and an upper limit; thus if the value of coupling is too low or too high, the circuit will not oscillate. This upper limit on M could be a practical disadvantage; however, it appears to be of academic interest, since it is only true for large values of L_p and C. That is, it actually applied only to low r-f or audio frequencies. At the higher radio frequencies the effect of tube capacitance and distributed circuit capacitance makes the value of M required to satisfy this condition so high that it is impractical or impossible to obtain. Thus, although there is a difference between the plate and grid-tuned circuits, theoretically, it is of no practical consequence.

The frequency of oscillation for the tuned-grid oscillator is given as:

$$f = \frac{1}{2\pi\sqrt{C\,(L_g r_p + L_p R_g)}} \qquad (5)$$

‘P

From this expression it maybe seen that if R_g is very small as compared with r_p, the quantity ($L_g r_p$ + L_pRJ is nearly identical with $L_g r_p$. Equation (5) may then be rewritten as:

$$f = f. \frac{1}{\sqrt{2\pi L_g C}} \qquad (6)$$

The tuned-grid circuit is similar to the tuned-plate version in that the ratio rp/R should be as large as possible for good frequency stability. One other fact may readily be seen if equation (5) is rewritten as:

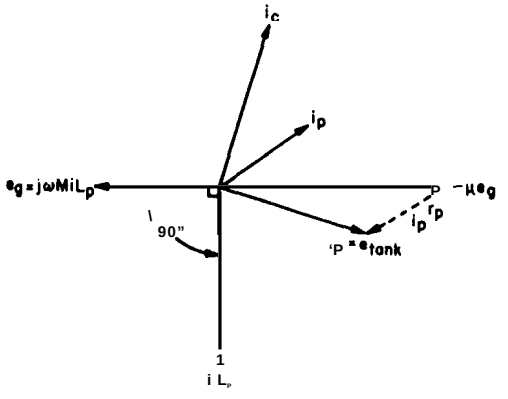
$$f = \frac{f.}{\sqrt{1 + \frac{L_p R_g}{L_g r_p}}} \qquad (7)$$

where f. is the same as in equation (6).

Since the operating frequency of the oscillator is equal to the tank resonant frequency divided by a number slightly greater than unity, the operating frequency is slightly less than the natural resonant frequency of the tank circuit. On the other hand, the tuned-plate version has a higher frequency of oscillation than its tank circuit, as shown by equation (3). Thus, at the operating frequency, the tuned-grid tank appears as an inductive reactance, and the tuned-plate tank appears as a capacitive reactance (neglecting the effect of resistance, which is of academic interest only).

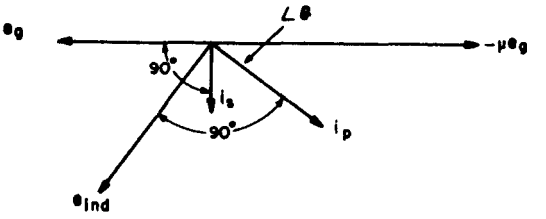
491.044 0-73 -38

Vector Diagram. It is sometimes "more helpful to use vectors to show the relationships of the various currents and voltages in the circuit. The following figure shows the vector diagram for the tuned-plate circuit. In this figure, The voltage $-\mu e_g$ is used as a reference. e_g is about 180° out of phase with $-\mu e_g$, as indicated by the negative sign preceding the real quantity $-\mu e_g$. The direction of i_{LP} may be established from the fact that e_g (the voltage induced in L_g) equals $-j\omega M i_{LP}$, and must lag i_{LP} by 900 because of the -j coefficient. Similarly, it can be seen from the ac equivalent circuit, that iLp will lag e_p by something less than 90° because of the resistance R in series with the coil. The amount of phase difference between e_p and i_{Lp} will depend on the Q of the coil, being closer to 90° with higher values of Q (uL/R). This makes e_p lag $-\mu e_g$ by some small angle, which is dependent on the circuit Q. i_c since it is considered purely capacitive, will lead e_p by 90°. The vector sum of $i_p r_p$ and e_p must equal $-\mu e_g$. For this to be true, $i_p r_p$ must lead $-\mu e_g$ by some small amount, and since the current through a resistance is in phase with the voltage drop across it, i_p may be shown as leading $-\mu e_g$. Thus with i_p having a leading phase angle, the tuned plate circuit is shown to be capacitive as was also proven in the mathematical analysis. Note that i_p is the ventor sum of i_C and iLp; therefore, i_C must be the larger quantity.



Tuned-Plate Vector Diagram

The tuned grid circuit may be similarly represented by means of the following vector diagram.



Tuned-Grid Vector Diagram

As with the tuned-plate oscillator, the vector representing the voltage –pe$_g$ is used as a reference; e_g is again shown displaced 180° from $-\mu e_g$. Since the plate circuit is inductive and resistive in nature, plate current i_p will lag $-\mu e_g$ by a small angle, 6. This angle will be small because $r_p >> j\omega L_p$. The voltage induced in the secondary circuit, e_{ind}, will lag i_p by 90° since e_{ind} equals _@. $\omega M i_{LP}$. The voltage e_{ind} may be represented by a generator in series with the grid circuit. It was shown in the mathematical analysis that the oscillator operates slightly below the tank frequency; therefore, the capacitive reactance of C will be slightly larger than the inductive reactance of L_P. Viewing the grid circuit as a series circuit in relation to e_{ind}, it is seen that the secondary current (i_s) is slightly capacitive and will lead e_{ind} by a small angle. Since grid voltage e_g is the same as capacitor voltage e_c, it will lag current i_s through the capacitor by 90°. From inspection of the vector diagram, it can be seen that angle θ is the same as the angular difference between e_{ind} and i_s. Higher values of circuit Q will tend to diminish this angular difference, thus diminishing angle $-\theta$ and improving the stability of the oscillator.

Failure Analysis.

No Output. If the circuit is in a non-oscillating condition, negative grid bias will not be developed; as a result, the applied plate voltage will be below normal because of the passage of additional current through the dropping resistor, R2. Excessive circuit losses present in the resonant circuit or the tickler (feedback) coil will prevent sustained oscillations. Reduced tube gain will also affect stage regeneration; changing values of the grid-leak bias components, R1

and C2, will directly affect the operating bias and, hence, the Class C operation and gain of the tube.

Reduced or Unstable Output. A relative indication of oscillator output is provided by the amount of bias voltage developed across RI. This negative bias voltage is normally from 2 to 40 volts, depending upon circuit design and the applied plate voltage.

A reduction in the applied plate voltage will cause the output to be reduced. An unstable voltage source will cause the output to be unstable in amplitude and may also produce some frequency instability. Losses in the tickler (feedback) coil, due to shorted turns or poor soldered connections, can cause reduced output or unstable operation resulting from changes in amplitude of the feedback signal coupled into the resonant circuit (Ll, Cl).

Incorrect Output Frequency. Normally, a small change in output frequency can be compensated for by realigning or adjusting the variable component of ,the L-c resonant circuit, assuming that all component parts of the circuit are known to be satisfactory. Since L1 and L2 are mutually coupled, any change in inductance of one coil will have an effect upon the inductance of the other. Thus, if several turns of tickler coil L2 should become shorted, the resonant frequency of Ll, Cl will likely be affected and the output frequency will change. This condition is also likely to reduce the oscillator output, since L2 is the means by which feedback or regeneration is accomplished. Furthermore, changes in distributed circuit capacitance, changes in the value of output coupling capacitor C4 and its associated circuit load, or changes in the value of r-f bypass C3 will produce a change in the resonant frequency of L1, Cl; thus, the output frequency will depend upon the amount of reactance reflected into the tuned circuit (L1, Cl).

ARMSTRONG (TICKLER-COIL) OSCILLATOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

Uses an L-C parallel tuned circuit to establish the frequency of oscillation, with feedback being provided by a separate tickler coil of proper polarity to sustain oscillation.

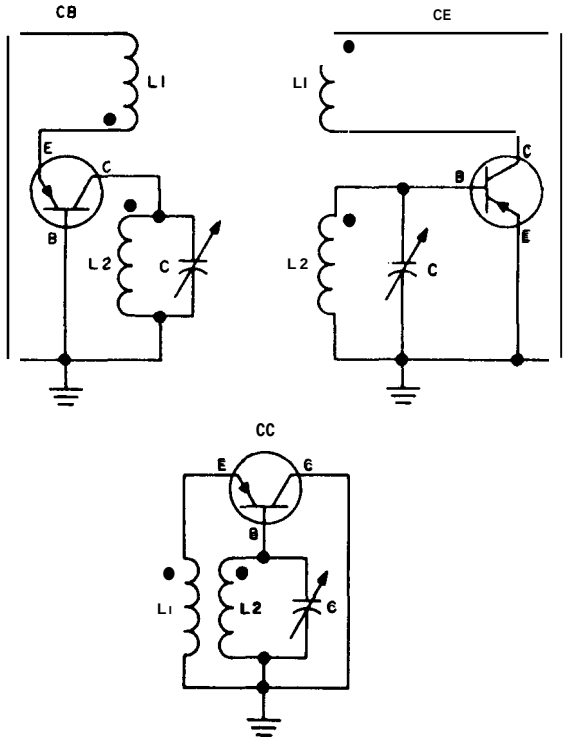
Operates Class C with stabilized bias for applications where linearity of waveform is not important, and Class A where linearity of waveform is important.

Frequency stability is fair (generally comparable to that of the Armstrong vacuum-tube oscillator).

Circuit Analysis.

General. A sine-wave output may be obtained from an oscillator utilizing a tuned L-C circuit, especially when the transistor is operating over the linear portion of its transfer characteristic curve. The L-C circuit (commonly called a tank circuit) determines the frequency of oscillation. The tank circuit can be located in either the base or the collector circuits to produce two versions of this circuit known as the tuned-base and tuned-collector circuits, respectively; these are similar to the tuned-grid and tuned-plate electron tube oscillators. Although three basic transistor configurations (common base, common emitter, and common collector) can be used, generally, only two, the common emitter and common base, are used in practice. A trend is developing towards the use of the common-emitter arrangement in preference to the others, since it so nearly parallels the electron tube and has input and output impedances that are more easily matched. In the CE circuit, since the input and output are 180 degrees out-of-phase (opposite polarity), it is necessary to provide a 180-degree phase shift (reverse polarity) to bring the output in-phase (of proper polarity) so that oscillation may be sustained. However, in the common-base and common-collector arrangements, the input and output are already in-phase (identically polarized); therefore, no phase shift (polarity reversal) is required (at extremely low frequencies excessive phase shift may prove troublesome). The basic advantage of the Armstrong oscillator, however, is that since the feedback is developed by a separate (tickler) coil, the amount and polarity of the feedback are easily adjusted at the time of manufacture by changing the number of turns or direction of the winding.

Circuit Operation. The three basic transistor configurations of the Armstrong oscillator circuit are shown in the following illustration.



Basic Armstrong Configurations

Bias and plate feed arrangements are omitted for the sake of simplicity, but will be discussed later. It is assumed that forward bias is applied to the emitter-base junction and that reverse bias is applied to the collector-base junction. Only junction transistors are discussed, since point-contact transistors require slightly different considerations and their use is constantly diminishing, except for special applications which will be discussed elsewhere in this technical manual when applicable.

The common-base circuit is usually preferred at the higher frequencies because the collector-emitter capacitance, C_{ce}, helps feed back an in-phase (properly polarized) voltage independently of tickler coil L1, and oscillation is more easily obtained. In the common-emitter circuit this capacitance feeds back an out-of-phase (oppositely polarized) voltage which requires additional feedback from the tickler coil to overcome it. In both the CB and CE circuits, since feedback is primarily provided by voltage induced through the manual induction between L1 and L2, and since the voltage gain of these circuits is greater than unity, oscillation is easily sustained. In the common-collector circuit, the voltage gain is always less than unity; therefore, feedback tends to be insufficient for stable oscillation at the lower frequencies, while at the higher frequencies it is assisted by Ccc. In some instances, an external capacitor is added between the collector and emitter to provide additional feedback, but when this is done the oscillator can no longer be considered an Armstrong circuit; consequently, the CC circuit is not often employed for this type of oscillator.

The CB circuit with the tuned collector permits convenient matching of input and output impedances, since the low input resistance is easily matched with the tickler coil, and the high output impedance is matched by the tuned parallel-resonant tank circuit. Moreover, the collector-base internal capacitance is swamped by the high-C tank circuit.

In the common-emitter circuit, the moderate input and output impedances are more easily matched, and the tank may be placed in either the base or collector circuits without noticeably affecting the performance.

The operation of the L-C circuit is identical to that of the L-C circuit for the Armstrong electron tube oscillator circuit described in the beginning of this section. The transistor action is as follows: As the oscillator is switched on, current flows through the transistor as determined by the biasing circuit. Internal noise or thermal variations (initial current) produce a feedback voltage between the collector and the emitter which is in-phase with the input circuit. Thus, as the emitter current increases, the collector current also increases, and additional feedback between L1 and L2 further increases the emitter current until it reaches the saturation region, where the emitter current no longer increases. When the current stops changing, the induced feedback voltage is reduced until there is no longer any voltage fed back into the emitter circuit. At this time the collapsing field around the tank and tickler coils induces a reverse voltage into the emitter circuit which causes a decrease in the emitter current, and hence a decrease in the collector current. The decreasing current then induces a greater reverse voltage in the feedback loop, driving the emitter current to zero or cutoff. Although the emitter current is cut off, a small reverse saturation current (I_{CEO}) flows; this current has essentially no effect on the operation of the circuit, but

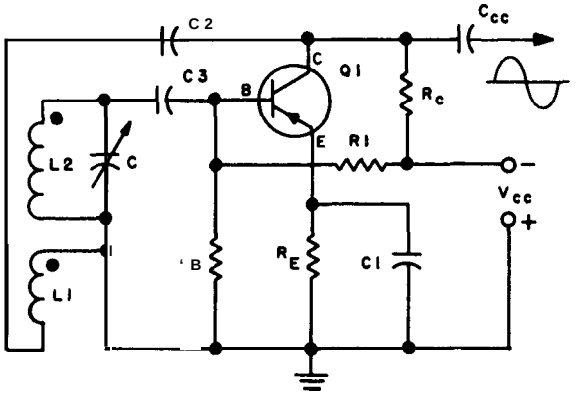
it does represent a loss which lowers the overall efficiency. In this respect, the transistor differs from the electron tube, which has zero current flow at cutoff.

The discharge of the tank capacitor through L2 will cause the voltage applied to the emitter to rise from a reverse-bias value through zero to a forward-bias value. Emitter and collector current will flow, and the previous described action will repeat itself, resulting in sustained oscillations. Actually, the shunting action of the transistor parameters provides both a resistive and capacitive effect, which causes the frequency of operation to be slightly lower than the tank circuit resonant frequency, but the frequency decrease is so small that the basic frequency of operation is considered, for all practical purposes, to be the tank frequency that is,

$$F_r = \frac{1}{27r\sqrt{LC}}$$

where L and C are the values of L2 and C at resonance.

Tuned-Base Oscillator. The tuned-base (tuned-grid) Armstrong oscillator using the common-emitter configuration is shown in the accompanying illustration. One voltage supply is used, with fixed bias being supplied by voltage-dividing resistors RI and R_B (see the introduction to the amplifier section of this handbook for bias explanation). Emitter swamping resistor R_E bypassed by Cl, is used for temperature stabilization.

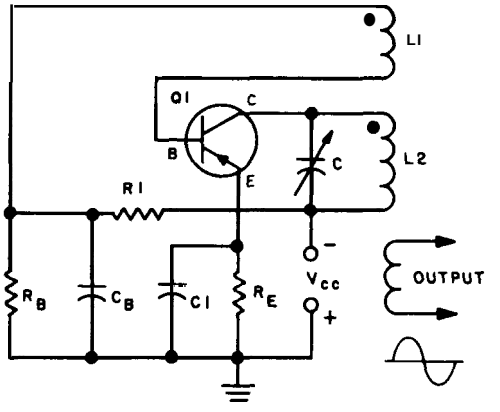


Tuned-Base Armstrong Oscillator

The collector is shunt-fed through R_C, with C2 serving as the coupling (and blocking) capacitor for the tickler coil, to prevent shunting of the dc collector voltage to ground. The tuned tank consists of L2 and tuning capacitor C, coupled to the base of transistor Q1 by capacitor C3, which prevents short-circuiting of the base bias to ground through the tank inductor.

When the circuit is energized, the initial bias is determined by RI and R_B, and oscillation is built Up by feedback from L1 to L2. Besides acting as a thermal stabilizer and swamping resistor, the combination of R_E and Cl acts similarly to a grid leak in an electron tube circuit and builds up a degenerative bias which places operation in the Class C region. That is, while R_B and R1 produce a forward bias, R_E produces a reverse bias, with the algebraic sum of the two biases providing the operating bias. Circuit constants can be adjusted by changing the values of parts to produce practically any of bias between Class A and C. The r-f output is taken from the collector through CCC. The output frequency is determined by the resonant frequency of the tank.

Tuned-Colleetor Oscillator. The tuned-collector (tuned-plate) Armstrong oscillator using the common-emitter configuration is shown schematically in the accompanying illustration. One voltage supply is used, with fixed base bias being supplied by voltage-dividing resistors R1 and R_B as in the tuned-base oscillator shown previously. The arrangement below uses series base feed, together with series collector feed through the tank inductor, although parallel feed may be used equally well.



Tuned-Collector Armstrong Oscillator

Since the collector is series fed through L2, tuning capacitor C is above ground and will be subject to hand-capacitance effects. In some circuit variations a radio-frequency choke may be used in series with the tank and bypassed to chassis to shunt any remaining rf around the power supply. Base bias resistor R_B is shunted by C_B, to prevent signal variations from affecting the fixed base bias. Emitter-swamping and base-biasing arrangements operate exactly the same as in the tuned-base oscillator previously discussed. The r-f output, however, is taken through inductive coupling to the tank circuit. Use of series collector and base bias feeds eliminates the need for coupling and blocking capacitors, and thus eliminates any dead spots caused by unwanted resonances of these parts with stray circuit or internal transistor capacitance. The feedback polarity is arranged to provide a 180-degree phase shift, in order to produce positive (regenerative) feedback similar to that obtained in the tuned-base oscillator. Placing the tank in the collector circuit provides an effective swamping capacitance across the collector and emitter, to minimize effects due to the variations of C_{CE}. Although this circuit appears to be more stable from a frequency standpoint than the tuned-base oscillator, it is not so stable thermally. Since the series feed arrangement is used in both the collector and base, there is a dc path of relatively low resistance for reverse saturation current I_{CBO}, which flows during cutoff. The path is from the negative collector supply through the low resistance of L2, through the collector to the base of Q1, and through the low dc resistance of Ll, then through the high base bias resistance R_B to the positive supply terminal. Thus the relatively high resistance of collector resistor R_C of the tuned-base oscillator circuit is replaced by the very low dc resistance of the windings of L1 and L2. As a result, the individual transistor I_{CBO} current determines how large a current will flow through the tank and feedback inductances to decrease the effective circuit Q and reduce the over-all efficiency of the oscillator. Where battery power supplies are used, such leakage current will provide a small but constant drain on the battery, an effect not possible with electron tubes.

Failure Analysis.

No Output. As in a vacuum-tube counterpart, loss of gain in the transistor can result in lack of oscillation through loss of feedback. It should be kept in mind that, unlike the electron tube, the transistor cannot lose gain through loss of emission. Failures of the transistor mostly result in short- or open-circuit conditions rather than deteriorated operation. An excessive time contant in the emitter bias circuit, produced by an increase in the resistance of R_E, could cause blocking effects. A change in the value of emitter bias capacitor Cl will affect the operating bias, will be rather unlikely to completely stop oscillation unless the change is large. Once oscillations have started, loss of forward bias through an open in the base circuit will not necessarily stop oscillations because the feedback signal swinging both positive and negative (on a reference of zero or the established self-bias) will apply on the negative or positive half cycle, depending on the circuit configuration and the type of transistor used, a forward bias and cause emitter collector current to flow (while possible, this condition is not very common). Particular care should be taken not to aggravate troubles by applying potentials greater than the rated voltages (or of the wrong polarity) to the transistor elements when checking the resistance of bias elements and circuit continuity. Failure of the tank and tickler blocking capacitors in the parallel-fed circuit will cause the shorting of bias or supply potentials and stop oscillation; however, at the low voltages used such failure is not very likely. Shorted tickler or tank inductor turns or poorly soldered connections may produce sufficient shunting (or high resistance) to stop feedback, although the tank inductor change would probably be indicated by frequency change rather than loss of oscillation. A short in the tuning capacitor can cause loss of oscillation, and it may be detected by a continuity check unless the tank coil is disconnected.

Reduced or Unstable Output. Instability should be resolved into one of two types–frequency or amplitude. If temperature variations are the cause of frequency instability, the trouble is most likely in the biasing circuit or the emitter swamping circuit. Opening of the bias voltage divider or shorting of one of its resistors will provide less stability, but such a condition is easily found by checking for proper bias with a high-resistance voltmeter, preferably of the electronic type. It is important, in the case of the electronic voltmeter, to make certain that its chassis does not have an above-ground voltage which could be accidentally applied to the transistor under test. Frequency instability can also result from poor connections or changes of L and C values. Mechanical, electrical, and thermal considerations affecting the tank circuit

should be considered. Lack of regulated supply voltage for bias and operation is important. In. general, the percentage of regulation in the supply voltage must be better for transistor oscillators than for vacuum tube oscillators. If external to the equipment, power supply regulation effects can sometimes be easily corrected by appropriate use of Zener diodes at the points affected.

Instability in the amplitude can be traced in most cases to variations in the supply voltage or to component failure in limiting diodes placed in the circuit for the sole purposes of maintaining amplitude stability.

While reduced output can result from loss of gain in the transistor, this condition is not as common as it is with electron tubes; therefore, it is more logical to investigate supply and bias voltages first before changing transistors. Excessive bias, rather than lack of bias, is more likely to reduce output.

Incorrect Output Frequency. Normally, a small change in output frequency can be compensated for by realigning or adjusting the variable component of the LC resonant tank circuit, assuming that all corm ponent parts of the circuit are shown to be satisfactory. Changes in distributed capacitance or reflected load reactance will also affect the frequency of operation. Additional capacitance will lower the frequency and less capacitance will increase the frequency; corresponding changes in inductance will produce the same effect. A change in transistor parameters will also affect the frequency; for example, an increase in the collector voltage will reduce the collector-base capacitance, while an increase in the emitter current will increase the collector-base capacitance. Power supply regulation effects can, therefore, be suspected when temporary frequency changes occur. Comparison of actual indications with those of the operational standard will generally indicate the area at fault, It may normally be assumed that major frequency changes will involve the transistor elements and components associated with the tank circuit, since they constitute the major frequency-determining portion of the circuit.

HARTLEY OSCILLATOR (ELECTRON TUBE)

Application.

The Hartley oscillator is used to produce a sine wave output of constant amplitude and fairly constant frequency within the r-f (and sometimes audio) range. The circuit is generally used as a local oscillator in receivers, as a signal source in signal generators and as a variable-frequency oscillator over the medium and high-frequency ranges.

Characteristics.

Uses an L-C parallel-tuned circuit to establish frequency of oscillation, with the inductance connected as an auto-transformer between grid, cathode, and plate to provide the feedback needed for oscillation.

Operates Class C with automatic self-bias for ordinary, or power, operation and Class A when output waveform linearity is important.

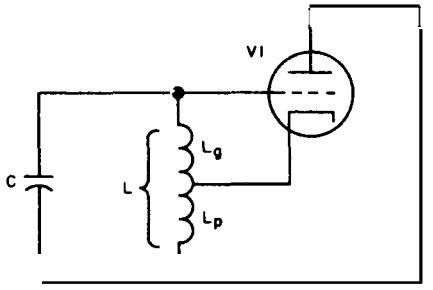
Frequency stability is only fair, but better than that of the Armstrong oscillator.

Circuit Analysis.

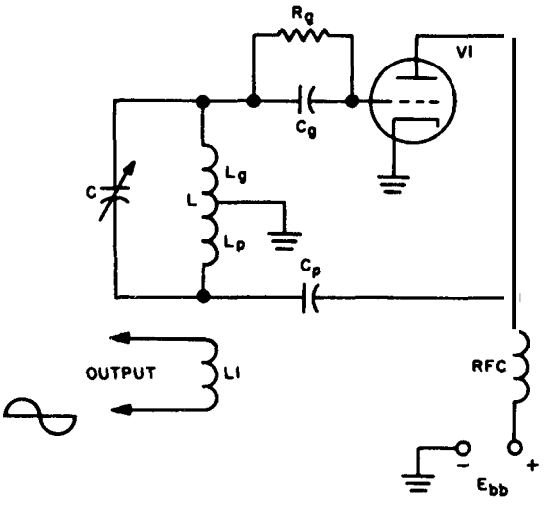
General. A sine-wave output may be obtained from an oscillator utilizing a tuned L-C circuit. The L-C circuit (commonly called a tank circuit) determines the frequency at which oscillation will take place. At any particular instant of time, the opposite ends of a tuned inductance are at different polarities, or 180 degrees out of phase. Likewise, the grid and plate of a triode are 180 degrees out of phase. Therefore, connecting the tuned circuit to the grid and plate of the triode will not affect the polarity of operation. When the cathode is tapped to the inductance of the tuned circuit and cathode current flows, a magnetic field will be produced between the cathode-to-plate turns of the inductor. A voltage will be induced in the turns of the inductor connected between the cathode and grid by the cathode current flow, and the polarity of the induced voltage will be in the proper direction to cause an increase of cathode current. Thus, a positive regenerative action is produced by the tapped, tuned-tank circuit connected between

the electron-tube elements. As long as feedback is sufficient to supply the losses in the tuned circuit, continuous, undamped oscillations are produced.

Circuit Operation. The basic Hartley oscillator circuit is shown schematically in the following illustration.



Basic Hartley Circuit



Shunt-Fed Hartley Circuit

Bias and plate feed arrangements will be discussed later. The tuned (tank) circuit consists of the L_g and L_p portions of inductance L, which is parallel-connected with capacitor C. Feedback is usually accomplished by transformer action between L_p and L_g operating essentially as an autotransformer, with the turns ratio (from about 0.6 to 1) determining the feedback amplitude. (Electrostatic coupling through the tank capacitor can also provide the feedback for oscillation.) Tapping the cathode closer to the plate increases the feedback when the feedback is primarily accomplished by electrostatic coupling through the tank circuit capacitance, with the size of the plate load, L_p, determining the feedback amplitude. Tapping the cathode closer to the plate reduces the plate load and the feedback amplitude. The manner of feedback is determined by the basic construction of the tank circuit inductance.

Shunt-Fed Harley. The circuit for the shunt-fed Hartley oscillator is shown in the following illustration. Grid bias is developed by R_g and C_g, connected in series between the tuned circuit and the grid of the triode tube. Shunt plate feed is accomplished by connecting the tuned circuit to the plate through C_p, which isolates the tank for dc, but connects it to the plate for r-f current flow. Radio-frequency choke RFC offers a high impedance to the rf, which flows through the tank circuit and not through the power supply, but it permits the dc to flow to the plate.

The manner in which oscillations occur and the automatic amplitude regulation by grid-leak bias are identical for both the Hartley and the Armstrong oscillators. Refer to the previous discussion of the L-C tickler coil oscillator for an explanation of this action, and assume that the L_p portion of inductor L is the tickler coil.

The use of a high-C tank circuit, consisting of C and L comected between the grid and plate of the electron tube, effectively swamps the tube electrode capacitances and produces better frequency stability. The operating frequency is determined by the values of L and C at resonance

$$f_r = \frac{1}{2\pi\sqrt{LC}}$$

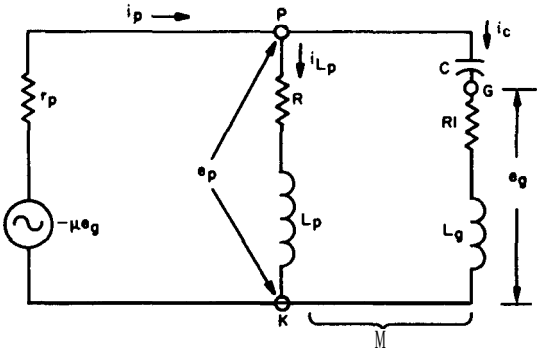
where L is equal to $(L_g + L_p + 2M)$.

Inductive coupling to the load through L_1 at the grouped end of the tank is usually used, but it does not preclude the use of capacitive coupling to the tank circuit where desired.

Series-Fed Hartley. The shunt-fed circuit may be easily modified to a commonly used series plate feed arrangement, by moving the ground connection from the cathode to the bottom end of L_p, and connecting the cathode to the top end of L_p. Thus plate current

will flow directly through L_p. Plate capacitor C_p, in conjunction with radio-frequency choke RFC, then serves only to bypass the rf around the plate voltage supply. The operation of the circuit is otherwise identical to that of the shunt-fed circuit previously described.

Detailed **Analysis. The** analysis of the Hartley oscillator is similar to that of the tuned-plate Armstrong oscillator previously discussed. The following equivalent circuit is labelled exactly as in the previous example. Since the tank coil is now tapped, the total tank inductance, L, is $L_p + L_g + 2M$. Resistors R and R_1 are equal to the r-f resistance of L_p and L_g, respectively.



Hartley Equivalent Circuit

Analysis of the Hartley circuit shows that the angular frequency is:

$$\omega = \omega_o \sqrt{\frac{R + r_p}{r_p + R(\mu + 1)}} \qquad (1)$$

$$\text{where } \omega_o = \sqrt{\frac{1}{L_T C}}$$

As in the case of the tuned-plate oscillator, when no power is taken from the circuit, the frequency is practically given by:

$$f = \frac{1}{277\sqrt{L_T C}} \qquad (2)$$

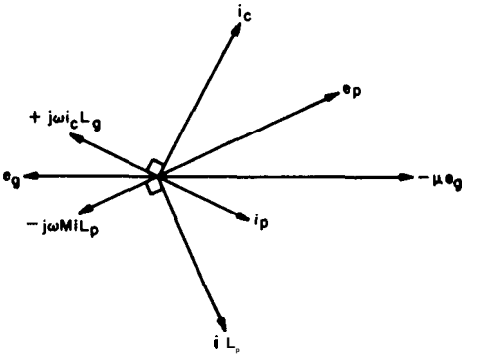
where $L_T = L_p + 2M$, or the resonant frequency of the tank circuit. Thus while the oscillation frequency is slightly lower than the tank frequency, if a high r_p and a small R are used, the tank will govern the frequency.

The criteria for oscillation is that:

$$g_m = \frac{\mu(R + RI)\, CL_T}{(L_p + M)\{\mu(L_g + M) - (L_p + \quad)} \qquad (3)$$

Examination of equation (3) indicates that even with M at zero the equation will be satisfied; therefore, oscillation can occur even when there is no inductive coupling between the plate and grid circuits, the feedback being capacitively coupled through C. As might be suspected, since the criterion for oscillation is not critical, the Hartley circuit oscillates easily.

Vector Diagram. The relationships between the currents and voltages in the circuit are shown in the following vector diagram. Refer to the equivalent circuit drawing for easier understanding of the development of the vector diagram.



Hartley Vector Diagram

The voltage $-\mu e_g$ is used as a reference vector, and e_g is 180° out of phase. It was pointed out in the mathematical analysis that the Hartley circuit operates slightly below tank resonance;. therefore, the tank circuit will appear resistive and inductive, causing i_p to lag $-\mu e_g$ by a small angle, and e_p, the voltage across the tank, to lead by a small angle. The current i_{LP} will lage e_p by some angle less than 90° dependent on the Q of that branch. The current i_c will lead

e_p by some angle less than 90° since that branch is largely capacitive. The voltage induced in the grid coil, $-j\omega M i_{LP}$, lags i_{LP} by 900 as indicated by its -j coefficient, while the positive component $(+j\omega i_c L_g)$, will lead i_c by 90°. Grid voltage e_g is the vector sum of the voltages developed across the grid coil Lg. Note that with higher values of circuit Q the voltages developed across the grid coil will more closely approach in-phase quantities, and the angle between i_p and e_p will also diminish, thereby improving oscillator stability.

Failure Analysis.

No Output. If the circuit is in a non-oscillating condition, negative grid bias cannot be developed; as a result, the applied plate voltage may be below normal because of the additional current drain unless the power supply is well regulated. For this condition, the plate current will be much higher than normal. Excessive circuit losses in the resonant tank circuit will prevent sustained oscillations. Reduced tube gain (if sufficient) will also affect oscillation. Changes in value of the grid-leak bias components, Cg and R_g, will directly affect the operating bias, and hence the class of operation and overall gain of the tube. Such changes, if sufficient, may cause a loss of oscillation. Too htgh a value of grid leak resistance may cause intermittent operation or "motor-boating". Shorted turns of the oscillator coil (s), in addition to affecting output amplitude and frequency, may cause loss of oscillation because of loading effects. A leaky plate capacitor C_p may also load the oscillator sufficiently to stop operation. In the shunt-fed circuit, a defective radio-frequency choke RFC or coupling capacitor C_c may stop oscillation since the oscillator is dependent on these components for development and application of feed-back voltages.

Reduced or Unstable Output. A relative indication of oscillator output is provided by the amount of bias voltage developed across R_g. Variation from the manufacturer's rated value is indicative of abnormal operation.

A reduction in applied plate voltage will cause a reduced output. Therefore, an unregulated voltage source will produce output amplitude variations and probably frequency changes or instability. Losses in feedback, due to shorted turns or poor soldered connections, can cause reduced output or unstable operation. A leaky plate capacitor, C_p, may cause reduced or unstable output by loading the oscillator or by reducing plate voltage by adding to the normal current flow through a series resistance. Care should be used in selecting a replacement for a defective r-f choke, since an improper replacement choke may cause unwanted oscillations by resonating with distributed circuit capacitance or with the distributed capacitances of its own windings. Similar care should be exercised in replacing a defective tube in those oscillators operating in the higher frequency ranges where interelectrode capacitances may consitute a considerable portion of the tuned circuits. Variations of this physical capacitance from one tube to another may, in addition to affecting output frequency, cause the oscillator to shift from one mode of operation to another as the oscillator is tuned through its frequency range. For example, a Hartley oscillator could shift to Colpitts operation under the right conditions. This shifting may cause frequency jumps and/or dead spots in the tuning range of the oscillator. At the higher frequencies it is good practice to try more than one replacement tube if the first substitution does not achieve the desired results in frequency of operation and stability. Realignment of circuit components to compensate for a tube substitution should be avoided wherever possible. 4

Incorrect Output Frequency. Normally, a small change in output frequency can be compensated for by realigning or adjusting the variable component of the L-C resonant tank circuit, assuming that all component parts of the circuit are known to be satisfactory. Changes in distributed circuit capacitance or reflected load reactance will affect the frequency to some extent. Thus, an increase in capacitance will lower the frequency, and a decrease in capacitance will increase the frequency. Therefore, care must be used in the removal and replacement of parts in order not to disturb the distributed capacitance of the circuit which is inherent in the placement of physical parts and the wiring of the circuits. Large changes in ambient temperature may affect the operating frequency of the oscillator. Such changes could come about through failure of an oscillator oven, changes in filament supply voltage, etc. The effects of tube substitution on oscillator frequency were discussed above.

HARTLEY OSCILLATOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

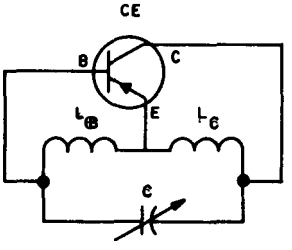
Characteristics.

Same characteristics as electron tube version, except inductance is connected as an autotransformer between emitter, collector, and base to provide the feedback needed for oscillations.

Circuit Analysis.

General. A sine-wave output may be obtained from an oscillator utilizing a tuned L-C circuit, especially when the transistor is operating over the linear portion of its transfer characteristic curve. The L-C circuit (commonly called a tank circuit) determines the frequency of oscillation. By using a tapped inductor for the tank inductance, a portion of the tank voltage can be fed back to provide positive feedback and sustain oscillation. The tapped inductor tank circuit may be used as either an autotransformer or a phase shifter, depending on the type of feedback needed for the specific circuit configuration. Unlike the Armstrong oscillator where feedback can be shifted in phase 180° by reversing the tickler coil, the Hartley oscillator will operate only in a common-emitter arrangement since the feedback is always shifted in phase 180°.

Circuit Operation. The basic transistor configuration of the Hartley oscillator circuit is shown in the following illustration. Bias and collector feed arrangements are not shown, but will be discussed later. It is assumed that forward bias is initially applied to the emitter-base junction and that reverse bias is applied to the collector junction. This discussion concerns junction transistors only; however, point-contact transistors operate in a somewhat similar manner.

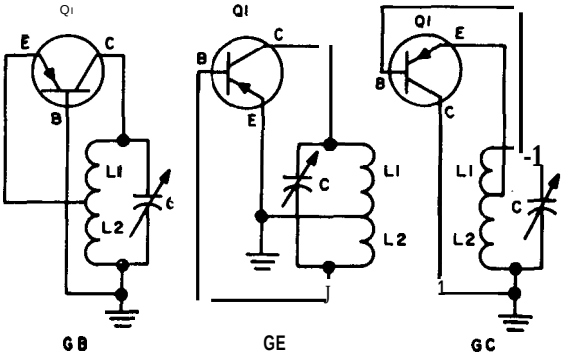


Basic Hartley Configuration

The common+ mitter circuit is similar to an electron tube oscillator in that it requires a 180-degree phase shift from collector to base to produce positive (regenerative) feedback. Grounding the emitter tap (see following illustration for grounding points) produces the effect of inverting the windings and thus provides the desired 180-degree Phase shift. The resonant frequency is determined by the tuning of the tank capacitor, C, and is given by the formula:

$$f = \frac{1}{2\pi\sqrt{(L_1 + L_2 + {}_2M)C}}$$

The figure shows three different arrangements of the common-emitter configuration for grounding the transistor elements. These circuits provide a convenient method for grounding the rotor of the tuning capacitor to eliminate hand-capacitance tuning effects and to obtain proper feedback phasing. Note that the three configurations in the illustration are all ***common-emitter*** arrangements and that the only difference from the basic schematic is the grounding point. In some texts, these configurations are referred to as ***common base, common emitter,*** and ***common collector,*** respectively. In all three grounding arrangements of the figure, the feedback is fed from collector to base, and the emitter is the common element.

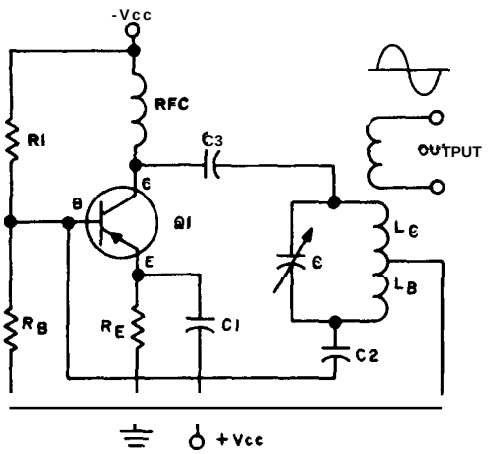


C E Hartley Oscillator Grounding Points

The discussion under the Armstrong circuit concerning the relative merits of the various configurations and the transistor action are applicable to this oscillator. Operation of the L-C circuit is similar to that of the tickler coil electron tube oscillator circuit discussed at the beginning of this Section. In fact, the operation of the Hartley circuit can be considered

exactly the same as that of the Armstrong circuit, with the tickler coil being an integral portion of the tuned tank circuit. The frequency stability of the Hartley oscillator is slightly better than that of the Armstrong oscillator because the tank tuning capacitor tunes the entire coil and feedback loop, and a high C-to-L ratio provides effective capacitance swamping.

Shunt-Fed Hartley. The shunt-fed Hartley oscillator using the common-emitter configuration is shown in the following figure. One voltage supply is used, with fixed base bias being supplied by voltage-dividing resistors R1 and R_B (see the introduction to the Amplifier Section of this handbook for an explanation of biasing). Emitter swamping resistor R_E, bypassed by Cl, is used for temperature stabilization.

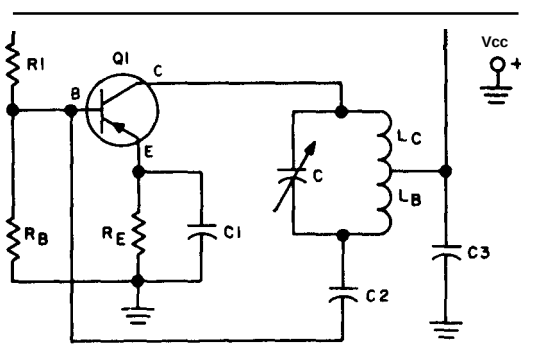


Shunt-Fed Hartley CE Oscillator

The collector is shunt fed through radio-frequency choke RFC, with C3 serving as the dc blocking and r-f coupling capacitor to keep the tank coil from shorting the collector. Similarly, C2 serves as the base blocking and coupling capacitor to prevent shorting of the base to ground through the tank inductor.

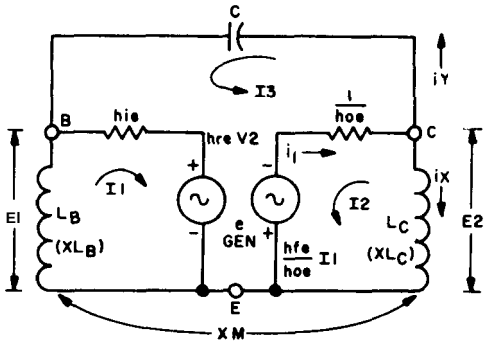
When the shunt-fed circuit is energized, the initial bias is determined by RI and R_B, and oscillation is built up by feedback supplied from the collector to the base through sections L_C and L_B of the tank inductor. Note that an ac path exists from the emitter through the L_C portion of the tank and coupling capacitor C3 to the collector, and that a similar path exists through L_B and C2 to the base. As oscillation occurs, a degenerative bias is developed across R_E (if Cl is of the correct value) similar to that of the grid-leak-capacitor combination used in electron tube oscillators, and this bias places operation somewhere between Class A and Class C depending on the parts values. Usually the values of voltage divider R1 and R_B are chosen to provide Class A bias for easy starting, and the values of R_E and C 1 are chosen to provide Class B or C bias for the desired efficiency of operation, with thermal stabilization. The output may be taken from a capacitor connected to the collector or from an inductor coupled to the tank.

Series-Fed Hartley. The series-fed Hartley oscillator is shown in the following illustration. The base circuit is voltage-divider biased and emitter stabilized as in the shunt-fed version. The collector voltage is applied through the tap on the tank inductor, the voltage source being shunted for rf by C3. Operation of the series-fed circuit is identical to that of the shunt-fed circuit discussed previously. Since a dc current flows through a portion of the tank circuit, the Q is lowered and the frequency stability is not as great as that of the shunt-fed circuit.



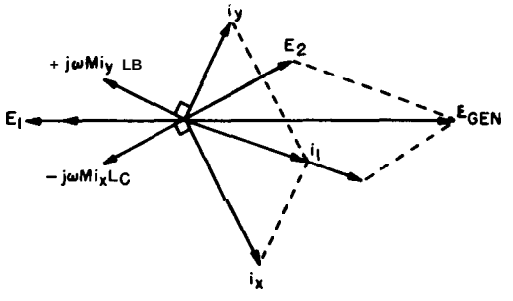
Series-Fed Hartley CE Oscillator

Detailed Analysis. Like the vacuum tube oscillator, the transistor oscillator can be converted to an equivalent circuit and analyzed mathematically to determine the conditions required for oscillation and the frequency of operation, using the h-parameters of the transistor. A typical common-emitter equivalent circuit for the Hartley oscillator is illustrated below. Since the mathematical analysis is complex and beyond the scope of this text, and exact only for low audio frequencies, the interested reader is referred to standard text books for this data.



Hartley Semiconductor Equivalent Circuit

The accompanying vector diagram may be more helpful to a better understanding of circuit operation, since it shows the voltage and current relationships. The common-emitter circuit is illustrated.



Hartley Vector Diagram

•

The voltage e_{gen} is used as a reference vector. Since the Hartley circuit operates slightly below resonance, the tank circuit appears resistive and inductive, causing i_1 to lag e_{gen}, and the voltage across the tank E_2 to lead by a small angle. Current i_y leads E_2 by some angle less than 90 degrees since that branch is largely capacitive. Current i_x lags E_2 by some angle less than 90 degrees, depending upon the Q of that branch. The voltage induced in the base coil $-j_m Mix_{Lc}$ lags i_x by **90** degrees as indicated by its—j coefficient, while the positive component $+_{j\sqrt{}} i_y L_b$ leads i_y by 90 degrees. The base voltage, E_1, is the vector sum of the voltages induced in base coil Lb. Note that with higher values of circuit Q the voltages developed across the grid coil more closely approach in-phase quantities, and the angle between i_1 and E_2 also diminishes, thereby improving the oscillator stability.

Failure Analysis.

No Output. Lack of oscillation may be due to a shorted or open-circuited transistor. Deterioration with age causing lack of gain may result under high-temperature conditions. Unlike vacuum tubes, however, transistors have operated for years without noticeable deterioration under proper operating conditions. Failure of the collector and base blocking capacitors will short-circuit the biasing arrangement through the tank coil and prevent operation. Open-circuit conditions of the biasing resistors may stop oscillation, though it is more likely that reduced output will result rather than no output. Where radio-frequency chokes are used to keep rf out of the supply or bias circuits, failure of these components may shunt the rf to gound through power supply capacitors. A more likely condition is an open circuit in the RFC caused by poorly soldered connections. A shorted condition of the tuning capacitor will stop oscillation, and it cannot be detected by a continuity check unless the tank coil is disconnected. When trouble-shooting with test equipment containing line filter capacitors, care should be exercised to prevent application of excessive voltage to the transistor by using a common ground on both the transistor and test chassis. Use high-impedance meters to avoid placing a dc shunt or return path in the circuit and causing improper current flow or voltage distribution.

Reduced or Unstable Output. Instability should be resolved into one of two types – frequency or amplitude. Frequency instability will most likely result from poor tank circuit connections, poor insulation between turns, or changes in L and C values. Also, changes in the supply voltage will produce changes in frequency because of changes in the operating point and changes in the internal capacitance of the transistor with different applied voltages. Excessive bias will probably cause a reduction in the output and will most likely be produced by an increase in value of the bias resistor or opening of the bias bypass capacitors with the consequent production of degeneration. Temperature changes are usually evidenced by increased current in the collector circuit and can be caused by a shorted emitter swamping resistor.

Incorrect Output Frequency. Normally, a small change in output frequency can be compensated for by realigning or readjusting the variable component of the L-C resonant tank circuit, assuming that all parts of the circuit are known to be satisfactory. A change of transistor parameters will also affect frequency; for example, increased collector voltages will reduce the collector-base capacitance, and increased emitter current will increase the collector-base capacitance, but these effects are not equal and therefore do not compensate each other. Reflected load reactance can cause a change of frequency depending on the tightness of coupling between the oscillator and the load. Changes in distributed circuit capacitance or in the tank inductor will also cause frequency changes. A comparison of operational indications against operational standard values will generally indicate the area at fault. For example, frequency changes that vary with power supply voltage fluctuations indicate that supply regulation is necessary and trouble is not in the equipment. Major frequency changes will involve the transistor elements and components associated with the tank circuit, since they constitute the major frequency-determining portion of the circuit.

CO LPITTS OSCILLATOR (ELECTRON TUBE)

Application.

The Colpitts oscillator is used to produce a sine-wave output of constant amplitude and fairly constant frequency within the r-f range. The circuit is generally used as a local oscillator in receivers, as a signal source in signal generators, and as a variable-frequency oscillator over the low- and very-high-frequency ranges, especially where inductive tuning is desired.

Characteristics.

Uses an L-C parallel tuned circuit to establish frequency of operation.

Features inductive tuning rather than capacitive.

Feedback is obtained through a capacitance-type voltage divider.

Operates Class C where wave form linearity is not important, and Class A where linearity of waveform is important.

Frequency stability is good (considered better than that of the Hartley at the lower and medium frequencies).

Oscillates easily at high frequencies, where inductive feedback types have difficulty securing sufficient feedback.

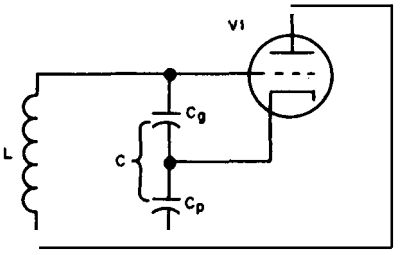
Circuit Analysis.

General. When a tuned LC (tank) circuit is connected between the grid and plate of an electron tube, the phasing is of the correct polarity to sustain oscillation. The capacitor of a tuned tank circuit may be a single capacitor, or it can be two series-connected capacitors with a total capacitance equivalent to that of the single capacitor. In either case, the frequency of oscillation is the same. The two series-connected capacitors will form a capacitance voltage divider across the tank circuit. Tapping the cathode of the tube to this voltage divider provides a convenient electrical (and mechanical) connection, and a means of controlling feedback between the grid, cathode, and plate elements. The ratio of the capacitances used will determine the amount of feedback, and the total capacitance value will determine the resonant frequency for any particular value of tank inductance. Varying the inductance is a convenient method for tuning the tank over a range of frequencies with a fixed amount of feedback. The use of capacitive tuning involves the simultaneous tuning of both capacitors to maintain the proper ratio of feedback. For tuning over a limited range, capacitive tuning is sometimes employed.

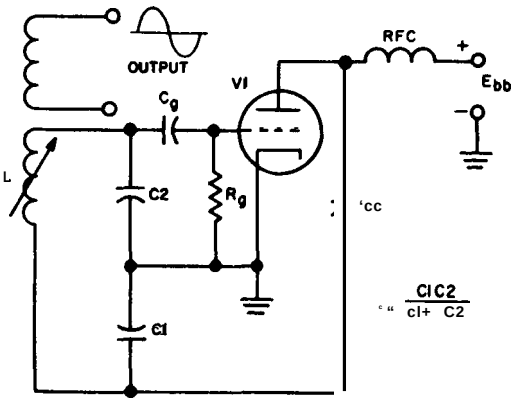
Circuit Operation. The basic Colpitts oscillator circuit is shown schematically in the following illustration. The tuned tank circuit consists of C_g and C_p, in series, and the parallel-connected inductor, L. Feedback is accomplished by the capacitive voltage-divider action of C_g and C_p (or by the use of a variable capacitor shunting C_g and C_p). The feedback ration varies as

$$\frac{C_g}{C_g + C_p}$$

thus, increasing the value of C_g decreases the feedback.



Basic Coipitts Circuit



Shunt-Fed Colpitts Oscillator

The capacitive ratios vary with circuit design and frequency, from about a 1:1 ratio to a 1:4 ratio, with the larger capacitor being C_p. For high-frequency use, the capacitance voltage divider may consist of ordy the interelectrode capacitances of the electron tube. The circuit may be arranged for grounded grid, cathode, or plate operation without affecting performance; the grounded-cathode configuration is probably the most frequently used circuit.

For simplicity, biasing and plate-voltage feed methods are not shown in the basic circuit, but are discussed where applicable in the following circuit variations.

Shunt-Fed Colpitts. The circuit for the shunt-fed Colpitts oscillator is shown in the following schematic. Grid bias is developed by R_g and C_g in the shunt grid-leak bias arrangement. Shunt plate feed is also used, with C_c serving as the plate blocking and coupling capacitor, and RFC as the r-f isolating choke. The tank circuit consists of inductor L and capacitor C, which are parallel-connected between the grid and plate of the electron tube. Capacitor C consists of two series-connected capacitors, C_1 and C_2, which are external to the tube and form a feedback voltage divider to which the cathode is connected.

The manner in which oscillations occur, as well as the automatic regulation of amplitude by grid-leak bias, is the same as explained in the previous discussion of the L-C tickler coil oscillator, except that feedback is obtained from a capacitive voltage divider instead of an inductive voltage divider. Assume that the tank circuit consists of L and C where C represents C_1 and C_2 in series. The tank circuit then is identical with the tuned grid circuit of the tickler-coil oscillator previously described. Since the tank is connected between the plate and grid of the electron tube, and C_1 and C_2 form a capacitive voltage divider, it is evident that there will be a division of feedback voltage in inverse ratio to their capacitance. For a specific frequency the large capacitor will have the lowest impedance, and the smaller capacitor the highest impedance. For equal capacitors, the voltages across the capacitors will be equal. Thus, with the cathode connected to the common connection of the capacitors, the tank voltage will be divided between cathode-and-grid and cathode-and-plate in accordance with the ratio of C_2 and C_1. Any voltage change in

the plate circuit will appear across C_1 and be fed back through C_2 in the correct phase to drive the grid in that direction to increase the initial change. That is, if the plate voltage is increasing, the grid change will cause a further increase, and if decreasing, a further decrease. This is exactly the same result that is achieved by the plate-grid coils of the Armstrong circuit or the tapped inductor of the Hartley circuit, as discussed previously, and sustained oscillations will occur.

Since the tank capacitance is composed of series-connected capacitors, each capacitor will be larger than the total capacitance that is effective in tuning the circuit. Since these series capacitors are connected in parallel with the grid-to-cathode and plate-to-cathode tube capacitances, they will swamp out the interelectrode capacitance variations and thereby increase the frequency stability. Note, however, that as the capacitance of the feedback capacitors approaches the value of the tube element capacitance, this swamping effect is decreased. Stability therefore, is at a maximum at the lower frequencies. The grid-plate capacitance, which is usually larger than the other element capacitance, remains in shunt with the tank inductor and will not be compensated for. If desired, capacitive tuning can be achieved by using a shunt tuning capacitor across L and leaving the feedback capacitors fixed. The advantage of the Colpitts circuit, however, is in the use of large variable inductors and fixed feedback-tank capacitors for operation in the low- and medium-frequency r-f ranges, where the greatest stability is obtained.

For high-frequency use, the Colpitts can be employed as an oscillator controlled mainly by the capacitance between the tube elements, so that inductance alone is needed to achieve oscillation. This arrangement results in higher frequencies of operation than with other L-C circuits, and is exemplified by the series-fed version of the Colpitts known as the ultraudion circuit, which is discussed as a separate circuit later in this section. The output coupling may be either inductive or capacitive, as desired.

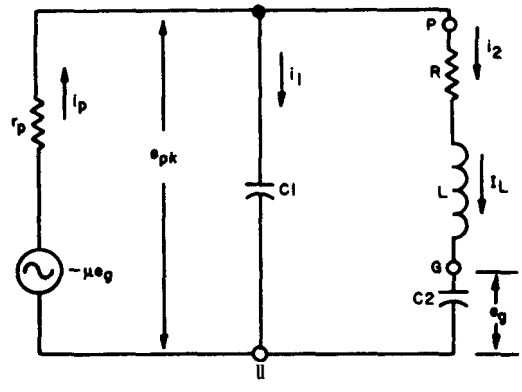
Detailed Analysis. The equivalent plate circuit for the shunt-fed Colpitts oscillator is shown in the following illustration. Assuming that the RFC has infinite reactance, neglecting the grid capacitor reactance, and assuming that the circuit has an infinite grid leak with no grid current, it can be seen that:

$$ip = i1 + i2$$

$$e_{gk} = \frac{i_2}{j\omega C_2}$$

$$e_{pk} = \frac{i_1}{j\omega C_1} \cdot i_2 (R + j\omega L) + \frac{i_2}{j\omega C_2}$$

$$- \mu e_{gk} - r_p i_p + \frac{i_1}{j\omega C_1}$$



Colpitts Equivalent Circuit

The analysis of the Colpitts oscillator is similar to that of the Hartley, except that the capacitive reactance of capacitors Cl and C2 is substituted for L_p and L_g, and the inductive reactance for C. The angular frequency is:

$$\omega = \omega_o \sqrt{1 + \frac{R}{r_p} \cdot \left(\frac{C_2}{C_1 + C_2}\right)}$$

For all practical purposes, the frequency is:

$$f = \frac{1}{2\pi \sqrt{L \frac{C1\,C2}{C_1 + C_2}}}$$

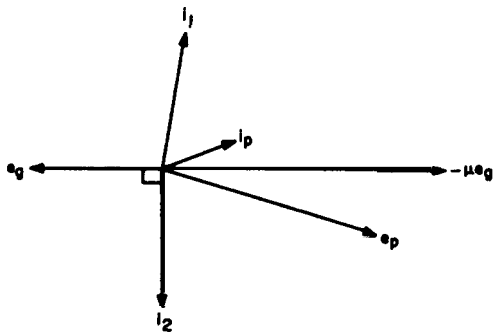
The criteria for oscillation is that:

$$\mu = \frac{C_2}{\epsilon_1} + \frac{r_p R(C_1 + C_2)}{L}$$

Capacitors Cl and C2 form a capacitive voltage divider across L, causing the grid excitation voltage to be proportional to

$$\frac{C^*}{C_1 + C^*}$$

Vector Diagram. The relationships between the currents and voltages are shown in the following vector diagram. Refer to the illustration of the equivalent circuit for development of the vector quantities.



Colpitts Vector Diagram

The voltage generator $-\mu e_g$ is the reference voltage, e_g being 180° out of phase. It was shown that the Colpitts oscillator operates above the tank frequency. Therefore, the tank circuit appears slightly capacitive, and i_p leads $-\mu e_g$ by a small angle while e_p lags e_g. The current i_1 through capacitor Cl will lead e_p by 90°. Current i_2 through the branch containing L and C_2 is primarily inductive and will lag e_p by an angle less than 90° determined largely by the Q of L. The voltage e_g, since it appears across capacitor C_2, will lag i_2 by 90°, thereby satisfying the conditions for oscillation. It can be seen that with higher values of circuit Q, the phase difference between i_p and e_p will be diminished.

Failure Analysis.

No Output. If the circuit is in a non-oscillating condition, the negative grid bias will be much less than it is in the oscillating condition, because it will consist of contact-potential bias only, which will allow the tube to operate at approximately zero instead of at cutoff or higher. Thus the plate current will be much higher than normal. Excessive losses present in the resonant tank circuit will prevent sustained oscillations. Reduced tube gain, if sufficient, will also affect oscillation, but will not be as noticeable as in the inductive feedback circuits. Changed values of grid-leak bias components R_g and C_g will directly affect the operating bias and change the amplitude of the oscillations; if the change is large, oscillation may even be prevented; if small, the effect may not be noticeable. A defective radio-frequency choke RFC or coupling capacitor C_c may cause loss of oscillation since the circuit depends on these components for the development and application of the feedback voltage.

Reduced or Unstable Output. A relative indication of oscillator output is provided by the amount of bias voltage developed across R_g. Variation from the standard operating value is an indication of abnormal operation. A reduction of applied plate voltage will cause a reduced output. Therefore, an unregulated voltage source will produce output amplitude variations and probably some frequency change or instability. Losses in feedback due to shorted turns, poor soldered connections, or changing values of feedback capacitance can also cause reduced output or unstable operation. Care should be used in selecting a replacement for a defective r-f choke, since an improper replacement may cause unwanted oscillation by resonating with the capacitance of its own windings or with distributed circuit capacitances.

Incorrect Output Frequency. Normally, a small change in output frequency can be corrected by adjusting the variable component of the L-C resonant tank circuit, provided that all component parts of the circuit are known to be satisfactory. Changes in distributed circuit capacitance or reflected load reactance will affect the frequency of operation to some extent, being most noticeable on the higher-frequency ranges. Changes in stray capacitance which parallels the tank circuit will have a greater effect in changing the frequency than grid-cathode or plate-cathode capacitance changes (provided that they are large enough to overcome the tank swamping effect). Care should be used in replacing a defective tube, particularly in oscillator circuits operating in the higher frequency

491-044 0-73- 39

ranges. It is good practice to try more than one replacement tube if the first substitution does not achieve the desired results in frequency of operation and stability. Realignment of circuit components to compensate for a tube substitution should be avoided wherever possible. Large changes in ambient temperature may affect the operating frequency of the oscillator. Such changes could come about through failure of an oscillator oven, changes in filament supply voltage, etc.

COLPITTS OSCILLATOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

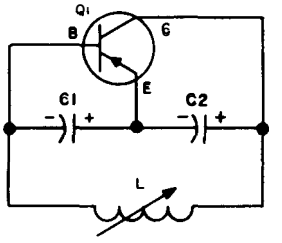
Same characteristics as electron tube version.

Circuit Analysis

General. A sine-wave output may be obtained from a transistor oscillator using a tuned L-C circuit, particularly when the transistor is operating in the linear region of its transfer characteristics. The L-C (tank) circuit determines the frequency of oscillation. The tank circuit consists of two series-connected capacitors in parallel with the inductor. The two series capacitors will act as a capacitance voltage divider across the inductor (in addition to tuning the coil to resonance) with the larger voltage appearing across the smaller capacitor. The capacitance feedback voltage divider may be connected so as to provide either an in-phase voltage or an out-of-phase voltage, to suit the various transistor configurations used. The reactance ratio of the two series capacitors is usually chosen to match the input-output resistances of the transistor used. Mathematical analysis predicts a larger ratio between them than is employed in electron tube practice. The large ratio between capacitor values makes it practical to employ fixed capacitors and tune the inductance over the desired frequency range. The use of capacitance (separate or ganged) tuning over small ranges is occasionally encountered. The frequency of operation is the same as the resonant frequency of the tank circuit, which is given by:

$$f = \frac{1}{2\pi \sqrt{L \frac{C_1 C_2}{C_1 + C_2}}}$$

Circuit Operation. The basic configuration of the Colpitts transistor oscillator is shown in the figure below. For simplicity, bias and collector feed arrangements are not shown, but are discussed later. It is assumed that forward bias is initially applied to the emitter-base junction and that reverse bias is applied to the collector-base junction. Only junction transistors are considered since point-contact transistors operate somewhat differently.

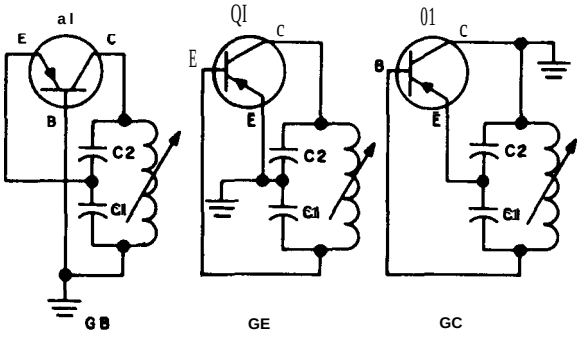


Basic Colpetts CE Configuration

Since in the common-emitter circuit the base and collector elements are out-of-phase, it is necessary to provide a 180-degree phase shift to obtain the positive (regenerative) feedback needed to sustain oscillation. This phase shift is achieved by grounding the common capacitor connection, to make the instantaneous polarity of the capacitor supplying the feedback to the emitter opposite to that of the collector. The discussions of transistor action and the relative merits of the various configurations of L-C oscillators made previously are also generally applicable to this oscillator. The frequency stability is better than that of the Hartley oscillator and the Armstrong oscillator, because the lumped tank capacitors effectively swamp out any slight capacitance changes that occur between the emitter and collector and between the emitter and base of the transistor.

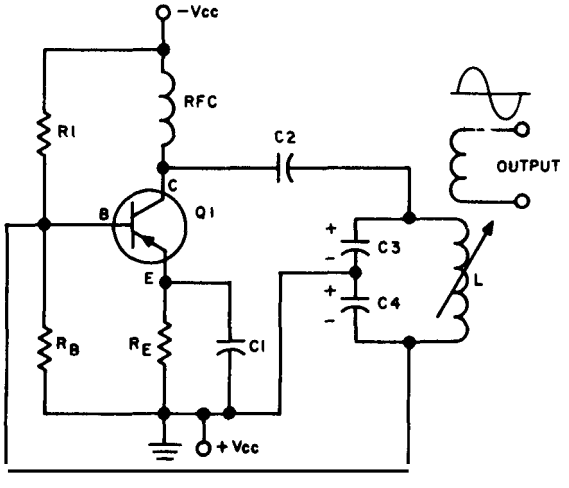
The following simplified schematics of grounding points show three different arrangements of the common-emitter configuration for grounding the transistor elements. These circuits provide a convenient method of grounding the tuning-capacitor rotor to eliminate hand-capacitance tuning effects and to achieve the proper phasing for the feedback. Note that the three gounding point configurations are all ***common-emitter*** arrangements and that the only difference from the basic oscillator is the grounding -

point. In some texts these configurations are referred to as ***common base, common emitter,*** and ***common collector,*** respectively.



CE Colpitts Oscillator Grounding Points

Shunt-Fed Colpitts. The shunt-fed Colpitts oscillator arranged in the common-emitter transistor configuration is shown schematically in the accompanying illustration. One voltage supply is used, with fixed bias being supplied by voltage-dividing resistors R1 and R_B (see the introduction to the Amplifier Section of this handbook for an explanation of biasing). Emitter swamping resistor R_E, bypassed by Cl, is used for temperature stabilization.

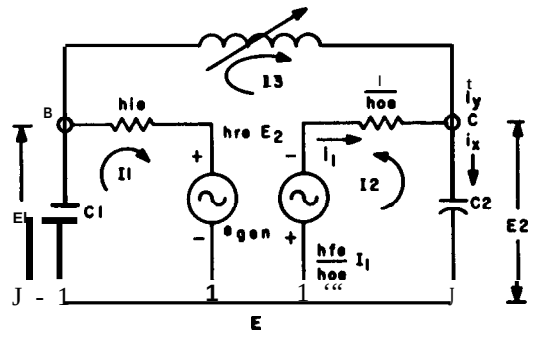


Shunt-Fed Colpitts GE Osallator

The collector is shunt-fed through radio-frequency choke RFC to keep the rf out of the supply circuit, with capacitor C2 acting as a coupling capacitor for the tank circuit. Capacitor C2 also serves as a blocking capacitor, preventing the dc supply from entering the tank circuit and shunting (actually shorting) R1 through the tank inductance.

When the circuit is energized, the initial bias is determined by R1 and R_B, and oscillation is built up by feedback from the tank circuit through divider capacitor C4. Since the divider is grounded at the common connection, opposite polarities exist across capacitors C3 and C4 in respect to ground, with the voltages across these capacitors being determined by the capacitive reactance ratio. Thus a voltage that is out-of-phase with the collector is applied between the emitter and base to supply a positive feedback and sustain oscillation. The combination of R_E and Cl provides an emitter swamping resistor for thermal stabilization, with sufficient capacitance as a bypass to permit degenerative voltage buildup to occur and bias the transistor into the Class B or C operating region after a few initial oscillations. The values of R1 and R_B are usually chosen to provide Class A bias for easy starting. The amplitude of oscillation is essentially regulated by driving the transistor to saturation on one portion of the cycle and to cutoff on the other portion. Although such action normally would cause abrupt changes and distort the waveform, the tank circuit effectively smoothes out the pulsations in Class C operation to provide oscillations that are essentially sine waves. In the linear Class A region, the circuit provides satisfactory sine-wave output for test equipment use. The oscillator output is normally taken inductively by a coil coupled to the tank inductor, although a capacitive tap may be used if necessary.

Detailed Analysis. A typical common-emitter equivalent circuit for the Colpitts oscillator is shown in the following illustration. As in the Hartley circuit, the mathematical analysis of the equivalent circuit is too involved for this text, but can be found in standard texts. With both the Hartley and C.olpitts equivalent circuits it is possible, with slight modifications, to represent most of the other oscillator circuits now in use. Thus, the interested reader will find these two circuits most useful.



Colpitts Semiconductor Equivalent Circuit

Note that the Colpitts is exactly the inverse of the Hartley. The reference vector is e_{gen}, with the induced base voltage, El, directed 180 degrees out of phase. Since the Colpitts oscillator operates above the tank frequency, the tank circuit appears slightly capacitive. Thus i_1 leads e_{gen} by a small angle, while E_2 lags. Current i_x through capacitor C_2 leads E_2 by 90 degrees. Current i_y through the branch containing the tank inductance and C_1 is primarily inductive and lags E_2 by an angle less than 90 degrees depending largely upon the Q of the tank inductance. Since the induced base voltage, E_1, appears across capacitor C_1, it lags i_y by 90 degrees, thereby satisfying the conditions for oscillation. It can be seen that with higher values of circuit Q the phase difference between i_1 and E_2 will diminish.

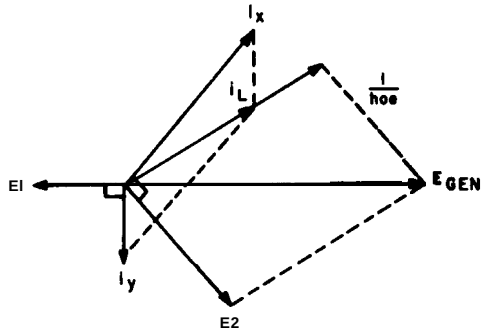
One interesting fact develops from the Colpitts analysis; that is, the starting conditions are found to be:

$$\frac{h_{fe}}{\Delta_{he}} = \frac{C_1}{C_2}$$

Where $Ah_e = h_{ie}\, hoe - h_{re}\, h_{fe}$.

Thus, when h_{fe} is large and Ah_e is small, capacitors C_1 and C_2 will have large differences of values (from 10 to 100 times), which is not the case with the electron tube counterpart.

The accompanying vector diagram shows the current and voltage relationships for the Colpitts oscillator equivalent circuit above.



Colpitts Vector Diagram

Failure Analysis.

No Output. Although oscillation may fail because of a shorted or open-circuited transistor, deterioration with age similar to the decrease of emission in electron tubes does not normally occur. High-temperature operation may cause premature failure or drop-off in performance of the transistor; however, this can normally be obviated by proper ventilation of the equipment. Reflected reactance from heavy loading due to tight coupling may occur and prevent oscillation, but it should not occur with proper design. Failure of collector blocking capacitor C2 will place a dc short circuit across the collector and base of transistor Q1 through the tank inductance and stop oscillation; it may also ruin the emitter-base junction. Changes in value of the bias resistors will probably reduce the output rather than prevent oscillation completely. Shorting of either of the tuning capacitors will prevent oscillation. In making continuity checks of these tuning capacitors with an ohmmeter, it is important to connect the ohmmeter with the correct polarity because, since the emitter-base junction is in parallel, use of the incorrect polarity would apply a forward bias and possibly damage the transistor.

Reduced or Unstable Output. As in the oscillators discussed previously, it is important to determine whether the instability is associated with frequency or amplitude. If amplitude instability is caused by temperature effects, the bias divider and emitter stabilizing resistors are probably at fault. Reduced output will most likely be due to excessive biasing caused

by changes in value of the bias resistors, or to excessive degeneration caused by an open capacitor (or a reduced value of capacitance) in the emitter bypass circuit. A leaky collector coupling capacitor will cause a change in bias by reflecting, through the tank inductarrce, a parallel resistance between the base and collector elements of the transistor. Frequency instability will indicate that the tank circuit or supply voltage is at fault. Although this circuit provides capacitance swamping of the elements to minimize transistor capacitance changes with supply voltage changes, it should be noted that a varying supply voltage also changes the transistor operating point and may therefore affect the frequency to some extent. As in the other oscillators, poor mechanical connections and shorted turns or deteriorated insulation in the tank circuit may cause unstable operation.

Incorrect Output Frequency. As in the other oscillators discussed previously, small changes in frequency can be corected by adjusting the tuning capacitor, assuming that all parts are in good condition. Variations of frequency with supply voltage changes indicate the need for external supply regulation. Major frequency changes will most likely indicate trouble in the tank circuit since it is the primary frequency-determining circuit. Although a change in transistor parameters may change the frequency to some extent, a major parameter change will most likely result in reduced output or unstable operation. Too tight coupling of the load is indicated if the frequency changes noticeably with changes in loading (a slight change is normaI).

CLAPP OSCILLATOR (ELECTRON TUBE)

Application.

The Clapp oscillator is used to produce a sine-wave output of constant amplitude and fairly constant frequency within the r-f range. The circuit is used as a beat frequency oscillator in receivers, as a master oscillator in transmitters, and generally as a variable-frequency oscillator over the high- and very-high frequency ranges. It is also employed as a crystal controlled oscillator in frequency meters and in signal generators.

Characteristics.

Uses a separate series tuned L-C circuit to determine the frequency of oscillation, with a capacitance voltage divider form of feedback to control oscillation.

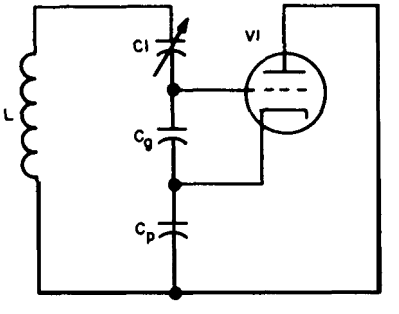
Operates as Class B or C with automatic self-bias for ordinary or power operation, and as Class A where output waveform linearity is important.

Frequency stability is good. The circuit is considered to have better stability than the Colpitts circuit.

Circuit Analysis.

General. The Clapp circuit is considered to be a variation of the Colpitts circuit discussed previously. It uses the stabilizing effect of a series tuned tank circuit, coupled loosely to the tube feedback loop, to provide better frequency stability. It incorporates capacitive tuning which require the use of only one tuning capacitor. It also offers a convenient method of tuning over a small band of frequencies where band-spread or vernier-type tuning is desired.

Circuit Operation. The basic Clapp oscillator circuit is shown in the following schematic. The tuned tank circuit consists of series-connected components L and Cl in parallel with the basic capacitance feedback voltage divider, C_g and C_p. For simplicity, the biasing and plate feeds are not shown in this basic circuit, but are discussed as necessary in the following circuit discussion.



Basic Clapp Circuit

The capacitance ratio for the voltage divider which provides the basic feedback (as in the Colpitts circuit) may vary with the circuit design and the frequency. Usually it is 1:1 with Cl being smaller (about one-tenth C_g for high-frequency operation).

The circuit may be arranged for grounded grid, cathode, or plate operation without affecting performance; the grounded-plate configuration is the most frequently used.

The frequency of operation is dependent upon the values of the three capacitors and inductor as follows:

$$F = \frac{1}{\sqrt{2\pi L C_1}} \qquad \sqrt{1 + \frac{C1}{C_g} + \frac{C1}{C_p}}$$

Thus it is evident that when the ratios of C_1/C_g and C_1/C_p are very small, the resonant frequency will be primarily determined by the values of L and C_1 alone. This is the condition usually desired.

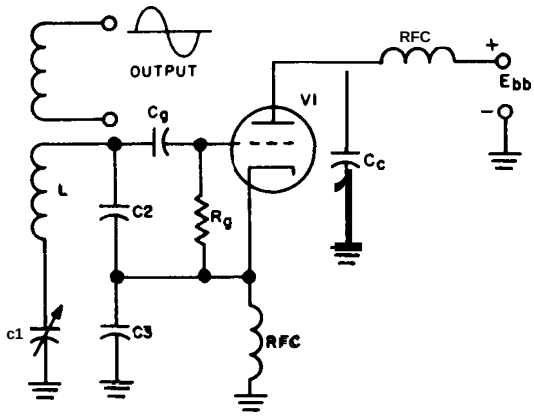
Since the resonant frequency is primarily determined by L and C_1 when C_p and C_g are comparatively large, the Clapp circuit may employ much larger values of capacitance in the feedback voltage divider than can the equivalent Colpitts. The larger values of capacitance much more effectively swamp interelectrode capacitances; it has been estimated that as much as a 400 to 1 reduction of change in capacitance by temperature or tube variations may be obtained.

As in the other L-C circuits, the most stable operation is obtained with a high loaded Q, which is produced for a series resonant circuit by a high L to C (not C to L ratio. Thus, for a given frequency, the tank inductance is larger than that used for the previously discussed circuits. Since it is easier to produce a high-Q coil when the inductance is greater than the usual high-C tank affords, the Clapp oscillator benefits from the 10wK tank. While the capacitance voltage divider consisting of C_g and C_p does not offer any greater stability in this Clapp circuit than in the Colpitts, the ratio of C_g to C_p is chosen to afford the greatest possible stability in conjunction with the higher Q offered by the series tuned tank. Tuning capacitor Cl is chosen to have the desired tuning range, with sufficient capacitance to sustain the feedback loop at the higher frequency (feedback increases with decrease of frequency).

Since the basic frequency-determining portion of the Clapp circuit is the tank inductor (Cl merely tunes over the desired range), which is coupled capacitively through Cl to the tube, the Clapp tank is generally considered to be more loosely coupled than the tank circuit of the other oscillator configurations. Thus tank circuit changes are normally minimized. This factor, in combination with the higher circuit Q obtainable, provides the Clapp oscillator with very high stability in the presence of supply voltage variations, the frequency changing only a few parts per million for a supply voltage variation of 15 percent.

Variations of the Clapp oscillator circuit may be encountered. For example, an RFC may be inserted between cathode and ground to keep the cathode at a high impedance above ground, and offer a dc return path to the cathode. Usually this choke is chosen to resonate with its distributed capacitance at the fundamental frequency, and occasionally a trimmer is included to adjust the parallel resonant choke circuit for proper impedance. In special circuit versions, the cathode tank may be used for frequency doubling. These circuit variations, however, are not a part of the basic Clapp oscillator circuit design.

Shunt-Fed Clapp. The complete schematic for a shunt-fed Clapp oscillator is shown in the accompanying illustration. Series plate feed is never used in this circuit and will not be discussed. Shunt grid-leak bias is used (R_g and C,J, with shunt plate feed. Capacitor C_c is the plate blocking and coupling capacitor, and inductor RFC is the r-f choke. The combination of C_C and RFC provide an r-f bypass to isolate the power supply from r-f. The plate is grounded to r-f, and L and Cl form the tank circuit, which is connected across the feedback divider consisting of C2 and C3. The cathode RFC provides a dc return path to ground for the cathode, and offers a high impedance to r-f to prevent any shunting of divider capacitor C3.



Shunt-Fed Clapp Osallator

Operation of the circuit and automatic regulation of the amplitude by grid bias are the same as described in previous oscillator discussions. Oscillation is caused by feedback through the capacitance voltage divider, C2-C3, as in the Colpitts oscillator, but the ratio of the capacitors is chosen for the best frequency stability. The output coupling is usually inductive, but it may be capacitive.

Failure Analysis.

No Output. High plate current will be indicative of non-oscillation and consequent loss of operating bias, with the tube operating at essentially zero (contact) bias. Reduced tube gain, if sufficient, will also affect oscillation. Changes in the value of the bias resistor and capacitor will directly affect the operating bias and the amplitude of oscillating – if the changes are large, oscillation may be prevented; if small, the effect may not be noticeable. Shorted turns of oscillator coil, in addition to affecting output amplitude and frequency, may cause loss of oscillation because of loading effects. A defective radio-frequency choke (RFC) or coupling capacitor (Cc) may stop oscillation since the oscillator is dependent on these components for the development and application of feedback voltages.

Reduced or Unstable Output. A relative indication of oscillator output is provided by the amount of bias voltage developed across R_g. Variation from the standard operating value is an indication of abnormal operation. A reduction of plate voltage will decrease the output amplitude. Therefore, an unregulated voltage source will produce output amplitude variations and possibly some frequency change, although the Clapp circuit is considered to be less affected in this manner than the Colpitts (a change of only a few parts in a million for a 15 per cent plate supply fluctuation is claimed). A partially open plate blocking capacitor will reduce the grid-to-plate coupling and feedback and thus affect the output or oscillation. At the higher frequencies it is possible for weak feedback to occur through the grid-to-plate tube capacitance and sustain oscillation even though the plate blocking capacitor is faulty. A leaky plate capacitor may cause reduced or unstable output by loading the oscillator or by reducing plate voltage by adding to the normal current flow through a series resistance. Care should be exercised in selecting a replacement for a defective r-f choke since an improper replacement choke may cause unwanted oscillation by resonating with distributed circuit capacitances or with the distributed capacitances of its own windings.

Incorrect Output Frequency. Changes in distributed circuit capacitance or reflected load reactance will affect the frequency of operation to some extent, although the design of this circuit provides fixed swamping capacitances to eliminate such changes. The largest change will be produced by a change of the tank circuit Q caused by shorted turns or poor soldered connections in the tank circuit. An incorrect output frequency resulting from a change of tube transconductance with age is normally corrected by slight readjustment of the tuning capacitor. Large changes in ambient temperature may affect the operating frequency of the oscillator. Such changes could occur through failure of an oscillator oven, changes in filament supply voltage, etc.

CLAPP OSCILLATOR (SEMICONDUCTOR)

Application.

The Clapp oscillator is used to produce a sine-wave output of constant amplitude and frequency within the r-f range. The circuit is generally used as a signal source in signal generators and as a variable-frequency oscillator for general use over the high- and very-high-frequency ranges.

Characteristics.

Uses a series-resonant L-C circuit to determine the frequency of oscillation.

Feedback is obtained through a capacitance-type voltage divider.

Frequency of operation is relatively independent of transistor parameters.

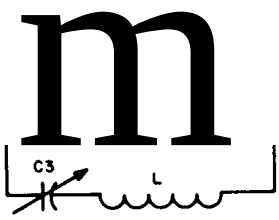
Operates Class C where wave form linearity is not important, and Class A where a linear waveform is required.

Frequency stability is good (better than that of the Colpitts oscillator).

Circuit Analysis.

General. The Clapp circuit is considered to be a variation of the Colpitts circuit discussed previously. It uses the stabilizing effect of a series-resonant tuned tank circuit, loosely coupled to the feedback loop, to provide good stability relatively independent of transistor parameters. It also offers capacitive tuning, using only one capacitor, without affecting the feedback ratio.

Circuit Operation. The basic transistor configuration of the Clapp oscillator is shown schematically in the accompanying figure. For simplicity bias and collector feed arrangements are not shown, but are discussed later. It is assumed that forward bias is initially applied to the emitter-base junction and that reverse bias is applied to the collector junction. Only junction transistors are considered because point-contact transistors operate somewhat differently.

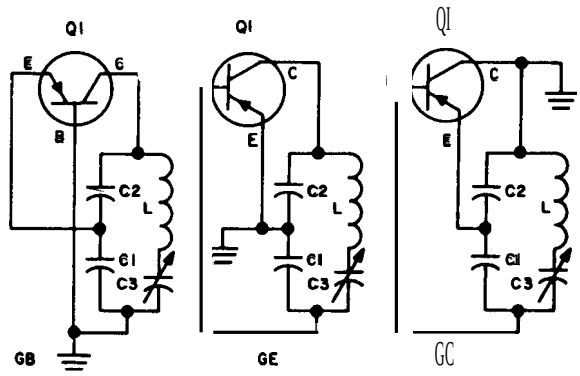


Basic Clapp CE Configuration

In the resonant tank circuit, the inductor is tuned by a capaictor which is essentially the sum of series capacitors C 1, C2, and C3. Since the total value of a string of capacitors in series is always less then the value of the smallest capacitor, it can be seen that when Cl and C2 are much larger than C3 the effective tuning capacitance is essentially the capacitance of C3 alone. Thus the series tuned resonant circuit consisting of L and C3 is the basic frequency-determining element, and the frequency is given by:

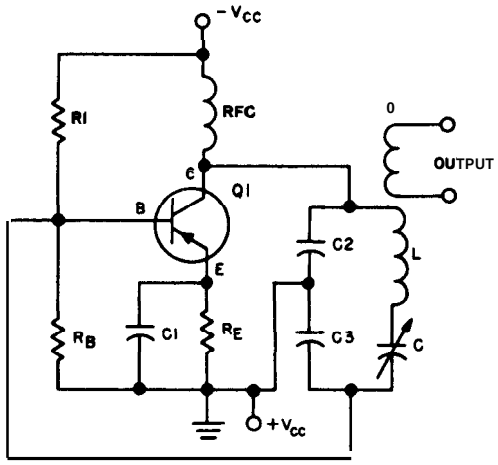
$$f = \frac{1}{277\sqrt{LC_3}}$$

Since the tank circuit is controlled by L and C3, it is clear that the feedback voltage divider consisting of Cl and C2 provides the feedback essentially alone, so that any changes of parts values in the tank circuit have negligible effect on the oscillation amplitude. The tuned tank is designed to have a high Q under loaded conditions (low C for series resonance) similar to the tank circuit of the electron tube counterpart. Thus the Clapp circuit has greater stability than the basic Colpitts oscillator from which it is derived. The following figure shows three different arrangements of the common-emitter transistor configuration for grounding the elements to achieve a particular result. Note that the three grounding point configurations in the figure are all common-emitter arrangements and that the only difference from the basic schematic is the grounding point In some texts these configurations are referred to as ***common base, common emitter,*** and ***common collector,*** respectively.



CE Clapp Oscillator Grounding Points

Shunt-Fed Clapp. The shunt-fed Clapp transistor oscillator is shown in the common-emitter and grounded-emitter configuration in the following schematic. One voltage supply is used, with fixed bias being supplied by resistors RI and R_B (see Section 3, paragraph 3.4.1, for bias explanation). Emitter swamping resistor R_E, bypassed by C 1, is used for temperature stabilization.



Shunt-Fed Clapp CE Oscillator

The collector is shunt-fed through radio-frequency choke RFC to keep r-f out of the power supply and avoid power supply shunting effects. Note that series feed cannot be used with the Clapp circuit because tuning capacitor C is in series with tank inductance. Thus a blocking capacitor in either the base or the collector lead is not required for this circuit. When the circuit is energized, Class A bias is supplied for starting by the bias voltage divider consisting of R1 and R_B, and feedback to the base is applied through feedback divider capacitor C3. Grounding the common connection between the feedback divider capacitors provides the 180-degree phase reversal necessary to provide positive feedback from collector to base. The emitter resistor and capacitor combination acts in the same manner as an electron-tube grid-lead to provide essentially Class C bias after a few oscillations. R_E aiso acts as a dc thermal stabilizer for collector-current temperature variations. In a properly designed circuit, the proper feedback voltage divider capacitor ratio for stable feedback with the transistor used may be selected, independently of tank circuit design considerations, to provide oscillation over the desired range of operation. The output may be taken capacitively or by inductance coupling to the tuned tank circuit. With loose inductive coupling, the output obtained is very stable and relatively free of the detuning effects of loading, since the tank circuit is loosely coupled to the feedback loop and relatively independent of any change in transistor parameters.

Failure Analysis.

No Output. Since no blocking capacitors are employed and since the tank circuit is essentially unaffected by changes in transistor parameters, lack of output is usually limited to lack of feedback or improper bias voltages. An open or shorted transistor or an open or shorted feedback capacitor will stop oscillation. A shorted tuning capacitor C will also stop oscillator because it will permit the collector voltage on tank "coil L to be shorted to the base. Poorly soldered connections may produce circuit losses sufficient to prevent oscillation, while changes in value or open bias resistors will probably reduce rather than stop oscillation completely.

Reduced or Unstable Output. Reduced output would most likely indicate a change in bias resistor values or a defective emitter bypass capacitor. An open or paritally open emitter bypass would produce excessive degeneration and perhaps complete cutoff, though the latter is very unlikely, whereas a shorted emitter bypass would probably be indicated by thermal instability. Frequency instability would be directly traceable to the tank circuit components and connections. An unstable output amplitude could be caused by an intermittent open or short in the bias circuitry or by a poor connection to the transistor or supply voltage. Lack of supply voltage regulation would normally be indicated by amplitude changes rather than by frequency changes.

Incorrect Output Frequency. Changes in distributed circuit capacitance or reflected load reactance will affect the frequency of operation to some extent, but can normally be corrected by resetting or adjusting the tuning capacitor. Large frequency changes will be produced by changes of tank circuit inductance caused by shorted turns or poorly soldered connections. At first glance it might appear that a shorted tuning capacitor would cause the frequency of oscillation to be determined by the inductance of the tank circuit alone (plus some distributed capacitance); however, for this condition oscillation could not occur because the shorted capacitor would short the collector voltage through the tank coil L to the base.

TUNED-PLATE TUNED-GRID OSCILLATOR

Application.

The tuned-plate tuned-grid (TPTG) oscillator is used to produce a sine-wave output of constant amplitude and fairly constant frequency within the r-f range. This circuit is generally used as a variable frequency oscillator over the high- and very-high-frequency r-f ranges. It is not often encountered in Navy electronic equipment.

Characteristics.

Contains two parallel-tuned L-C circuits–one in the grid circuit and the other in the plate circuit of the electron tube–and uses the internal grid-plate tube capacitance for feedback.

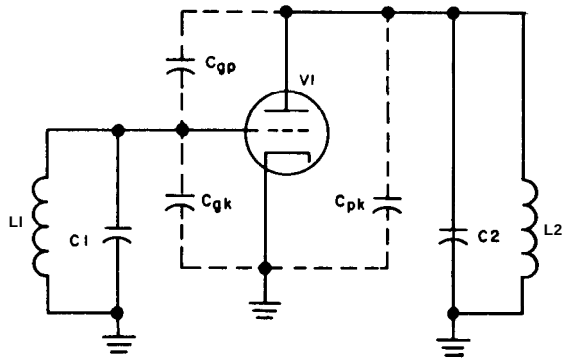
Operates as Class C with automatic self-bias for ordinary, or power, operation and is seldom used for linear waveform applications.

Frequency stability is good when properly adjusted.

Circuit Analysis.

General. When a tuned L-C tank circuit is connected between the grid and cathode of an electron tube and a similar tank circuit is connected between the plate and cathode of the tube with coupling existing between them, sustained oscillation will occur when these tuned circuits are resonated to the same frequency. The amplitude of the oscillation is determined by the amount of feedback from plate to grid, and is also affected by the tuning of the two circuits. To provide the proper phase to sustain oscillation, both the grid tank and the plate tank are tuned to a slightly higher frequency than the resonant frequency at which operation is desired. At the operating frequency both tanks then offer an inductive reactance, and the phase shift through the grid-plate tube capacitance is of the proper polarity to sustain oscillation. The condition for proper phasing is that the inductive reactance of the grid tank circuit be less than the capacitive reactance of the grid-plate interelectrode capacitance at the operating frequency. To sustain oscillation, it is only necessary to supply the losses in the grid circuit, which because of the high-Q grid tank are relatively small. Consequently, only a small capacitance is needed to supply sufficient feedback, and the grid-plate interelectrode capacitance of the triode tube is adequate for this purpose. When a pentode is employed in the circuit, it is usually necessary to supply an external capacitor to provide the feedback, because of the low electrode capacitance inherent in the pentode.

Circuit Operation. The basic tuned-plate tuned-grid oscillator circuit is shown schematically in the following illustration. The grid tank consists of Cl and Ll, while the plate tank consists of C2 and L2, no mutual inductance existing between L1 and L2. Feedback occurs through the plate-grid capacitance, C_{gp} (shown in dotted lines), when both tanks are tuned to the same frequency. The feedback amplitude can be controlled by detuning the grid tank with Cl. Thus, differences in interelectrode capacitance between tubes can be accommodated with no adverse effects.



Basic Tuned-Plate Tuned-Grid Oscillator

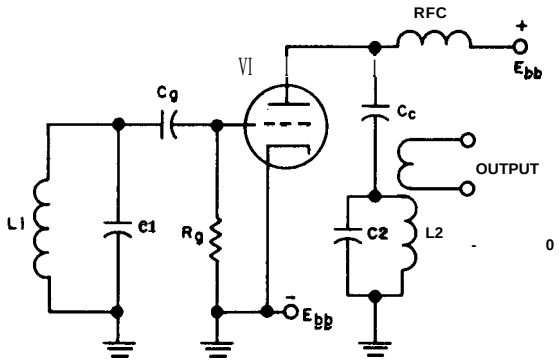
For simplicity, biasing and plate voltage feeds are not shown in the basic circuit, but are discussed when applicable in the following discussion. Since capacitive feedback determines oscillation, this circuit is a better oscillator at the higher frequencies and is not often used in the low or medium-frequency ranges. Although other configurations may be used, this circuit lends itself conveniently to grounded-cathode operation. The grid tank basically controls the excitation and operating stability, and the grid-cathode tube capacitance is in parallel with the tank, being effectively swamped by the tank capacitance. Likewise, the plate tank capacitor effectively swamps the plate-cathode tube capacitance, and the plate tank is primarily used to determine the operating frequency. Once oscillation occurs near the desired frequency, the plate tank is tuned to set this frequency to the desired value, while the grid tank is adjusted for proper excitation and maximum stability.

Upon examination of the shunt-fed tuned-plate tuned-grid oscillator circuit (following illustration), it is evident that shunt grid-leak bias (C_g, R_g) and shunt plate feed are used, with C_c serving as the plate coupling and blocking capacitor. The radio-frequency choke, RFC, keeps the rf out of the plate supply. Ll,

4

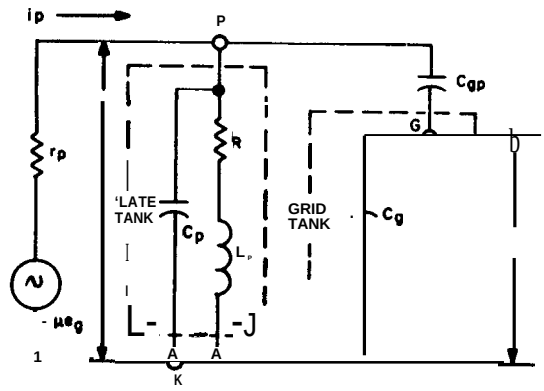
Cl is the grid tank and L2, C2 is the plate tank. The grounded-cathode connection is shown since it permits grounding the tuning-capacitor rotors to eliminate any body capacitance effects on tuning. Theme of shunt grid-leak bias isolates the grid tank as far as dc is concerned and reduces circulating grid current, although series grid bias could be used as well. Sometimes a series resistor is included between cathode and ground, to provide protective bias in the event of non-oscillation. Both the plate and grid capacitors are sufficiently large so that the tank circuits are affectively coupled to the grid and plate for r-f, yet isolated as far as dc is concerned. Grid-leak bias action and automatic amplitude regulation are the same as described previously in other oscillator discussions. The feedback action takes place as described above, making use of the coupling between the plate and grid tanks provided by the grid-plate tube capacitance. At radio frequencies which require the use of relatively large inductors and when appreciable power is used, it is important for the tanks to be shielded or turned at right angles to each other, to prevent possible inductive coupling effects which would deteriorate circuit performance.

Output is obtained by inductive coupling to the plate tank, although a capacitive connection may be made if desired.



Shunt- Fed Tuned-Plate Tuned-Grid Oscillator

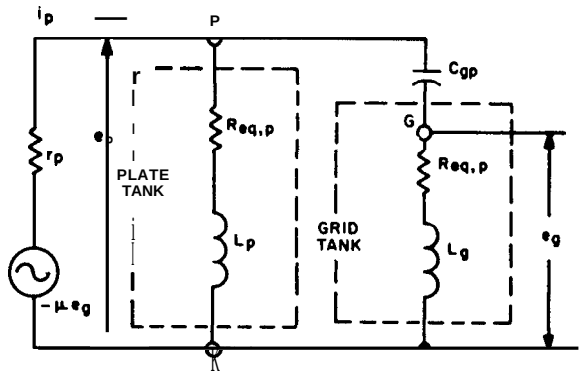
Detailed Analysis. The equivalent circuit of the tuned-plate, tuned-grid oscillator is shown in the following illustration.



Basic TPTG Equivalent Circuit

Since the oscillator operates below the resonant frequency of the tank circuits, both the plate tank and the grid tank will appear resistive and inductive to the signal source-peg.

The following figure shows the tank circuits replaced by their equivalent values of modified equivalent resistance and inductance at the operating frequency. Notice that this equivalent circuit closely resembles that of the Hartley oscillator which was shown previously.

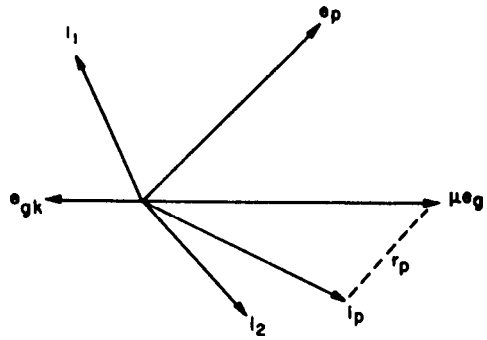


Modified Tuned-Plate, Tuned-Grid Equivalent Circuit

Therefore, the operation of the TPTG oscillator, at the operating frequency, is basically that of a Hartley

oscillator without the benefit of mutual inductance. However, adjustment of the tuned circuits to meet this condition is rather critical. Note from the equivalent circuits that the basis frequency-determining components are the plate tank and the plate to-grid capacitance of the tube, C_{gp}. The plate tank, therefore, is tuned to establish the frequency of operation, while the grid tank is tuned to establish the proper phasing and amount of feedback voltage for grid excitation.

Vector Diagram. The relationship between the current and voltages in the. circuit is shown by the following vector diagram.



Tuned-Plate Tuned-Grid Vector Diagram

The constant voltage generator output pe_g is the reference voltage. It is assumed that there is no inductive coupling between the plate and grid tank circuits and that the frequency of oscillation is slightly lower than the resonant frequency of the tanks. Since the tank circuits are tuned to a higher frequency than the oscillation frequency, they offer an inductive reactance. Also, since the feedback must occur through the grid-plate inter-electrode capacitance, the grid tank must offer a lower inductive reactance than the capacitive reactance of the electrodes (the grid-cathode and plate-cathode capacitance is assumed to be a part of the tuned circuits). Therefore, the inductive plate tank causes e_p to lead μe_g by some angle dependent on the circuit values, and $i_p r_p$ lags. The inductive plate tank current i_2 also lags e_p somewhat less than 90 degrees. Since the reactance of C_{gp} is greater than the grid tank reactance, i_1 leads e_p by almost 90 degrees. Voltage e_{gk} is developed across the inductive grid coil (tank) and, therefore, leads i_1 by almost 90 degrees. This voltage is exactly 180 degrees out of phase with μe_g, satisfying the requirement for oscillation.

Failure Analysis.

No Output. If something happens to either of the tank circuits so as to cause a large enough shift in that tank's resonant frequency, the circuit will not oscillate, and only contact bias will be developed. Plate current, therefore, will be higher than normal and the standard operating value of grid bias will not be obtained. Excessive losses if present in the tank circuit will prevent sustained oscillation. Changes in the values of grid-bias components R_g and C_g will affect the operating bias and change the amplitude of oscillation. A large change may prevent oscillation, whereas a small change may not have any noticeable effect. Although loss of tube gain will reduce the amount of feedback, the TPTG circuit is a vigorous oscillator when properly adjusted, so that considerable reduction in tube amplification is necessary to reduce oscillation. Too close coupling of the output circuit to the plate tank will produce the same effect as a lossy tank circuit, and reflected reactance may cause sufficient detuning to prevent oscillation. In the shunt-fed circuit, a defective radio-frequency choke RFC or coupling capacitor C_c may cause loss of oscillation since the oscillator depends on these components for isolation from the low a-c impedance of the plate supply and for coupling of the a-c signal to the tuned plate tank.

Reduced or Unstable Output. A relative indication of oscillator output is provided by the amount of bias voltage developed across R_g. Variation from the standard operating value is an indication of abnormal operation. A reduction of applied plate voltage will decrease the output. Therefore, an unregulated voltage source will produce output amplitude variations and probably some frequency change or instability. In this respect, the tuning of the grid tank is important, as is has a great effect on the stability of operation. A leaky coupling capacitor C_c may cause reduced or unstable output by loading the oscillator or by reducing plate voltage by adding to the normal current flow through a series voltage dropping resistance. Care should be used in selecting a replacement part for a defective r-f choke, since an improper replacement may cause unwanted oscillation by resonating with distributed circuit capacitances or with the distributed capacitances of its own windings.

Similar care should be exercised in replacement of a defective tube since the oscillator depends on inter-electrode capacitances as a part of the tuned circuits. Variations of this physical capacitance from one tube to another may be enough to seriously detune the oscillator. It is good practice to try more than one replacement tube if the first substitution does not achieve the desired results in frequency of operation and stability. Realignment of circuit components to compensate for tube substitution should not ordinarily be necessary.

Incorrect Output Frequency. Assuming that all component parts of the circuit are known to be satisfactory, changes in output frequency can be compensated for by realigning or tuning the tank circuits. Detuning effects caused by reflected load reactance will affect the frequency of operation to some extent, being most noticeable on the very-high-frequency ranges. Changes in tank inductance caused by shorted turns, particularly in the grid circuit, will result in a different frequency of operation, if oscillation still occurs. Large changes in ambient temperature, such as may occur through failure of an oscillator oven or changes in filament supply voltage, may affect the operating frequency of the oscillator. Changes in distributed circuit capacitances will also affect the operating frequency. Therefore, care should be used in the removal and replacement of parts, in order not to disturb the distributed capacitance inherent in the physical parts and wiring of the circuit. The effects of tube substitution were discussed above.

Series-Fed Tuned-Plate Tuned-Grid.

Series plate feed is easily accomplished with the tuned-plate tuned-grid circuit by connecting B + and the RFC in place of the ground to L2 (refer to shunt-fed schematic), connecting the plate directly to the top of L2, and bypassing the bottom end of L2 to ground with Cc. Circuit operation and failure analysis are exactly the same as for the shunt-fed circuit with two exceptions: (1) With the series .connection, unwanted low-frequency (or high-frequency) parasitic oscillations caused by resonances of RFC and C_c or of RFC and C_{pk} are eliminated. (2) The effect of dc in the tank circuit must be considered; since the capacitor and inductor must withstand both d-c and r-f voltages, their insulation to ground becomes an important factor.

EL ECTRON-CO UPLEO OSCILLATOR (ELECTRON TUBE)

Application.

The electron-coupled oscillator is used to produce an r-f output of constant amplitude and extremely constant frequency, usually within the r-f range. The circuit is generally used in any type of electronic equipment where stability is required, and the output waveform need not be a sine wave, as some distortion of waveform is normal.

Characteristics.

Uses the shielding effect between the plate and screen grid in a tetrode or pentode to isolate the plate load from the oscillator, and employs the electron stream between the screen grid and plate to couple the oscillator output to the plate load.

Operates with practically any circuit configuration of the L-C or R-C type, but is mostly used with L-C circuits.

Frequency stability of circuit is very good–better than that of the previously discussed types of oscillators.

Circuit Analysis.

General. In the triode-type oscillator, variation of the plate supply voltage and reflected load reactance causes slight frequency variations because the plate is involved in the feedback loop. By using the cathode, grid, and screen grid of a tetrode or pentode as the oscillator, the plate is eliminated from the feedback loop. Since the plate current in the tetrode or pentode is relatively independent of plate voltage changes and remains nearly constant for a specific value of screen voltage, variations in the plate load circuit have practically no effect on the other elements. Connecting the screen grid as the plate of the triode oscillator electrostatically shields the plate of the pentode or tetrode, and couples the output of the oscillator to the load through the plate electron stream.

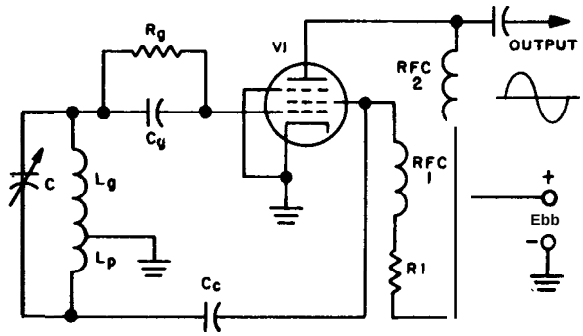
Any of the previously discussed oscillator circuits may be used for the oscillating portion of the electron-coupled oscillator circuit, and the electron tube can be either a tetrode, a pentode, or a beam-power tube.

The tetrode is a four-element tube, which uses a screen grid to accelerate the flow of electrons from the cathode to the plate under control of the control grid. As the electrons pass through the screen grid to the more positive plate, some of them impinge on the screen grid and produce a screen-grid current, which amounts to about one tenth of the plate current. Secondary electrons are emitted by the portion of the electron stream striking the screen grid and by the stream striking the plate. Normally, when the plate voltage is higher than the screen-grid voltage, these secondary electrons are attracted to the nearest element, plate or screen, and merely increase their respective currents. When the plate voltage is near or below the screen-grid voltage, space charge forms a virtual cathode between the screen grid and plate and thus nullifies the effect of electron coupling. Therefore, the screen grid is usually supplied from the plate source through a series voltage-dropping resistor, and it is bypassed to ground with a capacitor to provide an electrostatic shield. The beam-power tetrode uses special construction and beamforrning plates connected to its cathode to provide the same effect. The pentode utilizes a fifth element (the suppressor grid), usually connected to the cathode internally and 1 ocated between the screen grid and plate, to eliminate secondary-emission effects. In some tubes the suppressor grid connection is brought out externally, and may be connected to ground, screen grid, or plate as desired. In the electron-coupled oscillator, it is always connected to provide an effective electrostatic shield between the screen grid and plate, in order to eliminate coupling of load variations back to the oscillator circuit. When a pentode with an internally comected suppressor is used in the electron-coupled circuit, the cathode is always grounded; otherwise, full electron coupling is not obtained and a less stable circuit results.

The electron-coupled plate load may be another tuned tank circuit, a radio- frequency choke, or a resistor. The tuned plate tank may be operated on the same frequency as the grid tank, or it may be tuned to a harmonic, operating as a frequency multiplier. In test-equipment applications, a choke or a resistor (instead of a tank circuit) is usually used with tight loading to assure maximum frequency stability. A properly designed electron-coupled oscillator provides the stability of a master oscillator-power amplifier circuit combination with ordy one tube, and it has the power output of an equivalent triode operating at the same plate voltage and current.

When a resistor or choke is used in the output circuit, the waveform is not exactly sinusoidal because the plate current does not vary linearly with the screen-grid current. Although the control grid varies the screen-grid current linearly, and these oscillations effectively modulate the electron stream between the screen grid and plate, not all of the current controlled by the grid reaches the plate. Some of the electrons in the screen-plate region are attracted back to the screen grid, while others are shunted to the cathode by the suppressor electrode. Therefore, at any particular instant when the screen-grid current is being slightly increased, the plate current may or may not be increased by the same amount-in fact, it may actually decrease. Hence, the output waveform, which is the result of plate current flow through the load resistance, will not be exactly like the screen-grid waveform; it will be similar, but distorted. If a plate tank or an L-C filter is employed, the distortion will be corrected and a nearly sinusoidal waveform will result.

Circuit Operation. The schematic of an electron-coupled oscillator using a pentode tube is shown in the following illustration. The oscillator section utilizes the basic Hartley shunt-fed circuit, with a series grid leak as discussed previously in the Hartley oscillator circuit, and with the screen of the pentode acting as the troide plate.



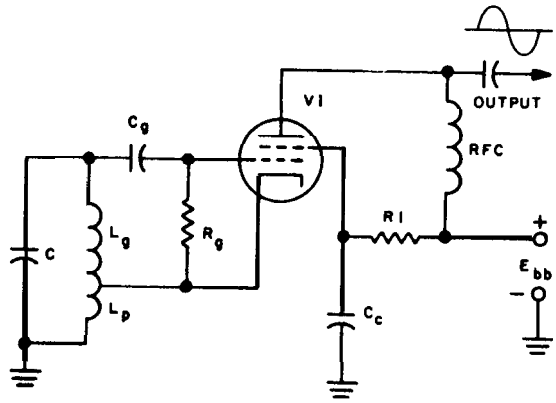
Pentode Electron-Coupled Oscillator

The E.C.O. load is taken from the plate circuit of the pentode. Operation of the oscillator portion is identical to that of the previously discussed Hartley oscillater. In the electron-coupled version, however, plate

voltage is applied to the pentode through RFC2 to keep r-f out of the power supply, and the output is capacitively coupled to the load (usually the next r-f amplifier stage). To insure that the screen of the pentode remains at a lower minimum dc potential than the plate, a dropping resistor, RI, is generally used, but may be omitted in some versions of this circuit. Since the screen is above ground at r-f potential, RFC1 is necessary to block the rf from the power supply. If R1 is a high-vahre resistor of say 5000 ohms or more, RFC1 may be omitted, because the high resistance of RI is comparable to the reactance offered by the r-f choke. Note that the suppressor element is connected to the cathode, which is grounded. If the cathode were above ground, the sup pressor could not be connected to the cathode or it would capacitively couple the oscillator into the plate circuit and destroy the shielding effect of electron coupling. Since in this instance the cathode is grounded, the suppressor performs its normal function of eliminating secondaiy emission and isolating the plate and the screen grid.

The oscillator normally operates Class C, and for each pulse of oscillation a corresponding pulse is produced in the plate circuit through modulation of the electron stream. Thus electron coupling exists between the screen grid and plate. Plate load variations produce plate voltage and current changes, but, since a change of pentode plate voltage has little effect on plate current, these changes have negligible effect on the screen-grid voltage and current. Hence, the stability of the oscillator remains relatively unaffected by load variations. It should be noted that, although the pentode is considered to be unaffected by supply voltage variations, only the tetrode circuit can be designed by selection of proper plate and screen voltages to be completely independent of supply variations. The advantage of the pentode arrangement is that grounded-cathode operation can be used to provide an electrostatic shield between plate and grid or screen, and secondary emission effects need not be considered.

The tetrode version of the electron-coupled oscillator which is particularly applicable to beam-power tubes is the grounded-screen circuit shown in the following illustration.



Tetrode Electron-Coupled Oscillator

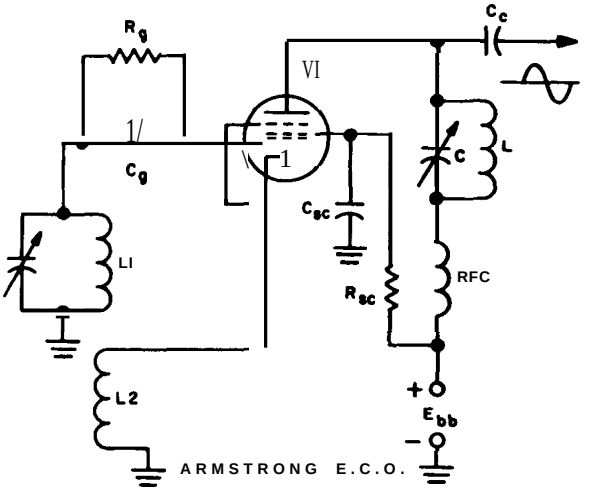
In this circuit, the shunt-fed Hartley is used; the operation and components of the circuit are the same as just described for the pentode E.C.O. illustrated in the accompanying figures, with the following exceptions.

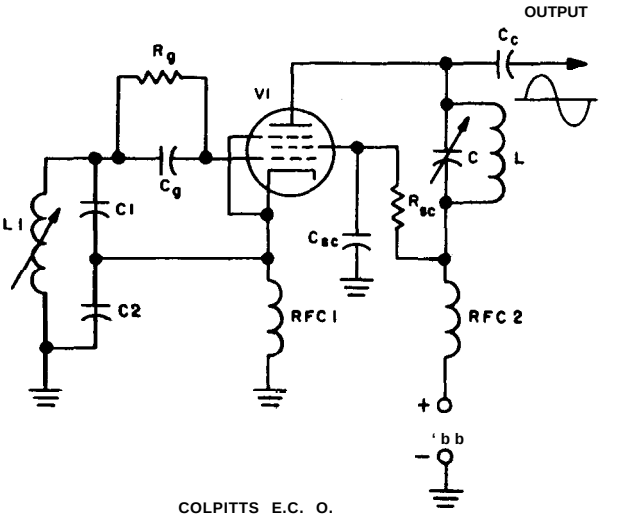
Since there is no suppressor element in a tetrode tube, secondary emission effects are encountered. Therefore, RI is needed to keep the plate voltage always higher than the screen-grid voltage, in order to avoid formation of a virtual cathode within the space-charge region between the screen grid and plate. Because the screen is grounded by Cc, an electrostatic shield is provided between the oscillator and output sections. Since the cathode is above ground and cathode current flows through the L_p portion of the tank, the full current of the tube is utilized to provide feedback through the tank inductor. Actually, this is a series platefed connection. Since the plate current of the tetrode is independent of plate voltage, being controlled by the potentials on the screen and control grids, no undesired coupling results from the flow of cathode current through L_p. The original derivation of this circuit utilized a variable resistor as R1, and the screen-grid voltage was adjusted for maximum stability. Since a slight increase of screen voltage (caused by supply or load variations) decreases the frequency,

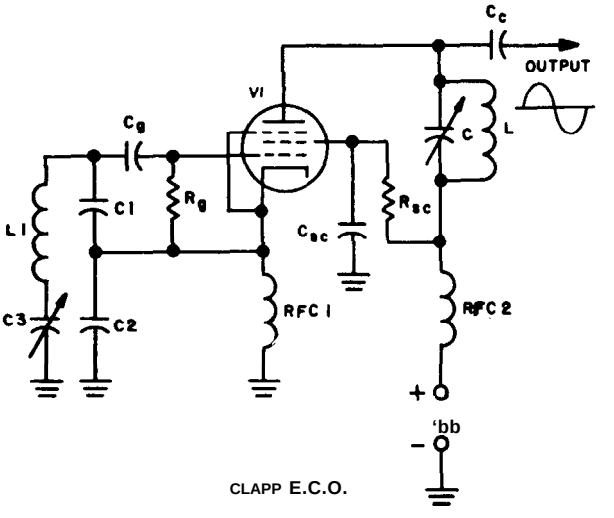
while a similar change of plate voltage increases the frequency, RI can be adjusted for specific screen voltage where a frequency change in one direction will cancel a corresponding change in the other direction and result in freedom from frequency changes due to supply voltage variations.

It should be noted that, if a pentode is used in the tetrode circuit, the suppressor should not be connected to the above-ground cathode, or capacitance coupling will exist between the suppressor and ground and inject an undesired coupling between the oscillator and output sections. Instead, the suppressor grid should be tied to the screen or the plate, making the tube effectively into a tetrode; a pentode with an internally connected suppressor is not usable in this circuit.

A number of electron-coupled-oscillator variations using the oscillators previously discussed are also illustrated. These circuits are drawn in their most usually encountered form; namely, with a plate output tank which may be operated either on the fundamental or a harmonic. Circuit operation is the same as discussed for the basic oscillator with the addition of the electron-coupled circuit theory just completed. The tuned-plate tuned-grid version is not shown because it is usually in the form of a crystal-controlled electron-coupled oscillator, in which the grid tank is replaced by the crystal and the plate tank is the output of the oscillator. This circuit version is discussed later in this section.







Typical E.C.O. Circuits

Failure Analysis.

No Output. Failure of oscillation would cause no output, and could result from the same effects described in the failure analysis section of the Hartley oscillator. In addition, lack of supply voltage caused by open components or a short from plate to ground would effectively stop output. ActuaMy, in this type of circuit tube emission could drop to the point where there is sufficient current for the oscillator section, but practically none for the plate. Therefore,

the circuit should be considered as basically a two-section tube, and checked for oscillator output first and then for continuity through the plate circuit. If the plate output circuit is known to be complete with all components in good operating condition, and the oscillator is operating, lack of plate output indicates a faulty tube.

Reduced or Unstable Output. In addition to those causes indicated for the basic oscillator in the Hartley oscillator circuit discussion, the following should be considered: If the basic oscillator is unstable or has a reduced output, then, with all other conditions equal, the plate output will also be unstable or reduced. Thus the oscillator should first be investigated for proper operation. Since the screen voltage determines the amount of plate current drawn by the tube, a reduction of screen voltage would have a more noticeable effect on the output before it dropped below the point where oscillation could be sustained. An increase in resistance of the screen dropping resistor, if used, is a primary cause of reduced output. Where the plate voltage is supplied through a load resistor, it is common for a high resistance to develop, reducing both the plate voltage and the output. This condition can result in instability if the plate voltage becomes lower than the screen voltage. If the output circuit of the plate includes a tuned tank circuit, a normal increase of output is to be expected when the tank is tuned to the same frequency as the oscillator or to a low-order harmonic. Therefore, any effects causing tank detuning will immediately result in a reduced output. When instability is produced by load variations, it can immediately be assumed that the electron coupling is involved; in this case, the circuit should be checked for capacitive coupling between screen and plate or for a change in voltage ratios d“ue to an excessive voltage drop or a short circuit in either the screen or plate. When the screen current increases abnormally, secondary emission effects or a defective (open) plate circuit can be suspected.

Incorrect **Output Frequency.** Since the output frequency is determined basically by the oscillator portion of the tube, any change in frequency with normal output amplitude indications would indicate that a change of oscillator components or voltages is the most probable cause. If the oscillator frequency change is not due to components in the oscillator itself, the electrostatic shielding between the plate and screen sections has probably deteriorated because of open or shorted bypass capacitors, changes in tube voltages, or the presence of stray capacitive coupling from other causes.

ULTRA-AUDION OSCILLATOR (ELECTRON TUBE)

Application.

The ultra-aud ion oscillator is used to produce a sine-wave output of constant amplitude and fairly constant frequency wit hin the r-f range. It is generally used as a variable-frequency osc illator on the very-high and ultra-high-frequency ranges.

Characteristics.

Uses a parallel tuned L-C circuit to determine the frequency of oscillation, with a capacitive voltage divider form of feedback to control oscillation.

Operates Class C with automatic self-bias for ordinary operation.

Frequency stability is fair-similar to that of the Colpitts operating at high frequencies.

Oscillates easily at frequencies which are too high for other types of oscillators, or at which they are very unstable.

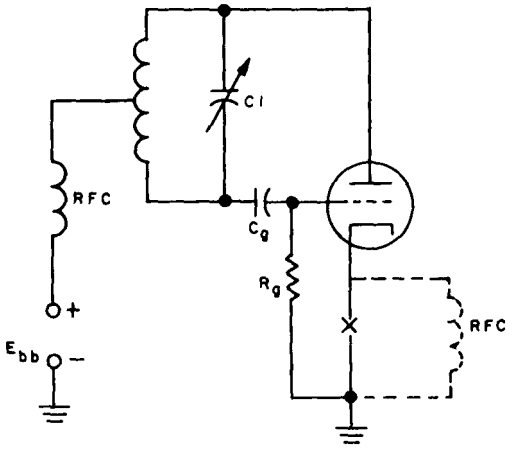
Has only one tuning control, and requires only two leads for connections between the tank and the tube.

Circuit Analysis.

General. The ultra-aud ion circuit is essentially a series-fed Colpitts OIC illator with a parallel-tuned tank c ircu it for determining the frequency of operat ion. The previous discussion of the Colpitts osc il - lator circuit is generally applicable to the ultra-aud ion oscillator. The following discussion will be 1 imited to pointing out the basic differences of operat ion between the two circuits and any special cons iderat ions necessary for high-frequency operation.

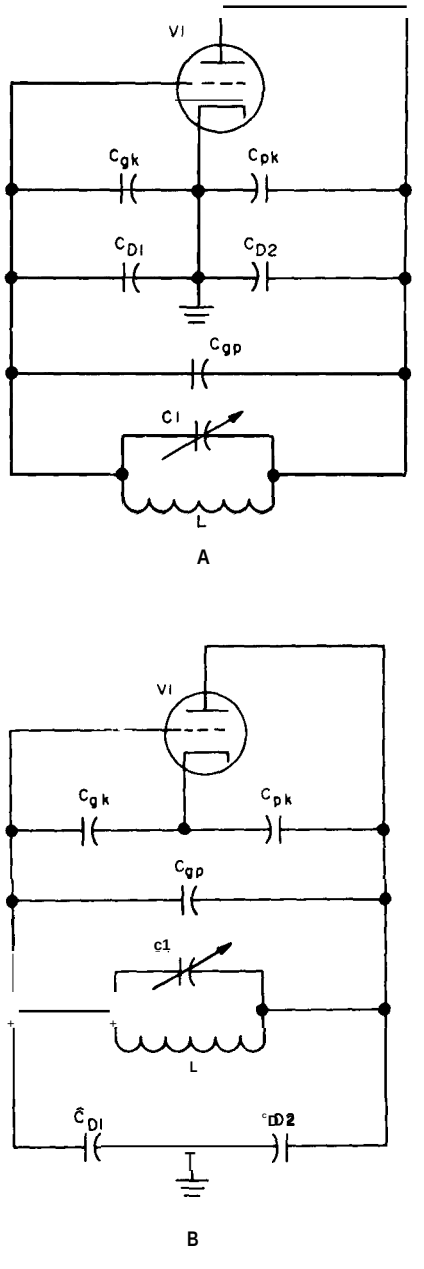
Circuit Operation.

The ultra-audion circuit is shown schematically in the following illustration. The tuned tank circuit consits of L and Cl, connected between the plate and grid of the tube. Shunt grid-leak bias is used (C_g and R_g) because of the series plate feed.



Ultra-audion Circuit

The radio-frequency choke shown in dotted lines in the cathode circuit is sometimes inserted (open cathode lead at x), to minimize the effects of stray wiring capacitance; it is usually self-resonant at the frequency of operation. Although the frequency is determined by the tank circuit, the feedback is controlled by the ratio of grid-cathode and plate-cathode electrode capacitance plus any stray wiring capacitance. Operation is exactly the same as previously discussed for the Colpitts oscillator circuit. To visualize the circuit operation and component relationships, refer to the equivalent circuits shown in the illustrations. Figure A shows the basic ultra-audion without the cathode RFC, and figure B shows the arrangement when the cathode choke is used; each circuit will be discussed separately.



Simplified Equivalent of Ultra-audion Circuit

Since this oscillator is designed for extremely high-frequency operation, assume that the tank inductor L is merely a single wire loop of small diameter connected between the grid and plate, so that the inductor includes the leads to the tube as part of the tank. For the moment neglect Cl; since the inductor is connected between the plate and grid, it is evident that the grid-plate tube capacitance is in shunt with the inductor and forms a part of the tuned circuit, as shown in A. The grid-cathode and plate-cathode tube capacitances form a voltage divider between grid and plate, with the cathode at ground potential. Likewise, the distributed wiring capacitances C_{d1} and C_{d2} are in parallel with the voltage divider and, since the tube-element capacitances are small, they form a major portion of the capacitance in the voltage divider. Referring to the Colpitts theory, it is seen that C_{gk} and C_{pk} in series form the capacitance across the tank inductor. The tube-element (interelectrode) capacitance is usually small, with the grid-plate capacitance being larger than either C_{gk} or C_{pk}. Therefore, the grid-plate capacitance acts as a swamping capacitor across the tank, being equal to, and in most instances greater than, the total seties grid-cathode and plate-cathode capacitances. Thus, when C_t is added across the tank inductor, the tank circuit is relatively independent of the feedback capacitors and is the primary frequency-determining component. Where the stray wiring capacitance is large, it assumes more control over frequency than the tube capacitance does; therefore, disturbing the wiring may cause extreme detuning of the circuit.

To eliminate this stray capacitance effect and allow the tube capacitance alone to control feedback, the arrangement of B is used. In this case the cathode is above ground, as the RFC is chosen to resonate with its self-capacitance somewhere within the tuning range. Wiring and stray capacitances to ground effectively form a balanced capacitive divider across the tank circuit, but have no effect on the feedback circuit. Thus the stray wiring capacitance affects the frequency of operation to some extent, but it does not affect feedback; consequently, the tube that is most effective for the frequency of operation desired can be used.

Failure Analysis.

No Output. Loss of, or improper, feedback will result in non-oscillation, as evidenced by a lack of grid voltage across grid leak R_g and by a high plate current because of operation near zero bias. Since the capacitance to ground of the measuring probe will change the feedback capacitance ratio at the frequencies used, a grid voltage measurement to detect non-oscillation is not as effective as at lower frequencies and in other oscillator circuits. High plate current is usually a more positive indication. At extremely critical frequencies, change of lead dress can produce stray-distributed-capacitance swamping in the unbalanced circuit. Loss of tube gain will also reduce output and, if sufficient, will cause a lack of oscillation. Tank circuit losses are more serious at the very high frequencies because the resistance introduced will prevent operation. Thus poor soldering or shorted turns will have a greater effect than at lower frequencies. Changes in the grid-leak resistance or grid blocking capacitor will also affect operation, and small changes will easily stop oscillation at the higher frequencies. An open or high-resistance connection in the cathode RFC (when used) or the plate RFC will also result in a lack of output.

Reduced or Unstable Output. Low plate voltage or too high a value of grid-leak resistance will reduce the output. Poor soldered connections or high-resistance joints will also reduce the output. Unstable operation will occur if the grid-leak time constant changes because of a change in the component values of C_g or R_g. If present in a sufficient amount, stray capacitance which affects the feedback voltage will also produce instability. A reduction of filament emission will affect both the output and stability. Large changes in ambient temperature may affect output, as well as operating frequency. Tube substitutions may be critical, particularly at the higher frequencies, because of minor variations in intereiectrode capacitance from one tube to another. More than one replacement tube should be tried if the first substitution does not achieve the desired results in output frequency and stability.

Incorrect Output Frequency. Any change in wiring-to-ground capacitance or lead length will affect the frequency. Changes in the tank circuit will have the greatest effect, and changes in the grid-plate capacitance and the grid- or plate-to-ground stray capacitance will have less effect, with the grid-cathode and plate-cathode variations having the least effect. Changes in the plate voltage will produce a greater frequency change at the higher frequencies than at the lower frequencies. The effects of tube

substitution and ambient temperatures on output frequency were discussed above.

R-C PHASE-SHIFT OSCILLATOR (ELECTRON TUBE)

Application.

The R-C phase-shift oscillator is used to produce a constant-amplitude, constant-frequency, sine-wave output.

Characteristics.

Utilizes a single-stage amplifier with resistance-capacitance network to provide in-phase feedback.

Output frequency in audio range; usually fixed-frequency, but may be variable for certain applications.

Frequency stability good.

Operated Class A to obtain a sinusoidal output.

Circuit Analysis.

General. In the basic circuit shown in the accompanying illustration, a sharp cutoff, pentode-type tube is used as the amplifier tube; however, a triode tube can be employed in a similar circuit. Bias voltage is developed across cathode resistor R4. Cathode bypass capacitor C4, by virtue of its filtering action, keeps the bias voltage relatively constant and places the cathode at signal-ground potential. The sine-wave voltage is developed across plate-load resistor R6; capacitor C6 is the output coupling capacitor. Any variation in plate current will cause a corresponding change in plate volatage. These plate volatage variations will also be present at the grid of the tube, since the plate is coupled to grid through the phase-shift network, ZI.

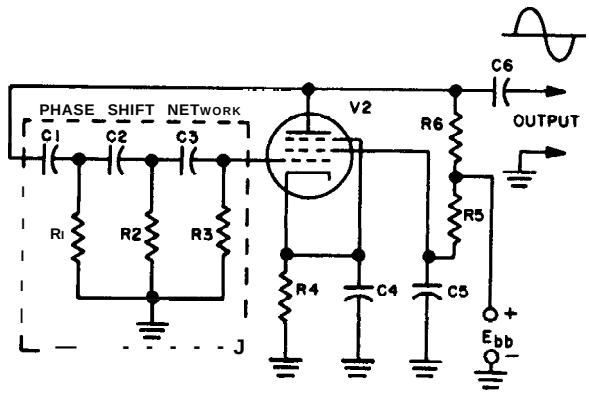


Figure A-465

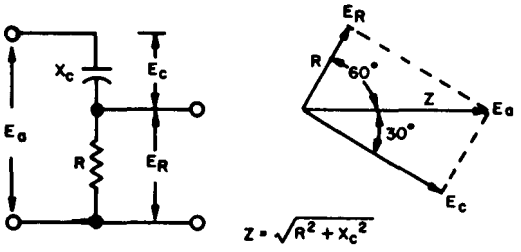
R-C Oscillator Circuit

The operating condition for oscillation is a function of the amount of bias established by the cathode bias resistor, R4. The use of degenerative feedback (cancellation) and regenerative feedback (reinforcement) in the circuit simultaneously for undesired and desired frequencies is made possible by the action of the phase-shift network, Z1. The phase-shifting network is comprised of three separate R-C sections; each section is effectively a series R-C circuit. The three R-C sections are designated as Cl, R1; C2, R2; and C3, R3. The discussion given in the following paragraphs describes the action of only one series R-C circuit, but applies to all three sections.

Phase-Shift Network. It is the property of a capacitor that an a-c voltage applied across the capacitor

lags the current through the capacitor by 90 degrees. In a series circuit containing both resistance and capacitance, however, the voltage lags the current by some angle less than 90 degrees. A series resistance-capacitance circuit is shown in the accompanying illustration, together with its vector diagram.



Vactor Analysis of R-C Circuit

The values of capacitive reactance (Xc) and resistance (R), chosen for each section of the phase-shift network, are such as to cause a total impedance (Z). Assuming that this impedance represents the first section of the phase-shift network, it is across this section that plate-voltage variations are applied. The applied voltage is represented in the vector diagram as Ea. The circuit current passes through resistor R and, since this current leads the applied voltage E_a by 60 degrees, the voltage drop E_R across resistor R leads the applied voltage E_a by 60 degrees. The voltage, E_R, developed across resistor R is applied to the second section and is shifted another 60 degrees in phase, so that the output voltage of the second series R-C section leads E_a by 120 degrees. The output voltage of the second R-C section is applied to a third section, and is again shifted an additional 60 degrees to lead the applied voltage E_a by a total of 180 degrees. The output of the third R-C section is applied to the grid of the tube.

Referring to the vector diagram, it is apparent that, since the capacitive reactance (XC) varies with frequency, the frequencies above or below the frequency for which the circuit is designed will be shifted more or less than 60 degrees by each section of the network, so that the total phase shift contributed by all three sections will be something more or less than exactly 180 degrees. In this manner, the circuit is caused to oscillate at only one frequency; that is, the frequency which is shifted exactly 180 degrees by the phase-shift network, Z 1.

By increasing the number of phase-shift sections comprising the network, the losses of the total network can be decreased; this means that the additional sections will each be required to have a lesser degree of phase shift per section so that the over-all phase shift of the network remains at 180 degrees for the desired frequency of oscillation. Assuming that the values of R and C are equal in all sections, networks consisting of four, five, and six sections are designed to produce phase shifts per section of 45, 36, and 30 degrees, respectively.

Circuit Oparation. Oscillations are initially started in this circuit by small changes in the B-supply voltage or by random noise. If it were not for the action of the phase-shift network, ZI, the voltage variations fed from the plate back to the grid of the tube would cancel the plate-current variations, since the tube introduces a polarity inversion between the grid and plate signals. For example, if the plate-voltage variation at any instant of time was positive, the positive variation would be present on the grid. This positive-going grid voltage would then cause the plate current to increase, in turn causing the plate-voltage variation to go negative and, thus, canceling out the original grid-voltage variation.

Assuming that the plate-voltage variations are applied to the grid 180 degrees out-of-phase with respect to the initial grid-signal voltage, maximum degeneration (or cancellation) will occur. However, if the plate-voltage variations fed back to the grid approach zero-degree phase difference, minimum degeneration will occur. Therefore, if the phase difference between the plate-voltage variations and the initial grid-signal voltage is exactly zero (in phase), the plate-voltage variations will reinforce the grid-signal voltage at any instant of time, causing regeneration; furthermore, these variations will be amplified by the tube and reapplied to the grid, amplified again, and so on, until a point of stage equilibrium is reached and no further amplification takes place. The phase-shift network provides the required phase shift of 180 degrees to bring the voltage fed back to the grid in phase with the initial grid-signal voltage and cause regeneration. The circuit then oscillates under these conditions with relatively constant amplitude.

The phase-shift oscillator is designed primarily for freed-frequency operation; however, the operating frequency can be made variable by using variable resistors or capacitors in the phase-shift network. An increase in the value of resistance or capacitance will decrease the operating frequency; a decrease in the value of resistance or capacitance will increase the operating frequency. In several practical applications of this circuit, three or more fixed R-C sections are employed together with a variable section to provide a limited range of output frequencies which are determined by the setting of a variable capacitor. In this circuit variation, the fixed R-C sections use values of R and C which will provide a phase shift somewhat less than 180 degrees at the operating frequency desired, and the last (variable) R-C section completes the required phase shift to exactly 180 degrees. The operating frequency is then determined by the setting of the variable capacitor.

Failure Analysis.

No Output. Assuming that the applied voltages are correct, the lack of output results from two possible conditions; either the gain of the tube has decreased to a point where gain is insufficient to overcome the losses inherent in the phase-shift network, or one or more sections of the phase-shift network is possibly defective and does not provide proper phase shift of the plate-to-grid feedback signal.

In some cases, the phase-shift network must be replaced as an assembly if found defective. In cases where the phase-shift network is composed of individual resistors and capacitors, the individual components may be checked and replaced if found defective.

Reduced Output. Reduced output is generally caused by decreased stage gain; however, a small reduction in gain may cause oscillations to cease before any appreciable decrease in output can be detected.

Nonsinusoidal Output. Nonsinusoidal output results when the tube is operating on the nonlinear portion of its characteristic curve. Such operation results from a change in B-supply voltage or bias voltage which causes partial or complete clipping of the output waveform.

Output Frequency Incorrect. Since the values of resistance and capacitance that form the phase-shift network determine the operating frequency of the oscillator, any change in component values will be reflected as a change in the frequency of socillation.

R-C PHASE-SHIFT OSCILLATOR (SEMICONDUCTOR)

Application.

The R-C phase-shift oscillator is used to produce a sine-wave output of relatively constant amplitude and frequency.

Characteristics.

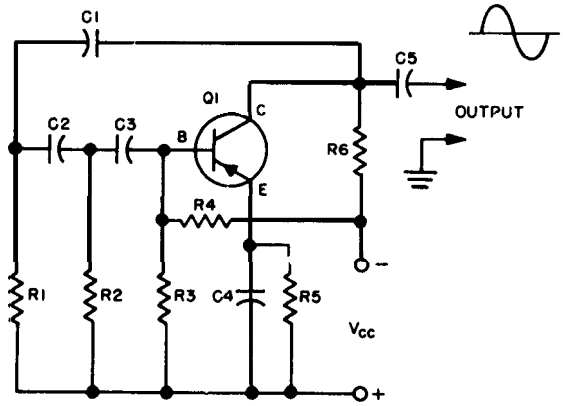
Utilizes R-C network to provide feedback.

Eliminates need for inductors in resonant circuit.

Output frequency is usually fixed within the range of 15 Hz to 200 kHz per second, although the circuit can be arranged to provide an output which can be varied over a wide range of frequencies by changing R or **C.**

Circuit Analysis.

General. A sine-wave **output may be obtained** from an oscillator using an R-C network in lieu of an L-C network. The **R-C** network determines the frequency of oscillation and provides regenerative feedback from the output circuit to the input. In the common-emitter circuit configuration for transistors, the signal between the base and collector is shifted in phase by 180 degrees; therefore, an additional 180-degree phase shift is necessary to provide the correct feedback signal when returned from the output circuit to the input in order to sustain oscillations. The feedback signal of proper phase relationship is obtained using a network consisting of three equal R-C sections; each section produces a 60-degree phase shift at the desired frequency of operation. In the accompanying circuit schematic, the three R-C sections are designated as Cl, RI, C2, R2; and C3, R3.



R-C Phase-Shift Oscillator Using PNP Transistor

Phase-Shift Network. The current in a series circuit comprised of resistance and capacitance is determined by the applied voltage divided by the series impedance of the components

$$(I = \frac{E}{Z}).$$

Since a series R-C circuit exhibits capacitive reactance, the current leads the applied voltage by a specific phase angle. The phase angle is determined by the relationship of resistance and capacitance. The voltage drop produced across the resistance is determined by the current through the resistance and therefore leads the applied voltage by a given phase angle.

For a vector analysis of the phase-shift network, refer to the discussion given for the electron tube R-C phase-shift oscillator.

At least three R-C sections are required to provide the 180-degree phase shift needed to produce a positive (in-phase) feedback voltage. The values of resistance and capacitance for a three-section network are chosen so that each section of the network will provide a 60-degree phase shift at the desired frequency.

The R-C phase-shift oscillator is normally fixed in frequency, but the output frequency can be made variable over a range of frequencies by providing ganged variable capacitors or resistors in the phase-shift network. An increase in the value of either R or C will produce a decrease in the output frequency; conversely, a decrease in the value of either R or C will produce an increase in the output frequency.

By increasing the number of phase-shift sections comprising the network, the losses of the total network can be decreased; this means that the additional sections will each be required to have a lesser degree of phase shift per section so that the over-all phase shift of the network remains at 180 degrees for the desired frequency of oscillation. Since the loss per section is decreased as the amount of phase shift (per section) is reduced, many oscillators employ networks consisting of four, five, and six section; assuming that the values of R and C are equal for each section, the individual sections are designed to produce phase shifts per section of 45, 36, and 30 degrees, respectively.

Circuit Operation. The previous circuit schematic illustrates a PNP transistor in a commonemitter configuration. Resistors RI, R2, and R3 and capacitors Cl, C2, and C3 comprise the feedback and phase-shift network. Resistors R3 and R4 establish base bias for the PNP transistor. Resistor R5 is the emitter swamping iesistor, which prevents large increases in emitter current and causes the variation of emitter-base junction resistance to be a small percentage of the total emitter circuit resistance. Capacitor C4 bypasses the emitter swamping resistor, R5, and effectively places the emiiter at signal ground potentird. Resistor R6 is the collector load resistance across which the output signal is developed. Capacitor C5 is the output coupling capacitor.

Oscillations are started by any random noise in the power source or the transistor when input power is first applied to the circuit. A change in the base current results in an amplified change in collector current which is shifted in phase 180 degrees. The output signal developed across the collector load resistance, R6, is returned to the transistor base as an input signal inverted 180 degrees by the action of the feedback and phase-shift network, making the circuit regenerative.

The output waveform is essentially a sine wave; the output frequency is a fixed frequency. When fixed values of resistance and capacitance are used for the feedback network, the 180-degree phase shift occurs at only one frequency. At all other. frequencies, the capacitive reactance either increases or decreases, causing a variation in phase relationship;

thus, the feedback is no longer in phase and is therefore degenerative. Note, however, that if the components comprising the phase-shift network should change value, the frequency of oscillation will change to the frequency at which a phase shift of 180 degrees will occur to sustain oscillations.

Failure Analysis.

No Output. All input voltages should be measured with an electronic voltmeter to determine whether the input voltage is present and whether the biasing voltages applied to the transistor are within correct operating limits. If it has been established that all voltages are correct, it is likely that circuit losses are present in the phase-shift network or that degeneration in the emitter circuit is preventing oscillation.

Reduced or Distorted Output. All voltages should be measured with an electronic voltmeter to determine whether the rnput voltage is present and whether the biasing voltages applied to the transistor are within correct operating limits. A change in base bias or load impedance or degeneration in the emitter circuit will cause reduced output and possible distortion; however, the output frequency will remain substantially correct.

Incorreet Output Frequency. The correct operating frequency of the R-C oscillator is determined by the circuit constants comprising the phase-shift network; therefore, if the output frequency is incorrect, it is likely that the phase-shift network components have changed vahre in such a manner as to permit a 180-degree phase shift to occur and sustain oscillations at the incorrect output frequency.

WI EN-BRIDGE OSCILLATOR (ELECTRON TUBE)

Application.

The Wien-bridge oscillator is used as a variable-frequency oscillator for test equipment and laboratory equipment to supply a sinusoidal output of practically constant amplitude and exceptional stability over the audio-frequency and low-radio-frequency ranges.

Characteristics.

It uses a bridge circuit to supply positive feedback voltage at the R-C frequency to produce oscillation.

It operates as a Class A linear amplifier and employs negative feedback to produce an almost perfect sine-wave output.

It also uses negative feedback to provide a practically constant output amplitude.

Frequency stability is excellent (2 to 3 parts per million).

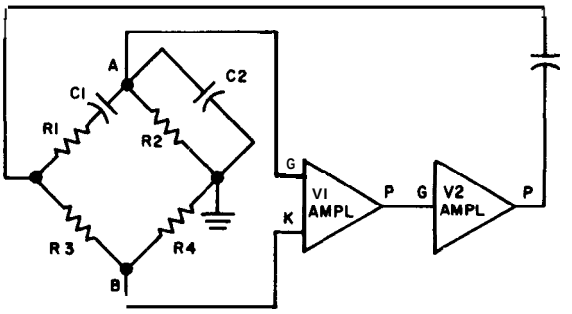
Operates over a wide frequency range (10 Hz to 200 kHz or higher).

Circuit Analysis.

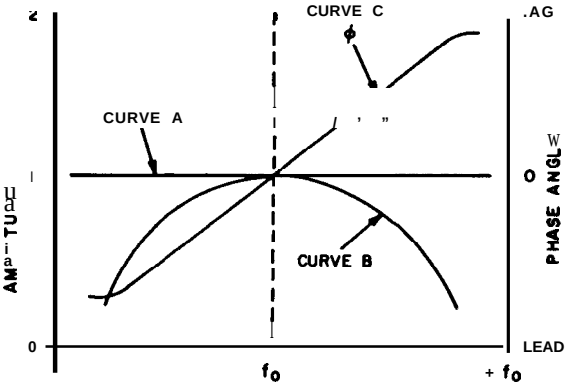
General. When the output of a linear amplifier is applied to its input, a feedback loop is produced. If the feedback is out-of-phase with the input, or negative, the amplifier output will be reduced. If the feedback is inphase, or positive, the amplifier will oscillate. The frequency of oscillation for positive feedback can be controlled by using a frequency-selective network in the feedback loop, such as the Wien bridge. When negative feedback is applied to the cathode circuit of an amplifier, it produces a degenerative effect which reduces the output and improves the amplifier response (this is called inverse feedback). By use of the impedance bridge circuit a differential input can be used to provide oscillation at the desired frequency, with amplitude and waveform control.

Circuit Operation. The basic bridge circuit and feedback loop are shown in the accompanying simplified diagram. In the actual circuit, R4 is a small incandescent lamp with a tungsten filament, and is normally operated at a temperature that produces a dull red or orange glow to give automatic control of amplitude (thermistors are also used). Resistors RI and R2 are of equal value, as are capacitors C 1 and C2, with R3 having twice the resistance of lamp R4 at the operating temperature. The bridge is balanced and the circuit oscillates at a frequency given by:

$$f. = \frac{\quad}{27r\ R1\ Cl}$$



Simplified Wien Bridge Oscillator



Phasing Diagram

It can be seen by inspection that resistors R3 and R4 form a resistive voltage divider across which the output voltage of V_2 is applied. Since these resistors are not frequency-responsive, the voltage at any instant from point B (and the cathode of Vl) of the bridge with respect to ground is dependent upon the ratio of R3 to R4 for any frequency which the amplifier produces at its output. Components RI, Cl, and R2, form a reactive voltage divider, between the output of V2 and ground, which is frequency-responsive, with the grid of V1 connected at point A. Thus the voltage across R2 is applied to the input of the amplifier, between grid and ground. When the voltage between point A and ground is in phase with the output voltage of V2, maximum voltage will appear between the grid and ground; therefore, maximum amplification occurs and a large output voltage is produced by V2. Two amplifier stages, V1 and V2, are used to produce a total phase shift of 180 degrees x 2, or 360 degrees, to insure that the voltage at the output is in phase with the input. Thus reactive networks RI, C 1, and R2, C2, are not required to shift the phase to produce oscillation, but are used to control the frequency at which oscillation takes place.

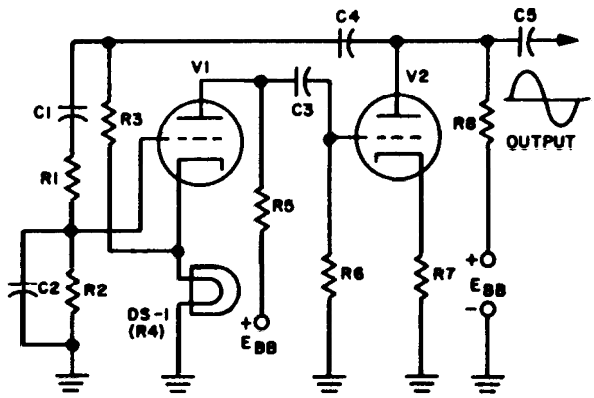
The manner in which these various feedback voltages vary in amplitude and phase are best shown by the following graphic representation. The center (dotted) vertical line (ordinate) represents the frequency at which the oscillator operates. The left and right vertical lines represent a frequency much lower than the operating frequency, and a frequency much higher than the operating frequency, respectively.

Curve A represents the negative feedback between point B of the simplified schematic and ground. Since it is the same at all frequencies, it is represented by the horizontal line covering the middle of the graph. Curve B represents the positive feedback voltage existing between the grid (point A) of VI and ground, or the voltage across R2. At frequencies below the operating frequency (f_o), the series reactance of Cl is large, and the voltage across R2 is reduced. As the operating frequency is approached, the reactance diminishes, and the voltage across R2 reaches a maximum at f.. As the frequency is increased above f_o, the parallel reactance of C2 shunts R2, effectively reducing the voltage across R2. Thus, both above and below $\mathbf{f_o}$ the voltage across R2 is reduced, and only at the operating frequency is it a maximum. At this frequency, the positive feedback voltage (at the grid) is exactly equal to (or very slightly greater than) the negative feedback voltage (at the cathode), amplification is at a maximum for VI and V2. Now consider the phase of the output voltage which is fed back to the input of V1; this is shown by curve C. Because of the phase shift produded by RI, Cl, a phase shift occurs above or below the operating frequency; at the operating frequency, however, the phase change is zero, and the output of V2 is exactly 360 degrees from the input voltage, because of the phase inversion through two stages of amplification. Thus, below $\mathbf{f_o}$ the phase angle leads and above f. it lags. The out-of-phase voltage above and below f_o, together with the

decrease in the regenerative feedback voltage applied to the grid as compared with the degenerative feedback voltage applied to the cathode of V1 effectively stops oscillation at all frequencies except the operating frequency, where RIC1 equals R2C2.

The schematic of the Wien bridge oscillator is shown in the accompanying illustration. Operation is the same as previously discussed. Amplitude regulation is provided by the use of resistor R4, which is an incandescent lamp (DS 1) with a tungsten filament. The current through this lamp consists of the cathode current of V1 plus the ac current at the oscillating frequency through R3 and R4. The design is such that the lamp is operated at a temperature-sensitive point (where the resistance of the lamp changes rapidly with temperature). When the amplitude of oscillation tends to increase, the ac component of the current through the cathode and through the lamp increases. The resistance of R4 (DS1) increases in value because of its higher temperature, and, being in the inverse feedback circuit causes an increase of degenerative feedback. Thus, the amplitude of oscillation is automatically reduced back toward the original level.

In the schematic, resistors Rl, R2, R3, and DS1 and capacitors Cl and C2 from the arms of the Wien bridge.



Wien Bridge Osallator

Tube VI is R-C-coupled through C3 to the grid of V2. R5 is the plate resistor of VI, which produces a 180degree phase inversion. Resistor R6 is the grid resistor for V2 across which the output of V1 is applied. The circuit design is such that the phase shift through the coupling network consisting of R5, C3, and R6 is kept to a minimum. The cathode of V2 is biased by R7, which is left unbypassed to provide degeneration and help keep the output waveform linear. The sinusoidal output waveform is developed across R8 and applied through C4 from the plate of V2 to the input of the Wien bridge as a 360-degree phase-shifted signal, which is now in-phase with the original signal. An output is also taken from the plate of V2 through capacitor C5 for external use. The values R8, C4, and C5 are also chosen to provide an absolute minimum of phase shift, so that the bridge circuit alone determines the feedback frequency. The operation of this circuit is similar to that of the basic circuit described above, with the oscillation frequency being at the frequency where R1 Cl equals R2 C2 and with waveform linearity retained by inverse feedback through R3 and R4. Biasing is a combination of cathode and contact bias, with a larger amount of degeneration (inverse feedback) being provided by the unbypassed cathode bias circuits; the output waveform is extremely linear. The output amplitude is small because of the large amount of degeneration employed, and circuit stability is excellent with a minimum of phase shift or frequency variation.

Failure Analysis.

No Output. Since the feedback loop involves two tubes and a bridge network, it is apparent that an open circuit in the coupling capacitors or bias resistors will stop oscillation immediately. An excessive phase shift caused by the change of coupling network values due to aging may also cause stopping of oscillation at the lower frequencies. It is rather improbable that changes due to the aging of tubes - would result in the stoppage of oscillation, although failure of one tube due to lack of emission or loss of gain could prevent operation. A defective lamp would produce an open cathode circuit in V1 and stop oscillation. Usually a resistance check will quickly isolate the trouble in this circuit.

Reduced or Unstable Output. The principal components to suspect in the case of reduced output are the electron tubes and the degenerative feedback components. An increase of cathode bias resistance with age or leaky capacitors which place improper bias on the grids not only will reduce the output, but will probably distort the waveform. Poor connections and soldered joints will also cause either condition.

4

Following the signal path from grid to plate with an oscilloscope will quickly show lack of amplitude and any waveform distortion. Motorboating at low frequencies may occur through common impedance coupling in the power supply, and should be suspected if oscillations are produced at more than one frequency simultaneously.

Incorrect **Frequency.** Since the frequency is primarily under control of the reactive portion of the bridge network, these components should be suspected when the frequency is incorrect. Where band switching and tuning arrangements are included in the design, faulty switches, poor contacts, and bad connections would be the primary causes of frequency shift.

WIEN-BRIDGE OSCILLATOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

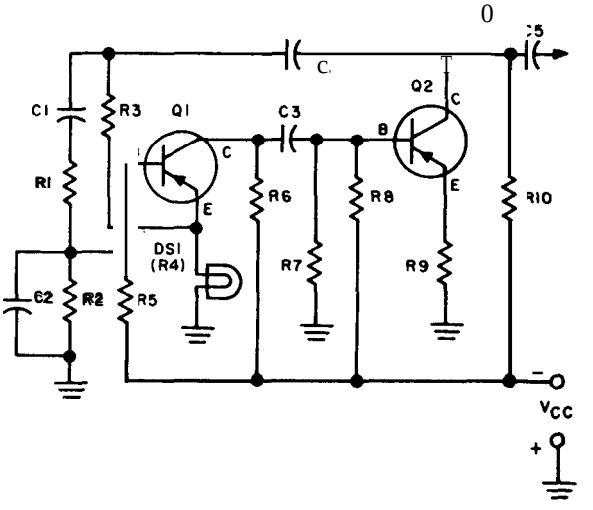
Characteristics.

Same characteristics as electron tube version.

Circuit Analysis.

General. The Wien-bridge circuit consists of a resistive element and a reactive element arranged in a bridge. The resistive element supplies an inverse (negative) feedback voltage to the emitter, and the reactive network supplies a regenerative (positive) feedback voltage to the base of the same transistor. When the bridge is balanced (at the operating frequency), the positive feedback is slightly greater than the negative feedback and oscillation occurs. The operating frequency is determined by the R-C networks employed in the reactive bridge arm. To obtain the feedback, two transistor amplifiers are used, each producing a 180degree phase shift, or the total 360degree phase shift necessary for positive feedback to the base circuit. The negative feedback is obtained by inserting a portion of the feedback into the emitter circuit of the input transistor to produce an out-of-phase or negative feedback. The operation of the bridge circuit and the development of the positive and negative feedback voltages are the same as described for the electron tube counterpart.

Circuit **Operation.** The semiconductor Wien-bridge oscillator is shown schematically in the following figure. Except for bias arrangement, it is practically identical to the electron-tube Wien-bridge oscillator.



Wien Bridge Oscillator Using PNP Transistor

Voltage divider base bias is used, with R2 and R5 biasing Ql, and R7 and R8 biasing Q2. Temperature stabilization is provided by series emitter (swamping) resistors R4 and R9 (see Section 3, paragraph 3.4, for an explanation of this action).

Resistors R3 and R4 form the resistive arm of the bridge across which the output of Q2 is applied; a portion of this voltage appears across R4 (DS-1) as a negative feedback, being in-phase with the emitter voltage. Resistor R4 (or DS-I or RT-1) is either an incandescent lamp or a thermistor with a positive temperature coefficient. When a lamp is used, it is operated at a current which produces a temperature-sensitive point (where resistance varies rapidly with temperature); when a thermistor is used, it is selected to have the desired temperature-current characteristic. In either case, the bias developed across this resistor is in opposition to the normal (forward) bias, and produces a degenerative effect. The feedback voltage is of the same polarity as the degenerative bias and increases the degeneration. However, since the output of the voltage divider is not frequency-sensitive, the feedback voltage is always constant

regardless of the frequency of operation. At frequencies other than the frequency of operation the degenerative feedback predominates and prevents oscillation. At the frequency of operation, which is controlled by the bridge reactive arms consisting of R1, Cl, and R2, C2, the positive feedback is a maximum. This in-phase feedback signal is applied to the base and is slightly greater than the negative feedback at the balance point or frequency of operation which is given by:

$$f. \quad \frac{1}{2\pi R1\ Cl}$$

where R1 is equal to R2, C2 is equal to Cl, and R3 is slightly greater than twice R4.

The amplified output of Q1 is developed across collector resistor R6, and it is applied by capacitor C3 and base resistor R7 which form a conventional resistance coupling network (designed for minimum phase shift), to the input (base) of transistor Q2. The signal is further amplified by Q2, and the voltage developed across collector resistor R1 O is supplied as an output through capacitor C5, and, as a positive feedback through C4 to the bridge network. Note that the Q2 emitter resistor, R9, is not bypassed and that the circuit of Q2 is therefore degenerative. Note also that R1O, C4, and C5 are designed to provide a minimum amount of phase shift. Thus, with a highly degenerative two-stage amplifier and Class A bias, the output signal is essentially a pure sine wave. Since the coupling networks are arranged for minimum phase shift, the phase shift required for regeneration is obtained from the inverting action of the common-emitter configuration, with each amplifier stage providing a 180-degree shift. The feedback input signal is thus shifted 360 degrees in phase to produce a regenerative (positive) feedback independent of circuit parameters. The reactive portion of the bridge (Cl, C2 and Rl, R2) determines the frequency at which maximum amplification (and feedback) occurs. Resistor R4 (DS-1) controls the degenerative feedback and also the output amplitude; that is, when the input signal to Q1 increases, more emitter current flows through R4 (DS-1), and the lamp or thermistor resistance increases, producing a degenerative voltage which opposes the input signal, and tends to restore it to the original operating vahre by reducing the amount of amplification through the feedback loop. This oscillator then, with amplitude stability, temperature stabilization, and degenerative feedback to control the waveform, and with an R-C frequency-selective circuit to determine the frequency of operation provides a signal of excellent stability and pure waveshape for test applications. In order to control the frequency, either resistors R1 and R2 or capacitors C 1 and C2 are changed in value or made variable. With a two-gang variable capacitor and a selector switch (or fixed and variable resistors), a continuous range of frequencies over a number of bands may be obtained.

Failure Analysis.

No Output. If the feedback loop or the coupling network between stages is open because of a defective (open) component or if the supply voltage is too low the circuit will not oscillate. Also, if the coupling capacitors are short circuited, the circuit will not oscillate because the bias circuits will apply an abnormal bias to Q1 and Q2. For example, with C4 shorted the emitter of Q1 will be negatively biased and stop oscillation; with C3 shorted the bias will be provided by the parallel combination of R6 and R8 in series with R7 and most likely will be too large to permit operation. If the R4 bridge arm opens, the emitter will be disconnected from the circuit and the transistor will not operate. A resistance analysis and continuity check of the circuit with a high-impedance voltohmmeter should quickly determine the defective component.

Reduced or Unstable Output. An intermittent open or short in any of the bridge reactive network parts will change the frequency of operation and cause instability. Poor contacts in band switches will also cause instability. When the output is reduced, it is logical to suspect that a defective component in the positive feedback loop is permitting the degenerative action to predominate. Since some positive feedback is required to maintain even a weak oscillation, the reduced output would most likely be caused by increased series resistance in the positive feedback loop, because an open in this loop would stop oscillation. Failure of the transistors with age or reduced output because of lack of emission as in an electron tube would be the least likely cause of reduced output. Normal aging of the transistor will have little effect on oscillation since operation is over only a small

range of amplitude and only small currents are involved. In the event of damage to the transistor, by the application of improper bias or by the application of ohmmeter voltages and polarities that exceed the transistor rating (through poor testing techniques) reduced or no output will occur, but this type of trouble is due to factors external to the circuit and normally should not happen. The supply voltage should be checked for the rated output voltage because a low supply voltage could readily affect the oscillator output.

Incorrect Frequency. Where the frequency of operation differs from the original calibration, the cause might be the aging of circuit parts such as changes in value of R and C in the reactive arm of the bridge or possibly poor switch contacts. Any large change of frequency which cannot be compensated for by retrimming or recalibration is most likely due to defective parts in the frequency arm of the bridge (Cl, C2, RI, R2). If the frequency change is linear, the resistive parts should be suspected; if it is nonlinear, the capacitive parts should be suspected. The circuits of Q1 and Q2 would not effect any frequency changes.

MAGNETOSTRICTION OSCILLATORS

Application.

The magnetostriction type oscillator is usually used at audio, supersonic, or low radio frequencies to provide an extremely stable sine-wave output. This circuit is employed in preference to the crystal type of oscillator at the very low frequencies because of its simplicity, ease of construction, and economy due to the lack of suitable quartz crystals. If finds particular application in laboratory test equipment and low-frequency standards.

Characteristics.

Uses a nickel-steel alloy rod to control the frequency of oscillation.

Feedback is through magnetostriction effects and not through externally coupled inductors.

Provides frequency stability of less than one Hertz at audio frequencies.

Produces an approximate sine wave of relatively constant amplitude.

Circuit Analysis.

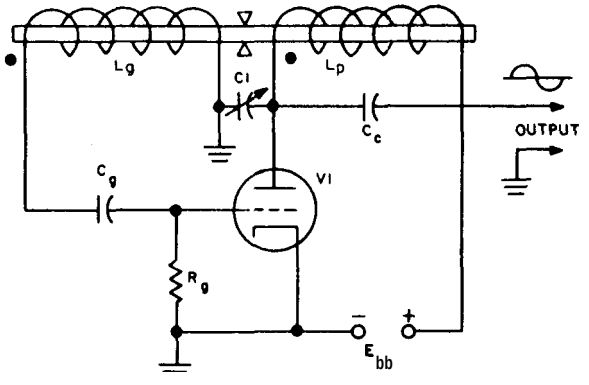
General. The magnetostriction effect is similar to the piezoelectric effect found in crystal oscillators. Instead of using electric charges, however, it operates by the effect of a changing magnetic field. When an iron-alloy rod is placed within a magnetic field, there is a change in length due to the strain placed on the rod by the magnetic field. This compressional strain, in effect, squeezes the rod and makes it longer; when the field is removed, the rod return to nearly its former length. Similarly, when a rod located within a magnetic field changes its length, it also includes a change in the magnetic field, increasing or decreasing the field. The induced change is dependent upon the original direction of the magnetic field and the polarization of the metal rod and its composition. When the change in length of the bar is performed at the resonant (mechanical) frequency of the bar, and the induced change is properly phased to enhance the field that produces the strain, mechanical oscillations are set up at the fundamental frequency of the bar. When clamped in a fixed position at the middle, the bar will vibrate with a flexural motion similar to a tuning fork. The metal composition of the bar determines its efficiency and effectiveness as a resonator. A pure iron rod will oscillate very feebly if at all, and a nickel rod will vibrate strongly, but has poor stability. A combination of nickel and iron, such as Invar or Stoic metal, oscillates strongly but has a poor temperature coefficient. With the addition of a small amount of chromium to the nickel alloy, one of the strongest vibrators and most readily available metals (Nichrome) is produced. A coupper-nickel alloy (Monel) has too little residual magnetism to operate without an external field, but when a permanent magnet is held nearby it oscillates strongly. Temperature effects will cause changes in the bar length and thus affect the frequency of operation; hence, for extreme stability, the alloy must have a small temperature coefficient or temperature control must be used. Operation in this respect is similar to the operation of crystal oscillators.

The change in length at fundamental longitudinal (mechanical) vibrations is on the order of one part in one million (of an inch) for a field of one gauss, using a nickel rod as an example, but when the rod is resonant, the change in length is multiplied one hundred times or more. Thus, at the resonant frequency the mechanical change in length is sufficient to produce a substantial change of field, and control the operation of the oscillator. At the lower audio frequencies, it is desirable to use an oscillator phased to oscillate very feebly, if at all, without the rod. At

supersonic and low r-f frequencies of from 25 to 300 kHz, the oscillator is not very greatly affected if the basic electronic circuit oscillates strongly without the bar. The stability of the bar prevails in either case. By utilizing nickel tubing with a negative temperature coefficient and filling the tubing with Stoic metal which has a positive temperature coefficient, temperature compensation may be achieved to produce a nearly zero-temperature-coefficient bar.

Although operation is possible at 2 MHz and higher, the oscillation is usually feeble and not nearly so strong as that of the conventional quartz crystal; therefore, operation of this type of oscillator is usually restricted to the lower frequencies.

Circuit Operation. The basic circuit of the magnetostriction oscillator is shown in the accompanying illustration. Grid bias is obtained conventionally through gridleak operation ($C_g R_g$), and series plate feed is used. The coils are wound so as to produce the same flux at the plate end of the bar for an increasing plate current or an increasing grid current (they are in-phase). This condition, which is opposite to that of the normal feedback oscillator, produces degenerative feedback, rather than regenerative feedback. In addition, these plate and grid coils have no coupling or only very loose coupling. Thus, the oscillator will normally not oscillate at all, or oscillate only feebly, as a result of feedback between the interelectrode capacitances. Capacitor Cl is the tuning capacitor, and is connected so as to tune both the plate and grid coils (either one along may be tuned if desired). For a single frequency or frequencies within a narrow range of operation, Cl may be fixed and different lengths of rod may be inserted in the coils (similar to crystal plug-in operation) for the different frequencies.



Magnetostriction Oscillator

Assume that plate voltage is applied and that the plate current is producing a steady strain on the rod. If a noise pulse occurs and produces an increase of flux in the plate coil, a compressional wave will be started at the plate end of the bar and will travel to the left toward the grid end. This compressional wave due to magnetostriction will travel through the bar in a manner similar to the propagation of sound waves through a metal bar. When the compressional wave reaches the grid coil, L_g, the lengthening of the bar induces a positive voltage in the grid coil, which is applied to the grid and causes the plate current to increase. The increased plate current induces a stronger field around the plate coil, inducing another compressional wave into the bar. The compressional waves in the bar are reflected from the grid end and travel back to the plate end, where they again are reflected back toward the grid end. When the compressional wave which is reflected from the grid or left end of the bar reaches the right or plate end, a voltage is induced in plate coil L_p by the lengthening of the bar. This voltage, by induction, creates a stronger field around the plate coil. Consequently, the motion of the plate end of the bar is further reinforced, causing it to vibrate more strongly. As a result, another compressional wave is started and the cycle repeats. When the induced and reflected are in phase, the grid-reflected wave arriving at the plate end will always reinforce the induced wave at the plate end, producing at stronger oscillation. Therefore, the length of time it takes for the wave to travel from one end of the bar to the other and return will determine the phasing of the reflected and induced waves. For each length of bar, there will be a specific time taken for a wave to travel to the end and return; if the length is made equivalent to an electrical half-wavelength, each wave will reinforce the other. When the frequency of the tuned circuit (as adjusted by Cl) is approximately the same as the resonant frequency of the bar, maximum reinforcement will occur and maximum mechanical vibration will be produced. With the bar initially unpolarized, operation will occur at the second harmonic. Therefore, the bar is usually permanently magnetized and inserted into the coils so that the field of the plate coil increases the polarization. Operation then takes place at the fundamental frequency (f = v/21 where v is the velocity of sound and 1 is the length of the bar). Adjusting

tuning capacitor Cl for maximum plate current tunes the oscillator to the bar frequency, and feedback is provided mainly through magnetostriction action. Even though there may be some coupling to produce oscillation without the bar, with the bar in place oscillation is strengthened and maintained, being controlled by the mechanical vibration of the bar.

When the bar vibrates at an audio frequency, the sound is audible close to the bar. The operation is similar to the operation of an ac driven tuning fork. The difference is that the tuning fork is actually driven by an ac signal (audio) from an oscillator operating at the frequency of the tuning fork. The tuning fork vibrations induce a magnetic change in a pickup coil around one leg of the fork, thus inducing a stable mechanically controlled sigml back into the driving oscillator. The output of the magnetostriction oscillator is usually capacitively coupled from the plate circuit into an amplifier, operating as a buffer on either the fundamental or the desired harmonic frequency.

Failure Analysis.

No Output. If the bar (or tube) is mechanically defective or the tuned circuit is not adjusted to the bar frequency, no output will result. A plate milliammeter connected in the plate circuit will abruptly indicate a two or three times increase of current when tuning capacitor Cl is adjusted to the bar frequency. Otherwise, the circuit is probably open and should be checked with an ohmmeter.

Low Output. A low supply voltage or poor soldered connections which introduce high resistance into the circuit can cause a reduction of developed signal. Excessive bias developed by an RC grid-leak combination which has too large a time constant can cause blocking of the grid and motorboating. Normal resistance and voltage checks will quickly isolate the defective portion of the circuit.

Incorrect Frequency. Since feedback occurs at the bar frequency and is practically independent of the tuned circuit, only a free-running oscillator operating considerably away from the fundamental bar frequency can produce an incorrect frequency. Actually, once the bar starts oscillating the tuned circuit can be varied over quite a noticeable tuning range before oscillations cease. Thus, small changes in the LC circuit will affect only the output amplitude. The usefulness of this circuit as a frequency stabilizer stems from the fact that only the mechanical vibration of the bar determines the frequency of oscillation. Therefore, at low audio frequencies it will be practically impossible to obtain a different frequency. At r-f frequencies, however, it is possible for spurious oscillations to occur at a frequency not related to the bar frequency because of operation of the electron tube circuit as another form of self-excited oscillator. The frequency of operation should indicate the relative values of components involved, so that the circuit can be examined for lumped capacitance and inductance which could resonate at the undesired oscillating frequency.

NEGATIVE RESISTANCE OSCILLATORS

General.

The negative resistance type of oscillator includes the dynatron, which operates by virtue of secondary emission effects in a screen grid tube, the negative transconductance pentode (or transitron) circuit, and the push-pull (or kallitron) circuit. There is also a possible fourth class, that is, the negative grid resistance type (better known as the tuned grid oscillator with capacitive feedback inherent within the tube); however, this oscillator is not used very much at present. Since it is sometimes included in the negative resistance group, however, it is mentioned here; the interested reader is referred to standard texts for this data.

Negative resistance is a somewhat vague term, which is not very well understood by the layman, or even by many engineers. Actually, it is a term used to describe an imaginary property dealt with in the mathematical analysis of oscillators (and also in amplifiers to a limited extent). It is often erroneously defined as the opposite of positive resistance, which is considered as conventional, or real, resistance. This definition is based on the fact that positive resistance manifests itself by an increasing voltage drop as the current is increased. Negative resistance, on the other hand, manifests itself by a decreasing current as the voltage applied to the device exhibiting the negative resistance is increased, or by a decrease in voltage as the current is increased. While these physical effects are real, the derivation and meaning of the term is purely artifical.

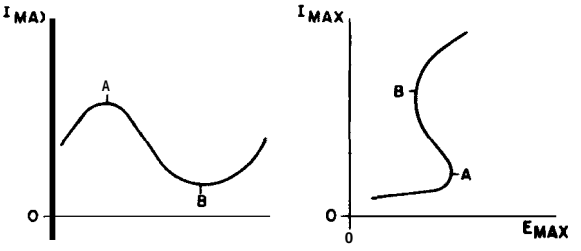
In the mathematical analysis of oscillators, a series of terms have been developed to describe the properties of the circuit; they are then added and equated

to zero. One of these terms is always positive resistance, which is real; it exists in the dc and ac resistance of the coils and leads, and is always assigned a positive value. Therefore, to be equated to zero, the series must contain certain other terms that are of equal, but negative, value. It is this negative resistance which, when it equals the positive resistance mathematically, permits oscillation. With any type of oscillator, both the positive and negative resistance concepts apply. In the oscillators considered previously, the negative resistance is created by an external circuit, such as an inductive or capactive feedback arrangement. In the true negative resistance type of oscillator, however, the negative resistance is an inherent property within the tube or device which exhibits it. There is no circuitry involved other than the requirements to supply a tank circuit or inductor in parallel (or sometimes in series) with the negative resistance. The basic simplicity of this type of circuit makes it useful if its inherent defects do not nullify the advantage of its simplicity.

A more effective way to understand ***negative resistance*** is to visualize it as a generator of energy. In contrast to positive resistance, which ***dissipates*** energy at a rate proportional to the square of the impressed voltage or current, negative resistance ***generates*** energy at a rate proportional to the square of the impressed voltage or current.

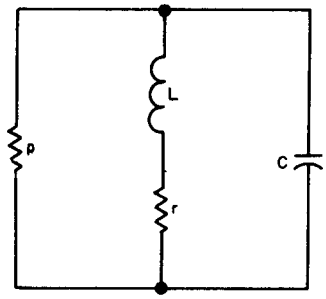
Negative resistance may be either voltage-controlled or current-controlled; the accompanying figure illustrates the volt-ampere characteristics of these two types of control. As can be seen, each type is the exact inverse of the other. In the voltage-controlled device, as the voltage is increased the current rises to a peak, and then drops to a low value from A to B (this is the negative resistance region) and then increases to a new peak value thus the voltage is a single-valued function of the current. In the current-controlled type, the voltage varies similarly as the current is increased, and the current is a single-valued function of the voltage. Note the characteristic "lazy S" pattern of these curves, which makes them easily identifiable. The oscillators described in the following discussions are all of the voltage-controlled type.

When either a parallel resonant or a series resonant tank circuit is connected across a negative resistance device, it can be mathematically demonstrated that oscillation will occur if certain conditions are satisfied. The basic equivalent circuit of a negative resistance oscillator is shown in the accompanying illustration. L, C and r in the figure represent the tank inductor, capacitor, and tank resistance respectively, and p represents the negative resistance.



Voltage-Controlled

Voltage-Controlled Current-Controlled



Basic Negative Resistance Oscillator Equivalent Circuit

It can be shown mathematically that when p is smaller than the ratio L/rC the amplitude of oscillations will build up. On the other hand, when p is greater than the ratio of L/rC, the oscillations will diminish in amplitude and eventually cease. The criterion for constant oscillation with no change in amplitude is that p be just equal to L/rC. Thus for oscillation to occur, p must be less than, or equal to, L/rC.

If a generator is substituted for p in the basic figure, it can be understood how the basic concept of negative resistance applies. The region where the device exhibits a negative resistance normally covers a limited range, and is never associated with positive resistance. That is to say, when the device is operated as a conventional feedback oscillator, the operating region is beyond that portion associated with the negative resistance properties. Thus, devices which exhibit negative resistance can also be employed in circuits involving the positive resistance region of operation without any conflict with their negative resistance characteristics. For example, the same type of tube which is particularly useful in the dynatron oscillator (because of its inherent secondary emission at plate voltages lower than the screen voltage) may also be used in conventional LC feedback oscillator circuits operating at higher plate and screen voltages in the so-called positive region. For good waveform, it is important that large capacitance values be used in the tank circuit of the negative resistance oscillator, as small capacitance will cause distorted output waveform.

DYNATRON OSCILLATOR

Application.

The dynatron oscillator is used to produce a stable sinsonidal output over the low, medium, and high-frequency r-f ranges (and sometimes the audio-frequency ranges). It is used mostly as a signal generator for laboratory or test equipment purposes or as a bent-frequency oscillator in receivers.

Characteristics.

Uses the negative resistance of a screen-grid tetrode to produce oscillation.

Provides very good stability, but at a low output amplitube.

Uses a two-terminal tuned circuit to determine the frequency of operation.

Circuit Analysis.

General. The dynatron circuit was originally based upon the use of the type 24 screen-grid tube, which exhibited considerable negative resistance at low plate voltages. The negative resistance was due to secondary emission from the tube plate. Present day tube manufacturing and design methods have minimized the undesired secondary emission, but it still exists at very low plate voltages in most tetrodes. Secondary emission occurs when the plate is much lower than the screen voltage, because of bombardment of the plate by electrons which have passed the screen grid. With high or normal plate voltage these electrons are attracted back to the plate and have no effect. With low plate voltage, however, the field of the grid extends into the plate region and attracts the secondary emitted electrons knocked out of the plate. Thus, the plate current is reduced by the amount of secondary electrons captured by the screen grid, and the screen current is increased. The accompanying figure illustrates typical plate and screen currents for a type 24 tube. These curves have the distorted “lazy S“ shape characteristics of negative resistance as explained previously in the general discussion. When the tube is operated in the region of negative slope with a tank circuit connected to either the screen or the plate, oscillation will occur. Maximum screen current flows when the plate current is minimum (point B on the curve). Useful oscillation is

possible between points A and B, with the oscillator adjusted to work at the midpoint of this negative resistance region. From points B to C and beyond is the positive resistance region, which cannot be used for dynatron operation. It can be clearly seen that the plate of the dynatron must be operated at extremely low voltages; therefore, the amplitude of oscillation is limited and the circuit is capable of a only a small output. The output amplitude is controlled by adjusting the grid voltage, which varies the slope of the negative resistance region.

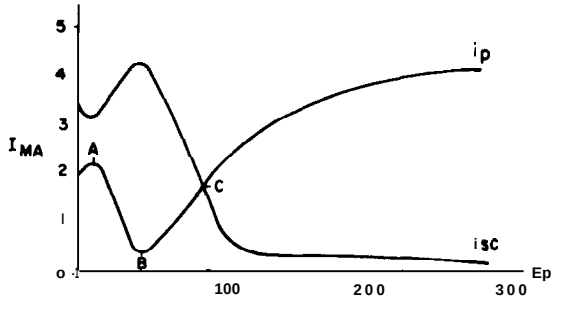


Plate and Screen Current Relationships

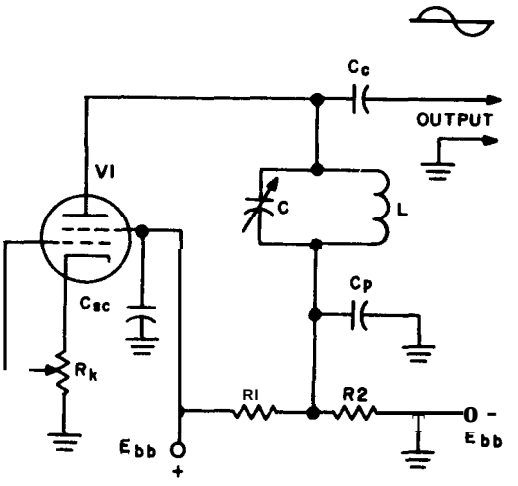
One of the advantages of this type of oscillator is that it requires only a single coil with tuning capacitor, instead of a tapped coil or an additional tickler winding. Thus its extreme simplicity made it popular. On the other hand, since secondary emission varies with the age and emission of the tube, and since tubes of the same type and manufacture have widely different secondary emissions, it is necessary to have a plate voltage control to permit adjustment for stability with tube aging and the use of different tubes. Because of the low output and the variation of secondary emission from tube, this circuit is not very widely used today.



Dynatron Oscillator

The grid is biased by means of potentiometer R_k when cathode current flows. Adjustment of the grid arm of the potentiometer effectively places the grid at a more negative potential with respect to the cathode in one direction of rotation, and at a less negative potential in the other direction of rotation. The screen is connected to the high side of the plate supply and bypassed by C_{sc}, and the plate is connected to a voltage divider consisting of R1 and R2. Thus, the plate voltage is reduced below the screen voltage. Capacitor C_p is the conventional series-feed bypass. The tuned tank, consisting of L and C, is placed in the plate circuit, although it could also be placed in the screen circuit. The output is taken capacitively from the plate by Cc.

The inherent stability in this type of oscillator is based upon the action of the tank circuit primarily, as in other types of the LC oscillator. Although operation at a low plate voltage limits the output to a low value, it also contributes some stability, because

load changes are a smaller percentage variation than in other self-excited power type oscillators. Since the feedback is inherent in the tube, rather than being provided by an external circuit, changes in tube element capacitances are not as effective in causing frequency changes, thus contributing to the stability of this type of oscillator. Therefore, a dynatron which is properly adjusted for the correct operating point and plate voltage is practicrdly equivalent to the electron-coupled LC oscillator, as far as frequency stability is concerned.

Operation at a low amplitude insures better linearity and less harmonic content in the output, accounting for the relatively pure output waveform of this type of oscillator. Variation of the grid voltage changes the slope of the negative resistance characteristic and thus governs the operating amplitude.

Detailed Analysis. Mathematically it can be demonstrated that when an LC tank circuit is connected to a negative resistance element oscillations will start and continue, with the negative resistance supplying the losses caused by the positive resistance of the tank. In the conventional external feedback oscillator, this same action is obtained by the feeding back of output voltage in-phase with the input voltage. In the dynatron it is inherent within the electron tube. Thus, in the conventional feedback oscillator, as the plate voltage is increased, the plate current is also increased and the amplitude of oscillation is primarily limited by the power supply voltage. In the dynatron, with the plate operating at a lower voltage than the screen, as the plate voltage increases the plate current decreases. As the plate current decreases, since the supply voltage remains substantially the same (considering a regulated supply), there is more voltage available for the load. Thus, as the tube current becomes smaller, the voltage across the load builds up. In effect, the tube is releasing energy from the power supply instead of absorbing it. Therefore, the tube can be considered as a generator which supplies power to the tank circuit. The generated energy is used to overcome the losses in the tank circuit, and the oscillation builds up until an amplitude is reached where a state of equilibrium is obtained, and continuous oscillations are produced without any external feedback circuitry. All that is required is to shock excite the tank circuit into oscillation, and once started the action continues. Starting is produced by turning the circuit on. The initial rush of current to the plate produces a transient oscillation in the tank circuit, at the approximate frequency to which it is tuned. In the absence of negative resistance, this oscillation would quickly die out, being damped by the positive resistance of the tank. The inherent negative resistance of the tube, however, provides an effective in-phase feedback. Consider the tank circuit and its operation. In an oscillator condition, the coil and capacitor are interchanging energy. First the capacitor tends to charge as the transient increases, and the charging current flows through the inductor in a direction which increases its magnetic field. As the transient reaches its peak and drops, the magnetic field about the coil collapses and induces a reverse voltage in the coil, which is in the direction of capacitor discharge. Consider now the instantaneous ac component of plate voltage. As the transient increases in amplitude, the total effective plate voltage is increased and the instantaneous plate current is reduced. With a lowered current the plate voltage tends to rise, and this constitutes a higher effective plate voltage. Thus, the action within the tube is such as to aid the transient, and the tube is quickly driven to its saturation region (point Bon the plate and screen curves shown previously). At saturation the plate current does not change, so the inductor field collapses and the reverse cycle occurs. Since the voltage is decreasing, the plate current increases; this in turn, reduces the available plate voltage, and the tube absorbs the power. The transient is now falling and effectively subtracts from the total applied plate voltage. Thus the plate voltage is driven in a negative direction (a peculiarity of the dynatron region), whereupon the plate current change reverses itself. At this time the capacitor, which is discharged, proceeds to charge again and the cycle is repeated. The limits of operation are set by the applied grid bias, which determines the operating point, and the static plate voltage.

Unfortunately, the effects of secondary emission are not completely controllable, and the setting for optimum amplitude and efficiency for each tube of the same type varies. The negative resistance oscillator circuits which follow are considered to be better from the standpoint of stabiiity and criticalness of adjustment than the dynatron circuit. When the tank tuning capacitance is reduced to that of the tube elements and leads, the output waveform is considerably distorted, and operation approaches that of the relaxation oscillator with the frequency of operation being set by the time constant of the resistance

and capacitance in the circuit, With the turned tank, however, the angular frequency of oscillation is approximately

$$\omega = \sqrt{\frac{r+p}{p}\,\frac{1}{LC}}$$

Since r, which represents the ac resistance of the coil and leads, is usually only a few ohms, whereas the negative resistance p is seldom less than two or three thousand ohms, the frequency of oscillation is practically equal to

$$f_o = \frac{1}{2\pi\sqrt{LC}}$$

As a result, small changes in p which result from changes in the supply voltage have negligible effect on the frequency of oscillation at the threshold value, where p is equal to or less than L/rC.

Failure Analysis.

No Output. A no output indication will be caused by lack of supply voltage, or by a plate voltage which exceeds the screen voltage and places operation in the positive resistance region, producing a non-oscillatory condition. An increase in coil resistance due to poor contacts or soldered joints can place operation in the non-starting region; such resistance will be so high that it will be revealed by a resistance analysis. With normal voltages applied and no oscillation, either the tank circuit is short circuited, or the secondary emission has changed and requires an adjustment of plate, screen, and grid voltages or a change of tubes. A change of load can change the negative resistance values and place the circuit in the nonoperative region. In this case, removing the load will restore normal operation and indicate the source of trouble.

Reduced Output. A primary cause of reduced output, which is common in this circuit, is for a change to occur in secondary emission, requiring a readjustment of operating voltages or the selection of another tube. A change in grid voltage to an operating region of small slope will also cause an amplitude change and reduced output. Such a condition will be evident by a grid voltage check. The reduction of applied plate voltage through a defective voltage divider can also cause the same condition. Thus, voltage and resistance checks should quickly reveal any defective components.

Incorrect Frequency. Changes in load or changes in applied screen and plate voltages will change the frequency slightly, but the effect is usually negligible. Since the tank circuit is the primary frequency-determining portion of the circuit, any large frequency change will be due to a change in tank circuit parameters. Usually the tuning range is sufficient to adjust the circuit to the desired frequency. Once properly set, any noticeable frequency change indicates either ambient temperature effects or poor contact resistances (soldered joints) in the tank circuit.

TRANSITRON (NEGATIVE GM) OSCILLATOR

Application.

The transitron, or negative transconductance (g_m), oscillator is used to supply a stable sinusoidal waveform at audio and low or medium radio frequencies. It is used mainly in test equipment, receivers, and laboratory instruments that require a simple band-switching oscillator.

Characteristics.

Uses the negative transconductance effects of a pentode to provide negative resistance type of oscillation.

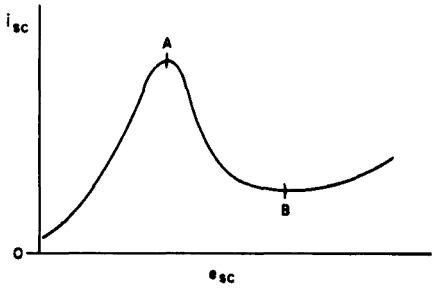
Uses an external capacitor coupled between the suppressor and screen to obtain negative transconductance.

Utilizes a two-terminal tank circuit to determine the frequency of operation.

Circuit Analysis.

General. When a negative voltage is applied to the suppressor grid of a pentode, it will cause electrons that have passed through the screen grid to return to the screen grid. If the negative suppressor voltage is decreased (made more positive), more electrons will be attracted to the plate, and the screen-grid current will be reduced. Thus, the screen-to-suppressor transconductance is negative. With proper voltages and circuit arrangements, the screen current will decrease with a small positive voltage increases on the suppressor, even when the screen voltage is also increased an equal amount. The accompanying figure shows a typical screen current versus screen voltage characteristic curve of a pentode which has its suppressor coupled to the screen through a capacitor. The

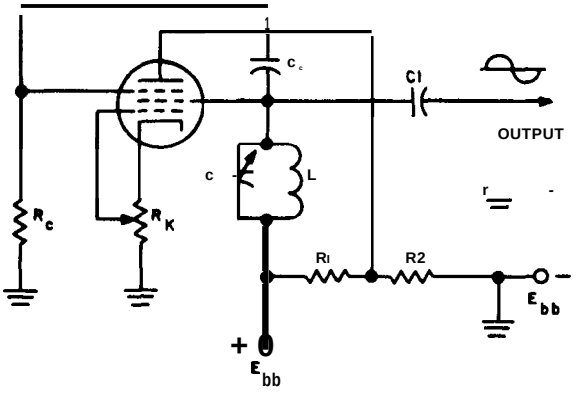
typical distorted "lazy S" pattern indicates that there is a negative slope. There, oscillation will occur if an LC tank circuit is connected in the screen circuit.



Negative Transconductance Characteristic

If the control grid is biased negatively, the bias may be adjusted to control the amount of negative resistance developed. With the negative transconductance arrangement, the control and development of the negative resistance effect is by electrode voltages and circuit parameters. Thus, the transitron oscillator does not depend upon secondary emission for its operation; therefore, it does not have the undesirable features of the dynatron oscillator, although the circuit is somewhat more complicated.

Circuit Operation. The schematic of the basic transitron oscillator is shown in the accompanying figure. In this circuit, the LC tank is inserted in the screen grid circuit, and the screen is capacitively coupled to the suppressor through capacitor Cc. The output is taken capacitively from the screen circuit through Cl.



Basic Transitron oscillator

Cathode bias is employed, and the grid is returned to potentiometer R_k. Variation of the negative grid bias permits the slope of the negative transconductance region to be controlled. Thus, both output and linearity control are effected. Note that the plate is placed at a reduced potential with respect to the screen grid by means of the voltage divider consisting of RI and R2. The basic arrangement is the same as in the dynatron oscillator, except that the pentode has an additional element, the suppressor. Since the suppressor is located between the screen and plate, it will control the current between these elements when properly biased. To produce the negative transconductance, the screen is capacitively coupled through C_c to the suppressor, and the suppressor is returned to ground through R_c. As a result of these connections, instantaneous ac variations of the screen voltages are effectively applied to the suppressor, and dc variations are effected through the RC network in accordance with the time constant. For proper operation, it is imperative that the reactance of C_c at the operating frequency be very small as compared with the resistance of R_c. This is necessary to ensure that practically all of the feedback voltage appears across R_c and that very little voltage divider action occurs, as when C_c has a large value of reactance. The effect of the voltage divider action is to reduce the feedback and produce a higher negative resistance, which is not desired.

In a pentode, the movement of electrons from the cathode to the screen and plate constitutes the screen (i_{sc}) and plate currents (i_p), respectively. Variations in suppressor voltage (e_{su}) have negligible effect on the total number of electrons leaving the cathode because of the shielding effect of the screen and control grids. The suppressor grid voltage, however, does control the division of the space current between the screen and plate. Making the suppressor voltage I_{CSS} negative results in a greater number of electrons passing through to the plate; consequently, the plate current, i_p, increases while the screen current, i_{sc}, decreases. On the other hand, making the suppressor voltage more negative results in fewer electrons being passed through to the plate, and a decrease of i_p, with an increase in i_{sc}. Typical variations of the screen and plate currents with changes in the suppressor voltage are shown in the accompanying graph. A decrease of

i_{sc} with an increase of e_{su} indicates the existence of a negative transconductance between the screen suppressor grids. Since the reactance of C_c is negligible at the frequency of oscillation, the alternating components of the screen voltage and the suppressor voltage are of the same polarity. Therefore, an increase in screen voltage instantaneously increases the suppressor voltage and, because of the negative transconductance, decreases the screen current. Thus, the negative transconductance of the tube produces, in effect, a negative resistance between the screen grid and cathode.

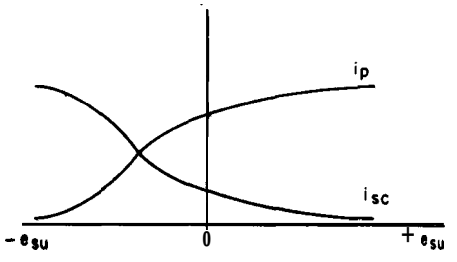


Plate and Screen Currents vs. Suppressor Voltage

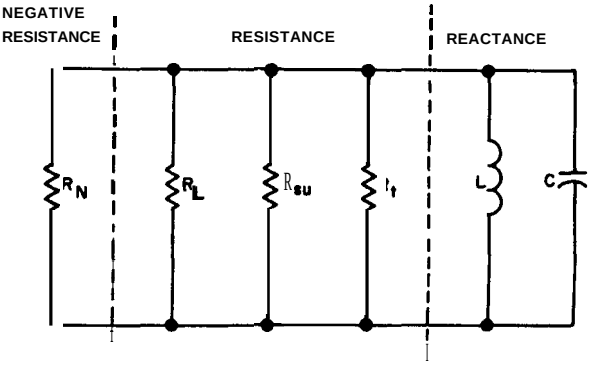
When the transitron oscillator is adjusted so that the negative resistance is smaller than the vrdue needed to produce continuous oscillations, any brief oscillation or transient caused by closing of the plate switch is amplified. As a result, the operating range on the screen current versus suppressor voltage characteristic curve is increased, and, because of the curvature of the characteristic, the average slope of the part used is decreased. Since this is the same as increasing the value of the negative resistance, the amplitude of oscillation increases until the value of the negative resistance is such that it maintains a constant amplitude of oscillation.

Detailed Analysis. For oscillations to be sustained, the losses in the tuned circuit must be replaced by energy supplied from the electron tube. The losses produced by the circuit resistances are best illustrated in the accompanying transitron equivalent circuit.

The negative resistance presented by the tube to the tuned circuit is represented by R_N, and the tank circuit losses by R_t in parallel with the LC tank. The shunt resistance of suppressor return resistor R_{su} and load resistor R_L are effectively in parallel with the negative resistance and the tank loss resistance. The sum of R_L, R_{su}, and 1$ is the effective positive resistance. The current in R_N must be equal and opposite to the total current through this positive resistance. If R_N is larger than the positive resistance, the current through R_N is too small and the oscillations die out. If R_N is smaller, the current is too large and the oscillations increase in amplitude. When the current through R_N is just sufficient to sustain oscillations, the circuit is the equivalent of a simple LC combination, and the frequency of operation is:

$$f = \frac{1}{2\pi\sqrt{LC}}$$



Transitron Equivalent Circuit

Failure Analysis.

No Output. The loss of plate voltage due to defective divider resistors, the lack of screen voltage due to an open tank coil or a defective supply source, or a defective tube will cause loss of output. A change in the value of the feedback capacitor can reduce the feedback below the amount required for oscillation, depending upon the frequency of operation. High resistance coil contacts (poor solder joints) will also cause circuit losses high enough to stop operation. Since there are relatively few components, trouble should easily be isolated by a voltage check to determine proper operating conditions, and by a resistance analysis if the voltage are apparently correct. It should not be necessary to select tubes to produce oscillation, because, unlike the dynatron, the circuit is operable regardless of secondary emission.

Restoring oscillation by the selection of tubes indicates insufficient feedback between the screen and suppressor due to incorrect or changed values of R_c or Cc.

Reduced Output. Excessive reactance in the suppressor-screen feedback circuit can change the negative resistance value and reduce the amplitude of oscillation. However, reduction of output is more likely to be caused by excessive bias on the control grid, which will restrict operation to a very limited range of negative slope. Also, excessively low screen and plate voltages will cause a reduction in over-all amplitude, even though the tank circuit at resonance will provide an increase of output. In oscillators covering a wide frequency range where the feedback capacitor value is changed by a switching arrangement to produce optimum feedback, difficulties with switch contacts may cause loss of amplitude on some of the ranges.

Incorrect Frequency or Instability. Since the tank circuit is the primary frequency-determining element, normal variations of frequency due to aging of components should be easily compensated for by adjustment of the tuning capacitor. After the capacitor is adjusted, if the frequency varies it is probably due to the effect of ambient temperature changes or r-f heating on the tank inductance and distributed capacitance.

KALLITRON (PUSH-PULL) OSCILLATOR (ELECTRON TUBE)

Application.

The push-pull negative resistance type of oscillator, known as the ***Kallitron,*** is used to produce pure audio-frequency waveforms, with low harmonic content. Its use is mostly confined to laboratory type audio generators and test equipment.

Characteristics.

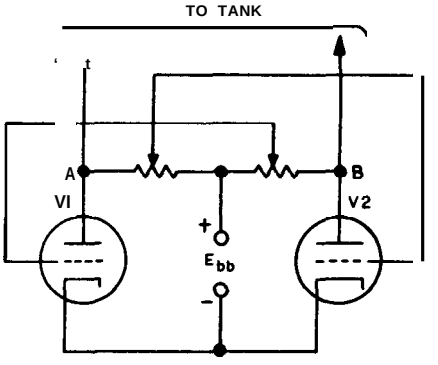
Uses two tubes in a push-pull feedback arrangement.

Uses a tuned LC tank to determine frequency of operation.

Produces a sinusoidal output waveform, with low harmonic content.

Circuit Analysis.

General. In a balanced push-pull circuit with no input voltage applied, the quiescent plate currents and voltages are equal. When an input is applied, first one tube conducts, and then the other conducts. Assuming a sine wave input, as tube 1 goes through a positive grid excursion, it develops an inverted polarity output across its plate load resistor. If this inverted output is applied to the grid of tube 2, a positive output will be developed in the plate load of tube 2. If the plate output of tube 2 is fed back to the grid of tube 1, the positive input excursion will be enhanced, and the tubes will be driven in opposite directions equally. As the input waveform changes polarity the opposite action occurs, with grid 2 now being driven positive and grid 1 negative. If a tank circuit is connected between the plates of these tubes, oscillation will occur because of current flow in the external circuit, and the frequency will be determined mainly by the tank circuit resonant frequency. The accompanying figure shows an elementary oscillator circuit of this type, with the tank connected between points A and B (bias voltage is not shown for simplicity).

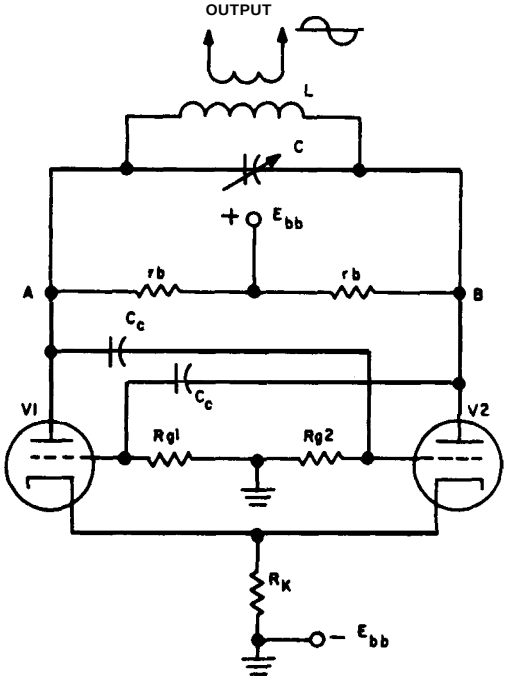


Elementary Push-Pull Oscillator

As can be seen, the circuit is basically a simple multivibrator. However, in a multivibrator the current (and voltage) changes abruptly from one value to another and is determined mainly by the values of R and C in the circuit. In the Kallitron oscillator, however, the oscillation is controlled by the tuned tank circuit, and there are no abrupt changes, the transition from one state to another or conduction being smoothly sinusoidal. Because the plate voltage of each tube increases when the plate current decreases, there is in effect a negative resistance between the

two plates. The second harmonic output is effectively reduced by the push-pull action, and the third harmonic content is reduced by the tuned circuit. Therefore, the output waveform is relatively pure, having a minimal amount of harmonic distortion.

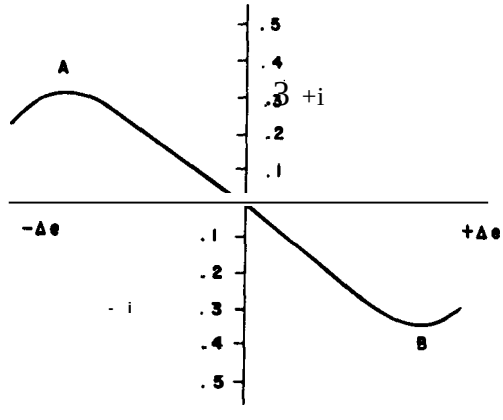
Circuit Operation. The schematic of a typical Kallitron oscillator is shown in the accompanying illustration. Usually a dual triode in one envelope with its accompanying circuitry is used to provide, in effect, a single tube oscillator. To keep the push-pull relationships in balance, the output is generally taken inductively, but it may be taken capacitively.



Kallitron (Push-Pull) Oscillator

Cathode bias is provided by R_k. Since the tubes operate in push-pull through a common cathode bias resistor, it can be seen that as the plate current of tube 1 increases the bias also increases, and, being applied to the V2 cathode, it reduces the plate current of tube 2. On the other half cycle, the operation is reversed, with the VI current decreasing and the V2 current increasing. The net result is a negligible change in cathode current. Feedback is obtained by cross-connecting the grids and plates through CC. Thus as the grid of V1 rises, the plate current increases, causing the voltage on V2 grid to fall, which increases the plate voltage of V2 and feeds back a rising grid voltage to VI grid, Likewise, on the opposite cycle the conditions reverse. The output amplitude is controlled by proportioning the grid resistors, R_g, and the grid coupling capacitors, Cc. The amplitude is also affected to some extent by the applied plate voltage and the values of the plate load resistors. However, the most effective method is to adjust the bias by means of R_k to obtain the desired amplitude. Actually, C_c and R_g operate essentially as grid leaks. When the reactance of the grid coupling capacitor is small in comparison with the grid leak resistance at the lowest operating frequency, the feedback is at a maximum, and the tank circuit can be connected in either the grid or plate circuits.

A typical curve showing plate voltage change versus external current flow between points A and B exhibits a continuous negative slope over most of its range, indicating typical negative resistance characteristics, as illustrated in the accompanying figure.



Typical Current-Voltage Characteristics

With the feedback action now understood, it can be clearly seen that when the LC tank is connected between points A and B it is alternately charged and discharged at its natural resonant frequency. Since the voltage on one plate is increasing when the voltage on the other tube plate is decreasing, points A and B are always of opposite potential. With a low-resistance tank circuit in place, the negative resistance action, produced by the tube operating at reduced

conduction, effectively supplies energy to the tank circuit to overcome its positive resistance losses, so that continuous oscillation is maintained.

Failure Analysis.

No Output. Lack of plate voltage due to an increase in external load resistance or short-circuiting of the supply will cause lack of output. Since the negative resistance primarily depends on the amplifying action of the tube, insufficient amplification may also result in no output. Any change in the feedback circuit which reduces the feedback below the critical point can also stop oscillation. Since these conditions are generally produced only by an open- or short-circuited component, resistance and voltage checks should quickly isolate the defective component. Tank circuit losses resulting from shorted turns or from increased resistance due to poor contacts (poor solder joints) can also be a contributing cause. Shorted turns will show up as a change in frequency if the circuit oscillates at all, and excessive resistance will cause reduced amplitude if it does not entirely stop oscillation.

Reduced Output. Excessive bias resistance will cause a reduction of amplitude. A reduction of applied plate voltage will also reduce the amplitude, but it can easily be detected by a voltage check. Changes in the feedback capacitors or the grid-leak resistors will also reduce the amplitude. Checking the capacitor with an in-circuit capacitor analyzer will quickly determine whether the capacitance is correct, and a resistance analysis will determine whether a grid-leak resistor has changed value. A decrease in the amplification factor of the tube with aging can also reduce the output.

Incorrect Frequency or Instability. Since the tank circuit is the primary frequency-determining element, major frequency change would indicate the possibility of shorted turns or a reduction of capacitance. The nature of the trouble is indicated by the direction of the frequency change. That is, an increase in frequency indicates shorted turns or a reduction of capacitance, and a decrease in frequency indicates an increase of capacitance, since the number of turns cannot increase.

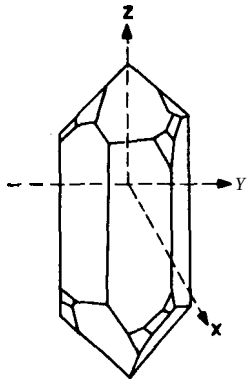
Usually minor frequency changes, which may be produced by slight changes in plate voltage with changes in load or line voltage, can be compensated for by retuning the tank circuit. Since the stability of this circuit is normally better than that of either the dynatron or transitron, small frequency changes will require the use of a reliable secondary frequency standard to determine them. At the frequencies used, changes in tube element capacitance with temperature is rather unlikely to affect the frequency. Unstable operation might possibly be caused by a reduction of the tank capacitance to a minimal value, due to such trouble as defective bearing contacts in the tuning capacitor. This could produce a distorted waveshape and possibly result in the relaxation type of oscillation. Such operation would be evidenced by abrupt changes in current and voltage from one value to another, and the frequency would, no doubt, be out of the frequency range for which the circuit was designed.

PART 6-2. CRYSTAL OSCILLATORS

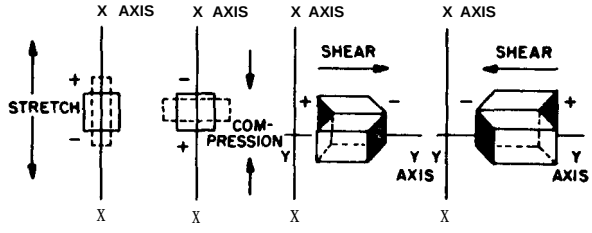
CRYSTAL OSCILLATORS

General.

The crystal type of oscillator uses natural or synthetic nonconducting crystals excited by the piezoelectric effect and vibrating at or near their natural frequency to control the frequency of oscillation. The electrical excitation of the mechanical device at or near its fundamental, harmonic, or subharmonic frequency produces stable mechanical oscillations; these are converted into electrical impulses of the same frequency are are fed back into the oscillation circuit to sustain highly stable oscillations at the desired frequency of operation. The most popular, economical, and plentiful kind is the quartz crystal (shown in the following illustration), which in its natural (alpha) state only requires cutting, grinding, and polishing to size. The frequency of oscillation is determined mainly by the thickness (or length for very low frequencies) of the crystal slab. The crystal cannot be made to vibrate too strongly or it will shatter. Tourmaline crystals were once popular for the higher frequencies since they are more rugged and thicker for a given frequency. Because of the expense and scarcity of large-sized crystal prisms, and since tourmaline has a negative temperature coefficient which prevents a zero-temperature-coefficient cut from being obtained, tourmaiine crystals are not in common use today, although they may occasionally be encountered.



Natural Quartz Crystal, Showing the X, Y, and Z Axes



Piezoelectric Action

A quartz prism has three basic axes, X, Y, and Z. The Z axis is the optical axis, the Y axis is considered the mechanical axis, and the X axis is considered the electrical axis (see quartz crystal previously illustrated). No piezolectric effects are directly associated with the Z axis; an electric field applied in this direction produces no piezoelectric effect on the crystal, nor will a mechanical stress along the Z axis produce a difference of potential. A simple compressional or tensional mechanical stress applied along the Y axes will cause a change of polarization of the X axis, but not the Y axis; however, if a shearing or flexural strain is applied along the Y axis a change of polarization will occur. When the crystal is stretched along the X axis, a positive charge will appear on one end of the crystal, and when the crystal is compressed along the X asix, a negative charge will appear. Thus, piezoelectric effects are produced for either X- or Y-cut crystals, as shown in the accompanying illustration.

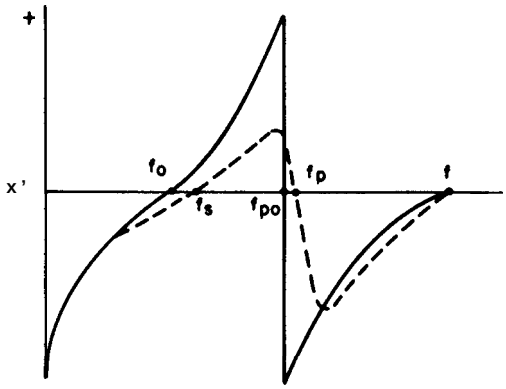
The piezoelectric effect is defined as that effect which produces a potential across the parallel faces of a crystal-line dielectric substance when pressure or torsional forces are applied between the faces, or, conversely, that effect which causes the crystal to distort itself when a voltage is applied between the faces. Thus, when alternating voltages are applied between the crystal faces, it will oscillate (vibrate mechanically) at a specific frequency, which is determined mainly by the thickness of the crystal.

When loosely coupled to a suitable oscillator circuit and excited at the proper frequency, the crystal will stabilize the frequency of oscillation. If the circuit is arranged to provide self-oscillation at the natural frequency of vibration of the crystal and will not oscillate without the crystal, it is a crystal-controlled oscillator. Normally, a crystal has two frequencies or modes of operation: the ***resonant*** (fundamental) frequency, or ***series*** mode, and the ***anti-resonant*** frequency, or ***parallel*** mode. The series and parallel modes are similar to the equivalent types of resonance. In the series mode, the crystal presents a low impedance and provides a maximum of stability. In the parallel mode, it presents a high impedance (usually considered infinite), since the crystal is used as a high-Q inductor which is resonated with the crystal circuit shunt capacitance (including crystal and holder capacitances), to form a highly stable ***parallel-resonant circuit*** operating at the antiresonant frequency of the crystal. The arrti-resonant crystal frequency is always slightly higher than the natural, or series-resonant, frequency.

The variation with frequency of the series reactance (X_s) of a typical quartz crystal is shown qualitatively in the accompanying figure. The solid line represents the condition where the resistance R is equal to zero (which is only theoretically possible); the dotted line represents the true conditions where R has some finite value. Thus, where R is equal to zero, the series reactance is equal to zero at

$$f_o = \frac{1}{2\pi\sqrt{LC}}$$

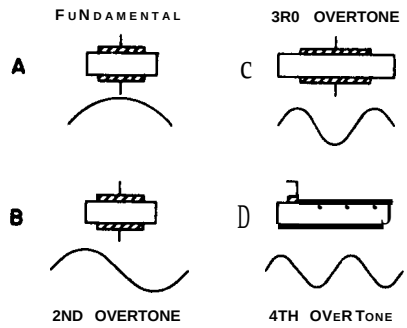
and changes from + infinity to – infinity at the frequency f_{po} (the solid line on the graph). **When R is** greater than zero, the dotted line indicates that the series crystal reactance has a finite maximum and minimum, and that it actually has a zero value at both f_s and f_p, the series- and parallel-resonance frequencies. For a resonably small R, the frequency difference between f_s and f_p is approximately the same as that between f. and f_{po} (they are quite close). In practice, the frequency difference between series and parallel resonance varies with the type of crystal and its cut. For example, a GT-cut quartz crystal can have a difference as low as 0.08 percent of the resonant frequency, and an AT-cut crystal can be as great as 2 percent.



Variation of Series Raactence of Crystal With Fraquancy

The series mode of operation is usually used for wave-filter circuits where a specific frequency is to be absorbed, or for *overtone* oscillators operating at high frequencies. A brief discussion of the basic principles of an overtone crystal is given in the next paragraph. The parallel mode is usually used in oscillator circuits where it is extremely high Q produces stable operation not normally possible with the ordinary inductor or LC tank circuit. As issued, the antiresonant (parallel-resonant) frequency is marked on the holder unless otherwise specified on the nameplate (overtone crystals are stamped at the overtone frequency). Crystal calibration and rating are for a specified shunt capacitance and holder, and for operation in a ***standard*** circuit. For MIL STD crystals the circuit is that specified in the Standard. For commercial crystals the schematic of the circuit used for calibration is generally supplied with the unit, or is otherwise specified. When used in a ***nonstandard*** circuit, the crystal will operate at a slightly different frequency from the calibration obtained in the standard circuit (±3 MHz maximum), depending upon the tolerance to which it is ground, the holder capacitance, and stray inductance and capacitance effects of wiring.

The following figure shows the basic flexural vibration modes for fundamental, second overtone, third overtone, and fourth overtone operation of a crystal bar. These modes are used at low frequencies, where a bar producing lengthwise vibrations instead of a plate is used.

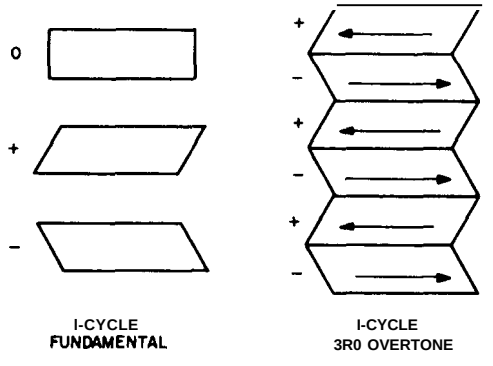


Crystal Flexural Vibration Diagrams for Lengthwise Vibrations

Part A of the figure shows the basic mode of operation as the fundamental frequency with the bar bending in the middle, and parts B, C, and D show second, third, and fourth overtone operation. In part B, note that the second harmonic flexing is of opposite direction, or phase, and that with a single plate extending the length of the crystal the bar cannot easily oscillate. On the other hand, the third overtone has the same motion or phase at both ends with the middle free to flex. In practice, the output on the third overtone is strong with a single plate, but the output of the second overtone, if not completely canceled, is so weak that it is unusuable (the bar has practically no piezoelectric effect). By plating a single

electrode and then dissolving the plating between nodes, it is possible to get free flexing and piezoelectric effect from even overtones, either separately through each set of plates, or by using one or the other of the end plates for excitation as shown in part D of the figure.

In the high-frequency crystal a different condition exists. Here the thickness shear mode is the mode of interest, and it is illustrated in the following figure. It is clearly seen that the vibrations in this mode are as if the crystal were squeezed with a shearing motion, distorting it somewhat as shown. Since this motion is essentially lateral, the crystal may be clamped at the edges, without being appreciably affected by the spring pressure between the plates; that is, the mechanical friction is negligible. When operating on an overtone, the high-frequency crystal appears to be formed of layers with the motions occurring in opposite directions. It should be understood, of course, that the illustrations are exaggerated to convey the idea. Basically, a crystal does not oscillate on one frequency; it has numerous nodes and modes, which can be affected by changes in temperature and excitation. For example, it is possible to heat the crystal by overexcitation, and cause it to change from a mode of operation at one temperature to another mode of operation at a higher temperature. It is also possible to cut and grind it so that it oscillates most vigorously on a particular frequency for ***fundamental*** crystals, and overtone frequency for ***overtone*** crystals.



Thickness Shear Vibration Diagrams

Overtone operation is normally restricted to the odd harmonics on high-frequency thickness shear type crystals. In the circuit to be discussed, the crystal will operate only at the overtone frequency if ground for overtone operation. The circuit, however, will also operate at an overtone of a fundamental type crystal (which is some odd multiple of the fundamental frequency), but it will not operate at the fundamental frequency unless the tank is tuned to the fundamental frequency. It is possible to operate up to the third or fifth overtone with fundamental crystals and up to the ninth or higher overtone with overtone crystals.

As a matter of academic interest, it should be noted that crystals have been made which will operate on even harmonics, but this is the exception rather than the rule; only crystals which operate on odd overtones are of practicaI interest.

Since the overtone crystal is usually very thin, its mounting is very important. Therefore, it is usually plated and connected to wire electrodes in a sealed container. It is also very sensitive to surface imperfections; for example, scratches that would not affect the operation of the fundamental crystal can prevent operation of the overtone crystal. Therefore, extra care should be observed in handling and cleaning operations.

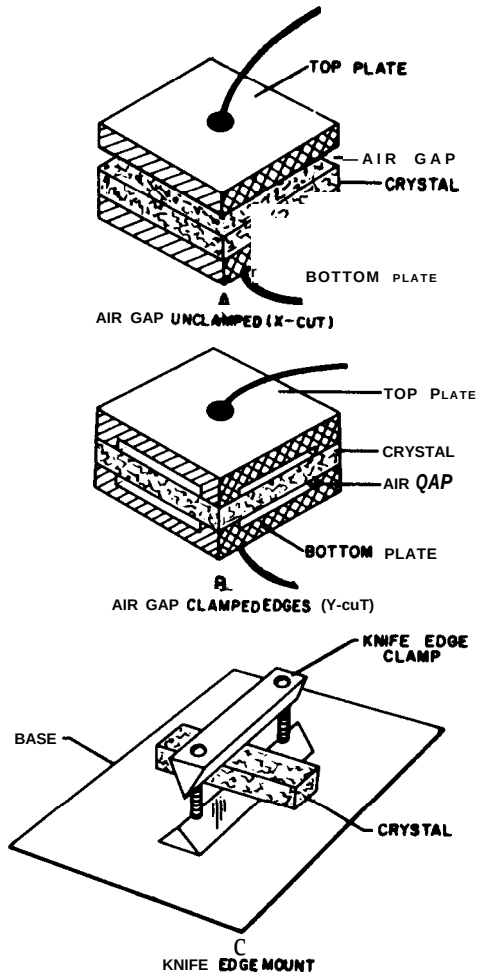
Generally speaking, the series-resonant crystal oscillator has greater frequency stability and can generate higher frequencies, whereas the parallel-resonant type oscillator is more economical to construct, can operate over a wider frequency range (by substitution of different crystals), and can generate greater output. However, there are a number of exceptions to this general rule. The ***parallel- resonant oscillator*** is primarily used with fundamental-mode crystals at frequencies below 20 MHz. In conventional circuits of this type, the crystal must operate between its resonant (series-resonant) and anti-resonant (parallel-resonant) frequencies, thereby behaving as an inductor. Under these conditions, the circuit will not oscillate if the crystal becomes defective and the oscillator is a true crystal-controlled type. Maximum stability is achieved with a low crystal drive and with operation in the class A to class B range. For maximum power output, the oscillator is operated class C. With normal voltages the electromechanical coupling in the parallel mode of operation tends to become too weak to sustain oscillation at the

higher frequencies. This reduction in coupling, plus the shunting effects of tube and crystal capacitances, makes increased drive and plate voltage necessary to produce oscillation, thus leading to crystal fracture or instability; hence, it is impracticrd to use the parallel mode at the higher frequencies. It is possible though, by frequency multiplication in a number of subsequent stages, to obtain high-frequency operation with a parallel mode basic crystal.

The ***series-resonant oscillator*** is almost always used with ***overtone*** crystals. Because the output is lower than that of the parallel-resonant type, the operating range is restricted, and more parts are required. The series-resonant crystal oscillator is usually used only for high frequencies, or for low and medium frequencies where special design considerations make its use justifiable (mostly for frequency standards and laboratory and test equipment).

The inertia of the mechanical equivalent of the crystal oscillator provides a stable oscillatory action that is little affected by the varying parameters of the electron tube circuit (and for which crystal-controlled oscillators are noted) so that changes of tube capacitance or line voltage have little effect on the frequency of operation. In fact, the change of crystal dimensions with temperature usually has a greater effect. In this respect, the X-cut crystal has a ***negative*** temperature coefficient of 20 to 25 parts per million per degree centigrade (a 10”C rise in temperature of a 5000-kHz crystal produces a lowering in frequency of 1000 to 1250 Hz), and the Y-cut crystal has a ***positive*** temperature coefficient of 75 to 125 parts per million per degree centigrade. Thus, it can be understood that various crystal cuts provide different temperature coefficients, each suitable for different ranges of operation, with each different cut designed for zero temperature coefficient (see previous illustrations for typical cuts and typical temperature-frequency variations) or as near thereto as possible. (The CT cut is the only one which covers a large range of temperatures.) For exact frequency operation, as needed in frequency standards or for special uses, temperature compensation is utilized, with the crystal ground and cut for a zero temperature coefficient over a temperature range easily sustained by the thermostatically controlled oven.

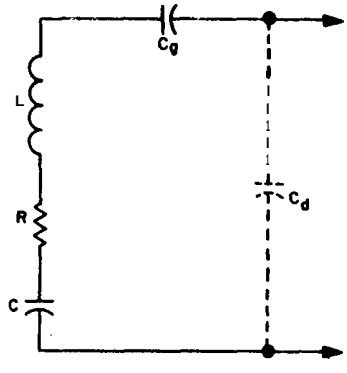
The effect of the crystal holder and the shape of the crystal have a slight effect on the resonant frequency, which varies with the cut. For example, a Y-cut crystal may be clamped at the edges without affecting operation (see accompanying illustration), whereas an X-cut crystal will oscillate only if all edges are free. Since the crystal is mounted between two metal plates and is a dielectric, there is an equivalent capacitance for the crystal determined by its dimensions, plus a capacitive effect due to the plates of the holder. Thus air gap holders, provided with a variable top plate adjustment, are sometimes used. Changing the effective capacitance by adjusting the gap changes the frequency of operation slightly (from 500 Hz to 3000 Hz maximum).



Typical Mountings

The electrical equivalent circuit of the crystal and holder is illustrated in the following figure, to show

the parameters and components needed to stimulate a single quartz crystal. The inductance, L, is on the order of henries (for low-frequency crystals) with a Q of 100,000 or better. The series resistance, R, varies from unit to unit but is usually less than **500 ohms** (the lower the better since it represents a loss of power). The capacitance of the crystal without a holder is represented by C and is on the order of a few picofarad. Where an air gap holder is used, the capacitance of the holder air gap is in series with the crystal, as indicated by C_g. The holder capacitance (with no air gap) appears in shunt with the crystal and also includes any wiring, stray, and distributed capacitance plus the grid interelectrode capacitance of the tube, all of which are lumped together as C_d. For the parallel-resonant mode of crystal operation, this capacitance is fixed at 32 picofarads for Military Standard crystals.



Crystal Equivalent Circuit

The discussion of electron-tube crystal oscillators is also generally applicable to semiconductor crystal oscillators. However, the basic semiconductor is less frequency stable than an electron tube, mostly because of its inherent ability to act as a variable capacitor with a change of collector voltage. In an LC oscillator the ***tank circuit*** is the frequency-determining and stabilizing element, but in the crystal oscillator, it is the ***crystal*** itself, because the crystal operates essentially as a parallel tuned tank or series tuned tank depending on the mode of operation. Therefore, whether semiconductors or electron tubes are used, the basic principles of operation of the resulting crystal oscillators are identical. The chief differences in operation are the effects on feedback and the circuitry used for the effective feedback control.

Like the self-excited semiconductor oscillator, the crystal-controlled semiconductor oscillator also has circuit configurations similar to those in the electron-tube field, but none so well known by name as the Miller and Pierce circuits. Therefore, the circuit discussions are identified primarily from a functional standpoint rather than by name. By the principle of ***duality,*** most of the electron-tube circuit configurations have duals in the semiconductor field. Since there are numerous circuit variations now in use and the state of the art in such that changes occur constantly, the circuits have been classified into three arbitrary groups and a circuit typical of each group will be discussed.

The first group, known as the ***transformer-coupled group,*** includes those oscillators using mutually coupled separate coils to provide feedback. The oscillators in this group have the advantage of extreme flexibility. They can be used in either CB, **CE,** or CC configurations, since polarities and impedances can be completely controlled by the number of turns and directions of the windings. The second group uses a capacitive voltage divider and is called the ***Colpitts-type crystal oscillator.*** The third group is the ***overtone group,*** which generally uses a tuned tank with a tapped coil in a Hartley type feedback arrangement operating at a desired harmonic or overtone. In any of these circuits, series or parallel resonance of the crystal may be employed. However, since the transistor is a low-impedance device, operating with relatively low voltage and high current, it conveniently lends itself to the use of series mode crystal operation, using only one stage instead of two stages as is necessary in the electron-tube circuit.

Because the transistor is basically a low-power device, it minimizes problems of heating and over excitation, which often cause crystal shattering in the power-tube oscillator. Thus, frequency changes due to thermal effects within the crystal are usually negligible, and ambient temperature changes are more important. For extreme stability, temperature compensation is necessary, particularly since the transistor itself is temperature sensitive and generally requires compensation. At normal room temperatures (or lower), and with average low-temperature or zero-temperature coefficient crystals, the transistor

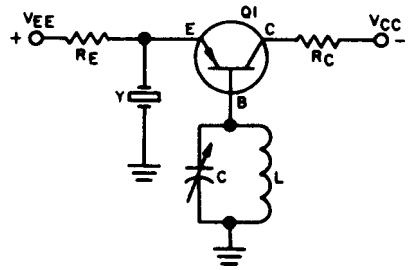
crystal oscillator is stable enough for average use without compensation. At higher temperatures, compensation of the transistor, if not the crystal, is necessary in most cases.

Dc stabilization (biasing) methods as discussed in the Amplifier Section of this handbook are used in crystal oscillators, as well as self-excited oscillators, to insure that variations of emitter and collector voltages and currents do not cause parameter changes. The use of the form of stabilization generally results in more power being consumed in the biasing circuits than in the basic oscillator.

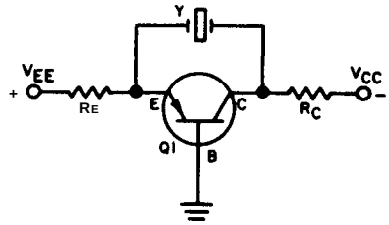
In considering output requirements, the load is generally in shunt with the crystal or the tuned tank circuit; as a result, increased power output usually affects the frequency stability by degrading the Q of the resonator or increasing the effective coupling impedance between crystal and feedback circuit. Or, as in self-excited oscillators, the less the output required, the more stable the frequency, and the less load changes affect the circuit. For all ordinary purposes, the good mechanical stability of the crystal resonator makes it almost free from the effects of load changes, particularly if the collector voltage is regulated.

Good crystal oscillator desigrr requires the use of low impedance coupling between the oscillator and resonator, the use of either resistance stabilization (in the form of series resistance in the emitter and collector circuits) or reactance stabilization, regulation of supply and bias voltages through the use of Zener diodes, the temperature control of both the transistor and the crystal.

In the following circuit discussions, the external feedback type of oscillator is discussed. However, it is possible to use the inherent negative resistance of a transistor to provide oscillation. In this case, a tuned or high-impedance circuit is employed in the base-emitter circuit, and the crystal provides a low-impedance (series) feedback connection resembling the Miller and Pierce electron-tube circuits, as shown in the accompanying illustration. These types of oscillators (primarily used with point-contact transistors), however, are dependent entirely upon the transistor parameters since the feedback is entirely within the transistor and varies with each one. Such circuits are considered undesirable, except for special applications; they have been mentioned only for general information and will not be discussed further.



EMITTER-BASE CRYSTAL



EMITTER-COLLECTOR CRYSTAL

Basic Negative-Resistance Type Oscillators

GRID-CATHODE (MILLER) CRYSTAL OSCILLATOR. (ELECTRON TUBE)

Application.

The Miller crystal oscillator circuit is used to supply a constant-frequency sine-wave output at a relatively constant amplitude, usually within the r-f range. This circuit is used wherever a highly stable specific frequency is needed, such as the basic oscillator in a transmitter, receiver, frequency standard, or test equipment.

Characteristics.

Utilizes piezoelectric effect of a natural or synthetic crystal to control frequency of oscillation.

Crystal is connected between grid and cathode of an electron tube.

R-F feedback occurs only through grid-to-plate inter-electrode tube capacitance.

Operates normally with class B or C automatic self-bias, but may be operated class A or with combination freed and self-bias for special designs.

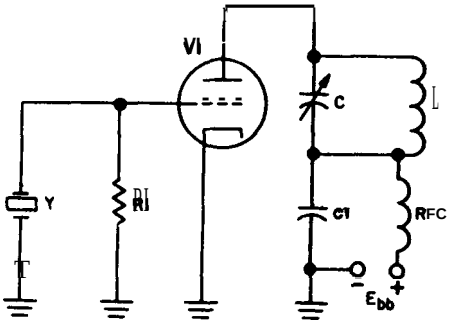
Frequency stability is excellent, with or without temperature compensation.

Output amplitude is relatively constant.

Circuit Analysis.

General. The Miller-type crystal oscillator uses the crystal connected between the grid and cathode tube elements. Because of its popular usage, it is sometimes considered the basic crystal oscillator. However, the Pierce-type crystal oscillator which uses the crystal connected between the grid and anode tube elements, and is discussed later in this section, is also a basic type of crystal oscillator. In some other texts the Miller oscillator may be called the Pierce-Miller oscillator. However, to avoid confusion in this Handbook, the grid-cathode-connected crystal is called the Miller oscillator, while the grid-plate-comected crystal is called the Pierce oscillator. The Miller circuit is popularly used because, for a given amount of crystal excitation, it provides a greater output than any other circuit arrangement; the output is greater because the basic feedback occurs between the grid and plate of the electron tube, and not through the crystal. This also prevents the crystal from being subjected to sufficient strain to cause fracture of the crystrd, and the tube may be driven harder.

Circuit Operation. The basic Miller oscillator is shown in the accompanying illustration. The crystal is located between the grid and cathode, and grid-leak bias is obtained through Rl, with the shunt capacitance of the crystal, together with that of the holder, acting as the grid-leak capacitor. The tuned tank circuit, LC, is located in the plate-to+ athode circuit. As shown, the rfc and Cl form a conventional series plate-feed decoupling circuit, but the tank may be shunt-fed, if desired.



Basic Crystal (Miller) Oscillator

Crystal action in controlling oscillation can be explained as follows: Assume that the tank circuit in the basic oscillator is tuned to a higher frequency than the anti-resonant (parallel-resonant) crystal frequency, so that the plate circuit appears inductive. Assume also that filament and plate potentials are applied and the crystal is not vibrating. A positive voltage is present between plate and ground, and a negative voltage is present between grid and ground (due to contact potential). By piezoelectric action, the negative grid voltage will cause the crystal to be deformed slightly. Assume that a noise pulse occurs and causes the grid to go more negative, thus further deforming the crystal. The deforming of the crystal produces a piezoelectric action, increasing the charge on the grid in the same direction, and drives it further negative. When plate current cutoff is reached, the feedback becomes zero, and the accumulated grid voltage discharges through grid leak resistor R1. As the grid voltage is reduced, the deformation of the crystal is reduced, and the negative piezoelectric charge on the grid is also reduced by a corresponding positive induced piezoelectric voltage until plate current again flows. This cumulative action causes the crystal to vibrate mechanically near its parallel-resonant frequency. Once started the vibrations continue and induce in the grid circuit an ac voltage of a frequency ahnost equal to the vibration frequency of the crystal. As long as the plate tank is tuned to present an inductive reactance, the proper phase for feedback is maintained. When the tank is tuned on the capacitive side of the frequency of oscillation (to a lower frequency), the phase of the crystal oscillation opposes the plate-to-grid feedback, and oscillation is reduced and eventually stopped. Tuning the tank circuit allows the feedback to be controlled from minimum to maximum with a corresponding output. To produce the proper phase relationship, tuning is approached from the high capacitance side of resonance. Plate current varies in a similar manner from a high value to a low value at the optimum point, then suddenly increases and abruptly reaches its normal static (non-oscillating) value as the series-resonant frequency is approached. The action described, although slightly exaggerated for ease of understanding, happens very quickly. That is, the tube reaches its class B or C operating condition in one or two cycles of operation.

Since the crystal is essentially the equivalent of a high-Q circuit, it resonates only over a very narrow range of frequencies (tuning is very sharp). Therefore, slight changes in tube parameters and supply voltages have a minimal effect, about 100 to 200 times less than in the conventional LC oscillator.

Biasing Considerations. In the basic Miller oscillator shown above, the bias is supplied by means of grid-leak action, as in the conventional LC feedback oscillator. Since the crystal represents a very high-Q circuit (a Q of 100 times or more than that of the conventional LC tank), it is evident that grid leak resistor RI effectively acts as a shunt for the voltage generated by the vibrating crystal. Therefore, an r-f choke is sometimes placed in series with the grid leak to reduce the load on the crystal and help it start oscillating more easily. When a bias battery replaces the grid leak and the series-connected r-f choke is also used, the grid operating point is freed by the battery bias, and the circuit can be adjusted for maximum power output, with minimum crystal excitation and good output waveform. The combination of battery bias and r-f choke, however, does not make for easy starting. The use of cathode bias, together with the r-f choke and with or without the grid resistor, normally provides the most effective starting, and is used where keyed oscillator operation is required (maximum stability dictates that keyed operation be avoided).

As the bias is increased, the crystal current increases, because more excitation is needed to swing the operation into the cutoff region and overcome the bias. The increased bias also increases the mechanical distortion of the crystal and causes it to vibrate harder. If driven excessively, the crystrd will shatter.

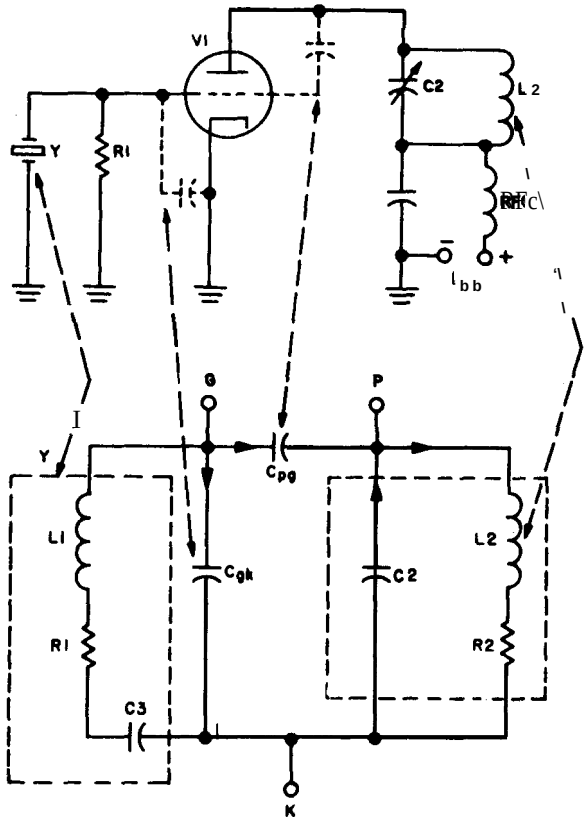
Other Considerations. The plate voltage applied to the crystal oscillator is limited to a value lower than that applied to the standard LC oscillator, because as the power increases with an increase of plate voltage, so does the feedback voltage, which in turn increases the current through the crystal. The increase of crystal current has two effects: (1) it may exceed the value where it causes the crystal to vibrate so strongly that it shatters; (2) since the temperature of the crystal depends upon the current flow through it among other things, unless the crystal has a zero temperature coefficient over a wide enough range, the frequency of operation will vary, either increasing or decreasing, depending upon whether the temperature coefficient is positive or negative.

Temperature changes external to the crystal will change the grid-to-plate interelectrode capacitance of the tube, and supply voltage changes will change the plate impedance and affect the frequency of operation. This frequency change occurs in parallel-resonant csystal operation because either a change in the feedback capacitance or the plate load impedance will affect the phase shift in the feedback loop, and cause the crystal to operate at a frequency somewhat nearer to or farther from the antiresonant frequency, to satisfy the conditions for sustaining oscillation.

The Miller oscillator provides an average frequency deviation of approximately 1.5 times that of the Pierce oscillator (to be discussed later) and is therefore less stable than the latter circuit. On the other hand, it will give the same output (or slightly more) with only half the grid excitation and crystal current. Thus, with the same excitation, the Miller oscillator can supply twice the power of the Pierce oscillator and effectively obviate the need for an additional stage of amplification to bring its output up to the value needed to drive a following power amplifier. (The high output power largely accounts for the popularity of the Miller circuit and its almost universal used.) When used with a pentode, the Miller circuit provides maximum output with minimum crystal strain and excitation, and also greater stability (see the Electron-Coupled Crystal Oscillator circuit discussion given later in this section).

Detailed Analysis. The basic Miller oscillator is considered to be a variation of the tuned-grid, tuned-plate oscillator, in which the feedback occurs solely through the grid-plate interelectrode capacitance. The equivalent circuit of the Miller oscillator is shown below with bias and plate voltages omitted for simplicity. The crystal tank (tuned-grid) circuit is represented by L_1, R_1, C_3, tuned by interelectrode capacitance C_{gk}, and the plate tank by L_2, R_2, tuned by variable capacitor C_2. The two circuits are coupled by the internal plate-grid capacitance, C_{pg}, for feedback purposes.

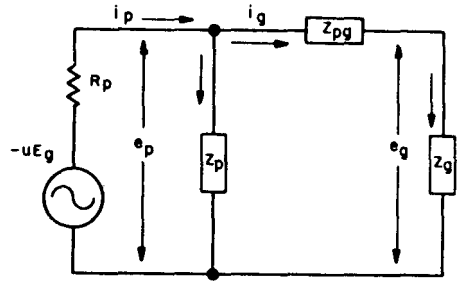
491-044 0 - 73 - 42



Basic Miller Equivalent Circuit

The plate circuit must appear inductive so that the correct phase shift will be produced in the developed r-f plate voltage to compensate for the effect of the resistance in the feedback loop; this resistance prevents the necessary 180-degree phase rotation of the equivalent generator voltage of the amplifier from occurring entirely in the feedback circuit. Since the load capacitance is a function of frequency, the Miller oscillator cannot be operated at more than one frequency and still present the same load capacitance to each crystal unit, unless provision is made for adjustment of the circuit parameters. Hence, the tuned tank circuit is required so that the plate circuit will appear inductive when the tank is tuned to the high-frequency side of crystal resonance.

Now examine the means by which the proper phase relationships between the grid and plate voltages are maintained to produce oscillation. In the conventionrd electron tube, the grid and plate voltages are always 180 degrees out of phase. When the grid voltage is positive, it causes the plate current to increase. Consequently, the voltage drop across the plate load impedance produces a negative-going output voltage. If this output were fed back to the grid, it would oppose the grid voltage and reduce or prevent any possible oscillation. To produce oscillation it is necessary to shift this phase another 180 degrees. Thus, a positive-going grid voltage must be reinforced and enhanced by a positive-going (feedback) voltage from the plate circuit. If the feedback voltage is sufficient to replace any losses in the feedback circuit, continuous oscillation will occur. Now consider the crystal oscillator equivrdent circuit which follows:



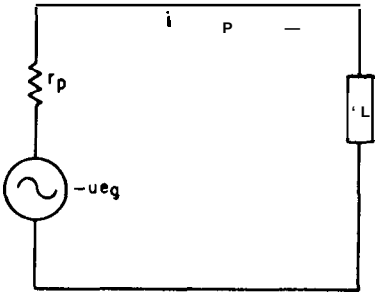
Crystal Oscillator Equivalent Circuit

The equivalent generator voltage is $-\mu E_g$, where μ is the amplificator factor of the tube and E_g is the excitation voltage on the grid. R_p is the plate resistance of the tube, and Z_p is the plate impedance from plate to cathode, with Z_g as the grid impedance from grid to cathode. These impedances are reactive, and must always have the same sign for oscillation to be produced. Considering an ideal circuit with no feedback losses, the plate-to-grid impedance, Z_{pg}, is the dominant impedance in the feedback circuit, and is always opposite in sign to Z_p and Z_g. If Z_p and Z_g are positive, Z_{pg} is negative; thus the current, i_g leads e_p and $-\mu E_g$ by 90 degrees. If Z_p and Z_g are negative, Z_{pg} is positive; thus i_g lags e_p 90 degrees. The voltage across Z_{pg}, of course, is in phase with e_p in both instances. Since Z_g is opposite to sign to Z_{pg}, e_g is thus opposite in sign to e_p, and the required phase reversal takes place. Note that i_g is first rotated in phase with respect to e_p; next, e_g is rotated in the same direction with respect to i_g.

In a practical circuit, the feedback losses cannot be zero; thus an exact 180-degree reversal cannot be obtained in the feedback circuit alone. This means that e_p must first be rotated by an amount exactly sufficient to make up the losses in the feedback circuit. To do this, the plate tank is tuned to a higher frequency than the antiresonant crystal frequency. Therefore, Z_P appears as an inductive reactance, and e_p is rotated in a leading direction. The smaller the value of R_P, the more nearly will Z_P control the phase of i_p, and the more detuned must the tank circuit become in order to produce the necessary rotation of e_p. If practically all the resistance in the feedback arm is between the grid and the cathode, as is normally the case when e_g is developed directly across the crystal unit, e_p must be rotated through a larger angle than otherwise, thereby requiring the tank circuit to be detuned to a greater degree.

In a conventional parallel-resonant crystal oscillator having an ideal feedback arm, the frequency would be entirely determined by the resonance of the tank circuit; thus fluctuations in R_P, although effective in changing the activity, would not affect the frequency. In practical circuits, changes in both R_p and Z_P will slightly shift the phase of E_P and, consequently, the frequency. The basic amount of frequency shift is fixed by the crystal used, varying directly with the Q and the shunt capacitance of the crystal. This is the reason for using a standard value of 32 picofarads for crystrd capacitance; the Q depends upon crystal processing and composition, and thus varies somewhat.

In the Miller circuit, the maximum permissible voltage across the crystal unit is (k + 1) times the maximum voltage, where k is the gain of the stage and is equal to e_p/e_g, as shown in the crystal equivalent circuit. Theoretically, this gain can approach the mu of the tube as a limit when the load impedance, Z_L, is large as compared With the plate resistance, r_p (as shown by the following simple electron tube amplifier equivalent circuit); this explains the large output obtainable from this circuit when used with hi-mu tubes.



Electron Tube Amplifier Equivalent Circuit

When a pentode, instead of a triode, is used as the oscillator tube, it is usually necessary to insert a small feedback capacitance between plate and grid, because of the small value of interelectrode capacitance present in the pentode. The output waveform is also improved by using a tuned tank circuit with a low L/C ratio. Since the tuning must be such that the tank impedance appears inductive, the tank circuit provides an effectively high-Q plate load when the tank capacitor is set for the proper load capacitance.

Failure Analysis.

No Output. Since the crystal controls oscillation, the crystal will not oscillate and no output will be obtained if the crystal is removed, if poor or loose holder connections cause an open or high-resistance circuit, if the plate circuit is detuned sufficiently, or if no plate voltage is present because of open- or short-circuit conditions. When sustained arcing (caused by too high a crystal r-f excitation current) produces burnt spots on the holder or crystal, it will not oscillate until cleaned (this condition normally does not occur in pressure type holders, but may occur in unloaded or air gap holders). Navy policy is to return defective crystals to the crystal laboratory for repair. Do not attempt to clean crystals. An open r-f choke or a short-circuited plate bypass capacitor will remove plate voltage from the tube, and the

crystal will not oscillate. Poor soldered connections on the tank coil in a series-fed circuit will produce a similar result. An open-circuited grid RFC in a circuit using no grid or cathode bias resistor will open the grid circuit and prevent oscillation unless the crystal is defective and has a low resistance. Insufficient feedback capacitance between tube elements (most likely to be associated with pentodes) will cause the crystal to stop oscillating (This condition will not occur in an oscillator which has previously oscillated unless the tube becomes defective).

Reduced Output. Low "plate voltage, a detuned plate tank circuit, or a crystal of low activity will result in reduced output. An open-circuited tank capacitor will allow the circuit to act as an untuned plate oscillator and, if the feedback is not too greatly out-of-phase, may permit weak oscillation; this trouble may be easily located because the tuning of the tank will not affect the plate current, and the plate current will be high, near its normal non-oscillating value. Increased resistance in the feedback arm due to poorly soldered connections will cause less phase rotation and, if excessive, will result in weak oscillation or entirely prevent operation.

Unstable Output. Any instability as far as oscillation is concerned would be associated with the feedback circuit and the crystal. A defective crystal, due to a partial fracture, may cause instability of amplitude and frequency. A defect causing the output to change from one mode of crystal operation to another could also cause instability, but in most instances it would be easily discovered because it would also change the operating frequency. An intermittent open, short-circuited, or partially open bypass capacitor may also cause a similar condition, although it is more likely to result in either no output or reduced output.

Incorrect Frequency. Since frequency is primarily determined by the crystal and tank circuit tuning, either a defective crystal or tank circuit may cause a change of frequency. The most probable trouble would be a defective, burnt, dirty, or fractured crystal. Changes of frequency on the order of only a few cycles per second may be due to tank detuning or temperature effects; changes greater than a few cycles per second indicate a change of crystal parameters. Temperature variations are generally indicated by a slow change of frequency in one direction with an increase of temperatures; such variations may occur if the ambient temperature is above the range of thermal compensation provided. A slight change in frequency, due to aging or a change in drive level, can normally be compensated for by a slight change or tank tuning; otherwise, the crystal must be replaced.

GRID-PLATE (PIERCE) CRYSTAL OSCILLATOR (ELECTRON TUBE)

Application.

The Pierce crystal oscillator circuit is used to supply approximatley a sine-wave output of relatively constant frequency, usually within (although not restricted to) the r-f range. This circuit is used wherever a specific frequency of extreme stability and of moderate power output is needed, such as the basic oscillator in multistage transmitters, test equipment, receiver-converters, etc. It is usually interchangeable with the Miller oscillator in low- and medium-frequency applications, but it is not often used in high-frequency applications, mostly because of its low output.

Characteristics.

Utilizes piezoelectric effect of a natural or synthetic crystal to control frequency of oscillation.

Crystal is connected between grid and plate (or any other element acting as an anode) of an electron tube.

Does not require an LC tank circuit for fundamental mode operation.

R-F feedback occurs only through crystal.

Operates normally with class B or C automatic self-bias, but may be operated class A or with combination freed and self-bias for special design.

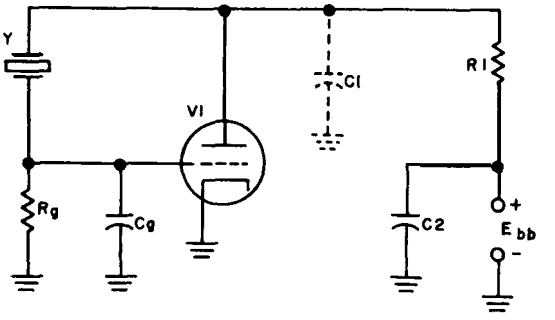
Frequency stability is excellent, with or without temperature compensation.

Output amplitude is relatively constant.

Circuit Analysis.

General. The generalities applicable to the basic crystal oscillator in the discussion of the Miller circuit are also applicable to the Pierce circuit. The simplicity of the Pierce oscillator, with its lack of tuned plate tank and its ability to oscillate easily over a broad range of frequencies with different crystals, makes it popular for use in crystal calibrators, receivers, and test equipment, and in transmitters not requiring much drive. The Pierce circuit is sometimes considered as the inverse of the Miller circuit since it exhibits opposite effects. Thus, instead of operating

as an inductive reactance as the Miller circuit does, the Pierce circuit operates as a capacitive reactance (when a tank circuit is employed, it is always tuned for a lower frequency). The crystal excitation voltage for the Pierce is approximately half that permissible with the Miller circuit. The plate load of the Pierce oscillator is resistive and is usually large enough in vahre that minor fluctuations in the tube plate resistance have much less effect on the frequency of operation than in the Miller circuit. This is used to best advantage when a pentode is employed, since its inherently high plate resistance and low grid-plate capacitance permit a greater range of plate load with the use of an external capacitor to fix the amount of excitation.



Pierce Crystal Oscillator Circuits

Circuit Operation. The basic Pierce oscillator circuit is shown in the accompanying illustration. Conventional grid-leak bias is obtained through C_g and R_g, which operate as described previously in the Amplifier Section of this handbook, and in the LC Tickler Coil Oscillator Circuit discussion given previously in this section. The crystal, which is connected between grid and plate, offers a high Q. The inductive reactance of the crystal, together with the capacitive reactance of Cl (which consists of tube and stray wiring capacitance), provides the final phase rotation required to produce the 180-degree shift in the feedback voltage in order to sustain oscillation. The plate load is resistor R1. C2 is the conventional plate bypass capacitor used in series plate feed arrangements. The use of resistor RI in the plate circuit provides a relatively flat response over a wide range of frequencies, so that various crystals may be substituted for operation on other frequencies without any tuning being required. In some instances, however, when it is desired to operate on a single frequency or over a narrow range of frequencies, with increased output, an r-f choke is substituted for R1. This choke eliminates the dc power loss in the resistor and provides a high r-f impedance for proper operation; since the plate voltage is increased, the (resistor voltage drop is eliminated) output is also increased.

Now consider one cycle of operation. Assume that crystal Y is at rest and that the circuit as illustrated above is inoperative, with no plate voltage applied. At rest, the crystal is unstressed and there is no charge on either plate. When the plate voltage is applied, since no bias exists initially, heavy plate and grid current flows. Simultaneously, the crystal is stressed by this plate potential, and a peizoelectric charge appears" across the crystal. The sudden shock of applied plate voltage causes the crystal to start oscillating at its parallel-resonant frequency. Assume also that the plate voltage stress induces a positive piezoelectric charge on the grid, which tends to increase plate current and grid current flow. The plate current quickly reaches saturation at some low plate voltage, caused by the drop through plate resistor R1. Meanwhile, grid current flow is producing a negative voltage drop across R_g, thus charging C_g. As the crystal vibrates in the opposite direction, it induces a negative charge which adds to the negative grid voltage produced by the charging of C_g. As a result, plate current is now reduced by the increasing grid bias, and the plate voltage rises. The rising plate voltage again induces a positive charge on the grid. The crystal now flexes in the opposite direction, and the plate voltage again induces a positive charge on the grid by piezoelectric effect. Grid current flow again tends to charge C_g, and the cycle is repeated.

For oscillations to occur, the crystal must be effectively synchronized in its vibration, so that the piezoelectric effect does not oppose oscillation by reducing the feedback between grid and plate. The proper phasing is accomplished by connection of the crystal between grid and plate. The inherently high Q of the crystal makes it act as a large inductor to shift the phase of the feedback voltage in the proper direction to cause oscillation. Capacitance Cl provides a ddi tionrd phase shift to complete the l?30-degree rotation needed.

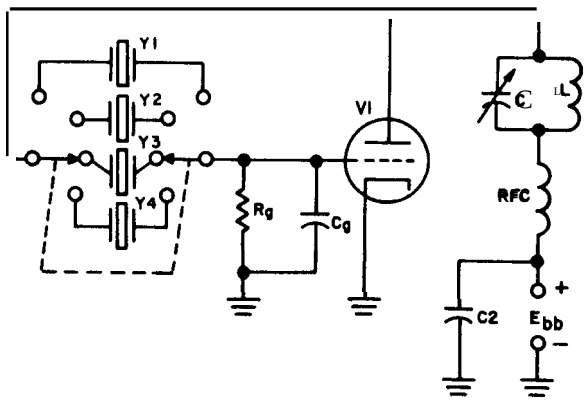
Bias **Considerations.** As in the conventional LC oscillator, grid-leak bias may be employed for self-bias and amplitude stabilization, but unlike the grid-leak circuit in the Miller oscillator previously discussed, it usually employs a grid capacitor (CJ because the crystal is connected between grid and plate and cannot provide the necessary grid-leak capacitance.

During operation, grid bias is produced by the grid leak and capacitor combination of R_g, C_g. As grid current is drawn the capacitor charges, and in the absence of grid current it discharges. After a few cycles of operation an equilibrium state is reached where the slight amount that leaks off during the negative cycle just equals the amount of charge during the positive cycle; thus a steady bias is maintained. This action is similar in all respects to that of the conventional grid leak in other forms of oscillator circuits.

Since the excitation in a Pierce oscillator is low, it is common to use a higher value of grid-leak resistance than in the Miller oscillator (grid bias is equal to $I_g R_g$). Fixed bias can be used in place of grid-leak bias to stabilize the operating point; however, fixed-bias operation normally requires that starting provisions be made, particularly if the bias voltage is at or below cutoff. When a power-type oscillator is required, a combination of cathode bias and grid-leak bias is sometimes employed. Use of the cathode bias provides a protective bias voltage in the absence of excitation and allows the use of a lower value of grid-leak resistance. However, the use of the combination bias also reduces the starting sensitivity and may be objectionable for keyed oscillators.

Other Considerations. Although the Pierce oscillator is normally used without a plate tank circuit, this is not always so. Where the output waveform is important, use of a selective tuned circuit in the plate circuit minimizes the harmonic content in the output and thus provides a purer waveform than is produced by a resistive plate load, which is not frequency responsive and provides a high harmonic content. Selection of the circuit with a resistor plate load for use in a crystal calibrator to supply harmonics of 200 to 300 times that of the fundamental proves particularly advantageous. On the other hand, when overtone operation is desired, the Pierce circuit ***must*** use a tuned tank circuit to select the desired overtone if a useful and practical output is to be obtained.

Since this circuit is a vigorous oscillator, it lends itself to use as a multifrequency oscillator which permits mumerous crystals to be switched into the circuit to obtain operation over a wide range of frequencies, as shown in the following illustration. A particular advantage of the Pierce oscillator is that, since crystal activity varies considerably from crystal to crystal, it will operate with a weak crystal as well as a strong one. Since the Pierce oscillator is normally operated at a low output than that of the Miller oscillator, an additional amplifier stage can bring the output up to the same level. Such operation can be accomplished conveniently by using a single dual-triode tube as oscillator and amplifier.



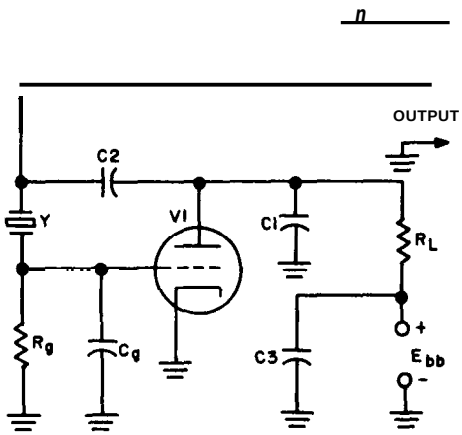
Multifrequency Crystal Oscillator with Plate Tank

Lack of a tuned output circuit sometimes causes difficulty when a crystal is used which has a strong overtone activity as compared with the fundamental, because the Pierce circuit tends to respond at the frequency of strongest activity. However, this is a fault of the crystal rather than the circuit, as a fundamental-ground crystal has its greatest activity at the fundamental frequency.

Because the plate impedance is resistive and of a high order, fluctuations in the plate resistance of the tube (which are only a small percentage of the totrd plate resistance) because of varying supply voltages or loads have less effect on the output frequency, so that this circuit is basically more stable than the Miller type oscillator.

Because the crystal is in series with the feedback from plate to grid and has full plate voltage across it, caution must always be observed to keep the fixed plate voltage below that which could cause excessive feedback and produce shattering of the crystal, or a frequency change due to heating of the crystal.

Circuit Modifications. Some typical circuit modifications made to improve the operation of the Pierce circuit or to overcome an inherent defect as shown in the following illustrations and are accompanied by a brief explanation. There are many variations of the basic Pierce circuit, because as long as the crystal is connected between the grid and any element other than the cathode, the resulting oscillator is basically a Pierce circuit.

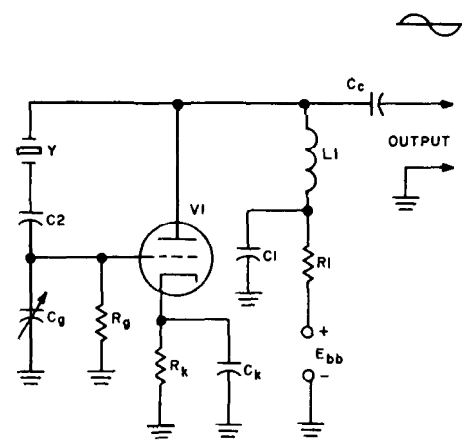


Grounded-Plate Pierce Circuit

The grounded-plate version of the Pierce circuit uses a capacitor, C2, to block the plate supply from the crystal and thus minimize the electrostatic strain on the crystal. Sometimes an r-f choke is placed in series with the cathode to reduce the shunting effect of Cl; however, this choke is unnecessary if the other components are properly chosen. The plate load resistor, R_L, may or may not be used (when it is not used, C3 is also eliminated). It might appear that, with no cathode choke and no plate load, the shunting effects of Cl and the power supply capacitor would effectively short-circuit the crystal output; however, since the output is taken directly between the crystal and ground, the shunting has little effect, and maximum crystal output is obtained.

The operation of this circuit is practically identical with that of the basic Pierce oscillator. Even though the schematic of the grounded-plate Pierce circuit shows that C2 prevents the dc plate voltage from straining the crystal, it does not prevent the plate voltage changes from appearing on the crystal. Furthermore, C2 is charged and discharged through the crystal capacitance. Therefore, the crystal is initially shocked into oscillation by the ac or r-f voltage changes occurring in the plate and grid circuits. Once oscillations are started, the operation is identical with that previously described for the basic circuit.

Another variation, using combination cathode and grid-leak bias, is shown in the following figure.

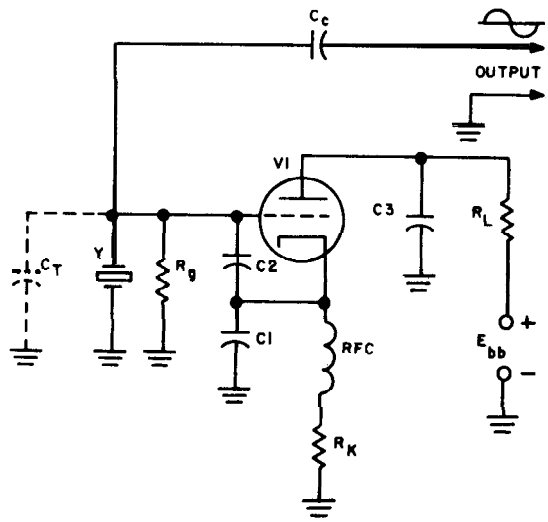


Combination Bias Arrangement

In the circuit above, R_k is a low-value resistor (Say 200 ohms) and furnishes cathode bias, being bypassed by C_k. Grid-leak bias is supplied by R_g (resistance on the order of 100,000 ohms) and C_g. The grid capacitor is made variable to provide a slight amount of tuning for the crystal, in order to permit operation with crystals of different frequencies. Actually, it has the same effect as C_1 in the basic Pierce circuit,

shown previously; that is, it provides the proper phasing for the predominantly inductive crystal to ensure oscillation. Capacitor C2 effectively reduces the strain on the crystal though it does not isolate it from the plate supply. In this respect, both this circuit and the preceding circuit show two variations of using a blocking capacitor in series with the crystal to reduce the crystal strain. This is done to protect the crystal; with a constant d-c potential applied to the crystal, it would be permanently strained in one direction, and could be shattered by the excessive strain produced when the oscillations are in the same direction as the applied plate voltage, causing it to vibrate greater in one direction than the other. In the circuit above, the plate load resistor is replaced by inductor L1 to avoid the d-c losses in a resistive load. The inductor also makes it desirable to have C_g variable to compensate for the phase-shifting of LI (it is assumed that the distributed capacitance of L1 in this case does not tune the inductor to the frequency of oscillation). Resistor R1 is a voltage-dropping resistor which is used to reduce the plate supply voltage to the desired plate voltage level; it is not required if the correct voltage is provided by the power supply. Capacitor Cl is the conventional series-feed decoupling capacitor.

Another method of connecting the crystal to avoid the strain produced by the plate voltage is to ground the crystal directly and to ground the plate through a capacitor, as shown in the following illustration. With this arrangement, the cathode must operate above ground, and an r-f choke is used to provide the necessary isolation. Capacitor C3 effectively grounds the plate so that the crystal is connected between grid and plate, but is unstrained by the d-c supply potential Resistor R_g, and capacitor C2, together with RFC and R_k, provide combination grid-leak and cathode bias, and C 1 and C2 form a typical Colpitts type capacitive feedback voltage divider. Capacitor C_t represents the total grid tuning capacitance (both the interelectrode and stray wiring) which is the effective tuning capacitance across the crystal (32 picofarads with MIL-STD types). In this case, it is clearly seen that the crystal acts as the tank circuit (see Ultraudion Oscillator equivalent circuit shown in the following illustration), but that it is shunted by the grid leak, which effectively reduces its Q. The output is taken from across the crystal through coupling capacitor Cc.



Grounded-Crystal Circuit Variation

Again, the circuit operation of the grounded-crystal stage illustrated above is practically identical with that of the basic Pierce oscillator previously described. The crystal is shocked-excited into vibration by the a-c plate and grid voltage changes. In addition, the capacitive voltage divider formed by Cl and C2 provides additional feedback to overcome the shunting effect on the crystal caused by grid leak R_g. Their value is such that the circuit will not oscillate with the crystal removed. Their use makes the circuit easier to start, and permits the use of crystals with much weaker activity than normal.

Detailed Analysis. The Pierce oscillator is considered to be the ultraudion version of the Colpitts type of L-C oscillator circuit, with the crystal taking the place of the plate tank as illustrated in the accompanying illustrations.

The Pierce circuit operates at a frequency which places it on the inductive side of parallel resonance in the crystal. When a plate tank circuit is used, it is always tuned to a lower frequency to make it appear as a capacitive reactance. Thus, the crystal operates somewhere between its series- and parallel-resonant frequencies. The tube grid-plate interelectrode capacitance, C_{gp}, is in shunt with the crystal, and the effective tank tuning capacitance of the inductive crystal is

the electrostatic crystal capacitance (represented by C in the Ultraudion equivalent illustration) in parallel with grid-plate tube capacitance C_{gk}, together with the series-parallel combination of grid+ athode capacitance, C_{gk}, and plate-cathode capacitance, C_{pk} (which includes the distributed wiring capacitances). For Military Standard crystals, this capacitance is always held to 32 picofarads total. Since the plate circuit is predominantly resistive, consisting of R_L only, as shown in the Pierce equivalent circuit above, any small fluctuation in any of these capacitances is minimized; as a result, the circuit has a more stable frequency of operation than the Miller oscillator. Capacitor C_p, previously illustrated in the basic Pierce oscillator circuit, is usually inserted to ensure that the circuit will oscillate with many different types of crystals. Although the crystal (tank circuit L,R, C in the illustration) is comected between plate and grid, and feedback occurs through the crystal, it is the basic piezoelectric charge applied to the grid-cathode interelectrode capacitance, C_{gk}, that couples the crystal into the circuit electrically, as is evident from examination of the Pierce equivalent circuit shown previously. Because the plate circuit is predominantly resistive, small fluctuations in tube plate resistance due to changes in operating voltages are a smaller percentage of the over-all total plate resistance; therefore, greater frequency stability is obtained than in the tuned plate oscillator, in which plate resistance changes are a much greater percentage of the total load resistance. The higher plate resistance and lower grid-plate capacitance of the screen grid tube are particularly advantageous in the Pierce oscillator. Since the crystal is effectively the tank circuit and represents the highest impedance in the circuit, it is evident that the largest voltage is developed across the crystal, but it is limited by the maximum voltage and power dissipation that the crystal can withstand without shattering. Thus, the maximum output from this type of circuit is limited by the crystal power-handling capability (area), rather than by circuit components. (Modem, l/2-inch-square, crystals have only 1/4 the power-handing ability of the old l-inch-square type.)

Failure Analysis.

No Output. If the crystal is removed or if poor or defective holder connections cause an open (or high-resistance) circuit, the crystal will not oscillate, and no output will be obtained. Also, if the plate load resistor is open or if a short circuit lowers the plate voltage sufficiently, the crystal will not oscillate. In the case of over+ xcitation when unloaded or air gap holders are used, the crystal may be burnt because of r-f arcs between the crystal and mounting plates, and it will not operate until cleaned. (Return crystal to repair center; do not attempt to clean it yourself.) In a poorly sealed holder, dust accumulation or moisture from condensation may also make crystal cleaning necessary. Normally, with the sealed, pressure-type holder, cleaning is unnecessary. An open series blocking capacitor will disconnect the crystal and stop operation.

Insufficient feedback capacitance between electron tube elements (most likely with pentodes) will prevent the crystal from oscillating, but this condition will not occur with a tube which has previously oscillated unless the tube becomes defective. An open grid resistor or capacitor will probably prevent operation, but may result in reduced output. Usually, only open-circuited or short-circuited conditions will prevent the circuit from operating. In the case of overtone operation, excessive detuning of the plate tank can cause a stoppage of oscillation, which will resume after the circuit is properly tuned.

Reduced Output. Since the Pierce crystal oscillator operates vigorously when excited, any reduction in output will result from lack of excitation or low plate voltage, rather than from high resistance or poorly soldered contacts. An open or shorted grid capacitor or grid-leak resistor will change the bias conditions and result in either reduced output or no output. When the grid-leak bias is combined with cathode bias, failure of the grid-leak bias will cause reduced output and perhaps hard starting. A dirty crystal may not oscillate at all or only weakly, and could be the cause of reduced output. With unsealed crystal holders a reduction in output, hard starting, or stoppage of oscillation was a signal for possible cleaning; however, with modern sealed holders the possibility of crystal contamination is not very likely, but should be kept in mind. (Return crystal to repair center; do not attempt to clean it yourself.)

Unstable Output. Instability may be due to an intermittent or poor (high-resistance) connection in the feedback circuit, but it is more likely to be due to a defective crystal which has been partially fractured by over-excitation. A crystal which normally operates satisfactorily in a tuned Miller oscillator may be defective and have a spurious frequency which is produced alternately with the desired frequency, when the crystal is used in a Pierce circuit, and thus cause an unstable output. Such a condition is evidenced by changes in frequency, due to erratic jumping from one frequency to the other.

Incorrect Frequency. Since the crystal frequency is primarily determined by its own constants, an incorrect frequency is probably the result of a change in the crystal itself or in the holder and associated wiring capacitances. Normally these changes are very small. If the crystal is not temperature-controlled, over-excitation can cause sufficient heating of the crystal to change the frequency; this condition is normally indicated by a continuous drift in one direction as the crystal is heated. A zero-temperature-coefficient crystal operating within its range of compensation will not be affected by minor temperature changes. Since a tuning adjustment is usually not provided, a noticeable change in crystal frequency indicates a circuit or crystal parameter change which should be checked. With the few parts concerned in this type of oscillator, it should not be too difficult to determine the defective component. Crystal or tube aging effects may also cause a change in frequency, which would be indicated by a slow change over a long time. Any decrease in grid circuit resistance may cause an increase in frequency, and an increase in the grid resistance due to high-resistance contacts may decrease the frequency. Cleaning the crystal sometimes restores it to its normal frequency of operation. However, do not attempt this yourself. Return it to the repair center. Actual aging of the crystal may cause a change of frequency, which is not correctable except by grinding or plating (at the repair center) to restore the proper thickness. Such aging usually does not occur quickly, but is cumulative over a long period of time. It should be noted that frequency is based upon time and that time is controlled astronomically and does vary in very minute parts. Thus, primary frequency standards are only accurate to 2 or 3 parts per 100 million for short

time operation, but this accuracy decreases as the time interval is lengthened. Therefore, crystal frequencies should not be expected to be absolutely accurate. However, they should be as accurate as their rated tolerance, and should normally require a stable secondary frequency standard to determine their error. Where crystal-controlled receiving and transmitting frequencies are involved, it may sometimes be suspected that either one or the other is in error when, in fact, both could be in error.

ELECTRON-COUPLED CRYSTAL OSCILLATOR (ELECTRON TUBE)

Application.

The electron<oupled crystal oscillator is used almost universally to provide an approximate sine wave rf output over the low-, medium, and high-frequency rf ranges. It utilizes a screen grid or pentode tube to provide extreme stability and greater output than is possible with a basic triode-crystal oscillator, and is widely used in transmitters, receivers, test equipment, and other equipments which require crystal frequency control. Its widest application is for frequency multiplication in the plate circuit.

Characteristics.

Utilizes piezoelectric effect of a natural or synthetic crystal to control frequency of oscillation.

Uses electron coupling to the load to reduce strain on crystal, to minimize load variations, and to provide extra stability.

Normally operates with automatic self-bias and class C, but may be operated with combination fixed and self-bias and class A or B for special design purposes.

Frequency stability is better than frequency stability of triode crystal oscillator, and power output is also greater.

Output waveform is a relatively constant amplitude sine wave, but if output is primary consideration it may be a distorted sine wave.

Uses a tuned plate tank for harmonic operation.

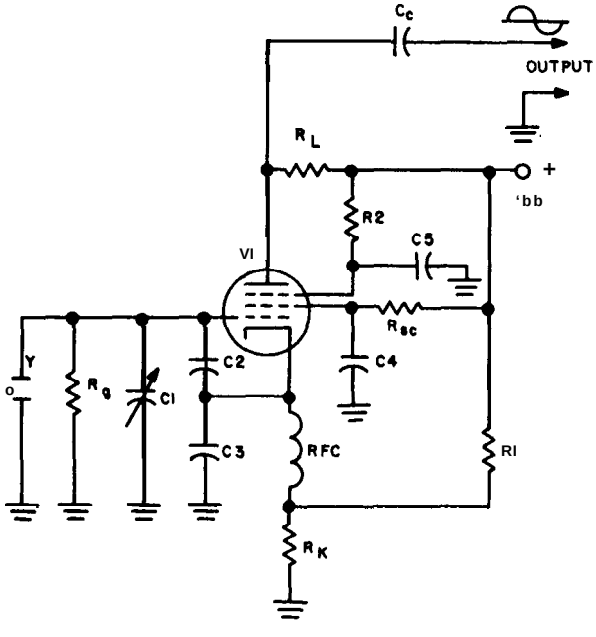
Circuit Analysis.

General. The discussion on the Electron<oupled LC Oscillator given earlier in this Section is generally applicable to this circuit. The basic crystal-controlled circuit employs either a Miller or Pierce oscillator which utilizes the screen grid of a tetrode or pentode tube as the anode. Either grounded-cathode or grounded-plate circuits may be used, with the grounded cathode being used mostly with a basic Miller oscillator, and the grounded plate being used mostly with the basic Pierce oscillator. The basic Miller oscillator is usually used for single-frequency operation, and always incorporates a tuned tank circuit. The Pierce oscillator is used where a number of frequencies are to be covered by changing of crystals, with no tuning adjustment being provided; however, plate tuning is required if harmonic operation (frequency multiplication) is desired.

Circuit Operation. A typical electron-coupled Pierce type oscillator is shown schematically in the following illustration. The grounded-plate version of the basic circuit is used to minimize the electrostatic strain on the crystal. The illustration shows a pentode tube rather than a tetrode because better electron coupling, or looser coupling, between load and crystal oscillator is possible because of the effect of the suppressor element. The looser coupling results from the fact that the screen grid completely surrounds the control grid and effectively isolates it from the plate circuit, and from the fact that the suppressor, if grounded or properly biased, minimized capacitance coupling between screen and plate. Thus, the coupling between oscillator and load circuit is provided by the electron stream alone, and any reflected load changes have negligible effects. Although the circuit shown may at first glance appear to be a Miller oscillator, it can be seen that the cathode is effectively above ground and that the oscillator plate (the screen grid) is grounded for ac by capacitor C4; hence, the crystal is connected (as in the typical Pierce circuit) between grid and plate (screen). This type of comection prevents the supply voltage from placing permanent electrostatic strain on the crystal, ans is preferred for that reason.

I n the schematic, the suppressor is shown grounded through C5, and it is held effectively at zero bias with respect to the plate by its connection to B+ through R2 (an internally connected suppressor type tube should ***not*** be used in this circuit). Thus, by construction, the grid is effectively shielded from the plate, and the coupling effects of plate-cathode capacitance are therefore reduced. Since the oscillator plate (the screen) is grounded, the RFC is used to keep the cathode above ground for rf. The output is

taken from across plate load resistor R_L through capacitive coupling. Actually, the plate load can be an r-f choke or a tuned LC circuit when the circuit is operating on the fundamental frequency. When it is desired to double or triple the frequency, it is necessary to tune the plate circuit to the desired harmonic, or overtone, for maximum output. Combination freed-bias (from voltage divider R_1 and R_k) and self-bias (from R_k) is used to stabilize the circuit against frequency changes caused by bias variations because the excitation changes for various crystals and frequencies of operation. Therefore, with a fixed oscillator anode (screen) voltage which is relatively unaffected by load variations caused by supply changes or tuning, plus a stable operating point established by the fixed bias, usually only temperature effects need be considered with evaluating the short-time frequency stability of the circuit. In a typical circuit of this type, changes in resistor values of 20% result in a frequency change of only 1 part per million (ppm), and capacitance changes of up to 10% produce frequency changes of less than 8 ppm, whereas changes in temperature of the crystal and other circuit parts produce frequency changes as high as 35 ppm per degree centigrade above ambient room temperature.



Grounded-Plate Pierce Electron-Coupled Oscillator

Use of a crystal with a better temperature coefficient and with temperature control can reduce this to a short-time frequency variation of only 2 to 3 ppm.

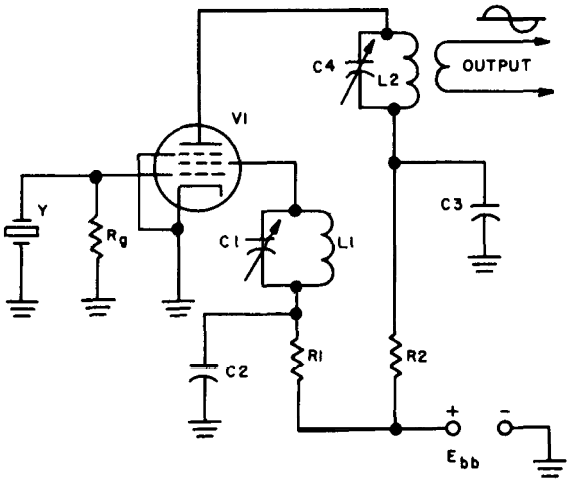
Electron coupling also affords greater output because the circuit employs the equivalent of two tubes, the triode section operating as a low-voltage oscillator with low grid excitation and low crystal strain, and the pentode section operating as an amplifier loosely coupled to the oscillator by the electron stream between screen and plate. Thus, the amplifier portion may be operated at high voltages, which if used in the basic oscillator would normally shatter the crystal; consequently, the power output from the amplifier plate is greater than that from the basic unit. The over-all result is a stable crystal oscillator operating with crystal excitation on the order of a few milliwatts and providing a power output on the order of watts. In most cases, the output is equal to or greater than the output available from the basic Miller type power oscillator, and has a greater frequency stability.

Now consider one cycle of operation. When B+ voltage is applied, the fixed cathode bias produced by voltage divider R1 and R_k permits a heavy flow of screen and plate current. Since the plate is isolated from the oscillator portion of the circuit by the zero-biased suppressor grid, and is coupled only through the electron stream in the tube, plate current flow has no effect on oscillator operation. Since the grid is located between cathode and screen, electrons will be intercepted from the space current, causing a small grid current to flow. Grid current flow through R_g develops a negative bias on the grid, which tends to charge Cl. Thus R_g and C 1 act as a grid leak and grid capacitor, respectively. Simultaneously, the crystal is shock-excited into oscillation by the changing grid and screen voltages. The crystal vibrations produce a piezoelectric voltage across the crystal, and between grid and ground (the screen is bypassed by C4, and acts as the oscillator anode). The crystal oscillates in synchronism with the grid and plate voltage changes. On the negative swing, the crystal-generated voltage adds to increase the bias and reduce the anode (screen) current. On the positive half-cycle, the total bias is decreased. Consequently, the screen current (and thus the electron stream through the tube from cathode to plate) is caused to alternately decrease and increase at the oscillator frequency. The capacitive voltage divider (C2 and C3), connected between grid

and cathode, and plate and cathode, fixes the minimum amount of feedback. Thus it helps stabilize the circuit and overcome any tendency toward hard starting because of the initial fixed cathode bias. The cathode is kept above ground potential by the rfc; otherwise, oscillation would not occur (screen and cathode would be short-circuited for r-f).

The electron stream between screen and plate varies in accordance with the crystal oscillation frequency. Since the plate voltage and current are greater than the screen voltage and current, the r-f output voltage developed across load resistor R_L is larger than the voltage developed across the crystal. Since the plate is isolated from the screen and oscillator section of the tube by the zero suppressor bias, any load variations or supply voltage changes have little or no effect on the oscillator. Thus, a more stable and higher-powered output is taken from the plate circuit of the electron-coupled crystal oscillator. The dc power dissipated in R_L, of course, appears as a loss of efficiency, since it is wasted in heating the resistor.

The accompanying circuit schematic shows the Miller version of the electron+ oupled crystal oscillator. Although this circuit requires two tank circuits, it has the advantage that doubling (or tripling) can be accomplished in the final tank, while the basic stability of the fundamental frequency is retained.



Miller Electron-Coupled Oscillator

Note that in this circuit the cathode is grounded; hence, even though the suppressor is shown externally connected, an internally connected suppressor type of tube could be used without impairing the electron coupling. Actually the second tank circuit (C4, L2) need not be used; a resistor or RFC could be used in its place, but tuning the plate circuit ensures that the proper output frequency is selected and reduces the harmonic content to a minimum. From the illustration it is evident that the basic oscillator circuit is connected between the cathode, grid, and screen (anode) tube elements, just as in the Pierce electron-coupled oscillator. However, the crystal is connected between grid and cathode, and the operation of the oscillator is as descrived previously (see Grid-Cathode (Miller) Crystal Oscillator discussion at the beginning of this section of the Handbook). Electrostatic isolation of the plate by means of the grounded suppressor limits the coupling to the electron stream alone, thus providing increased stability because of freedom from the effects of load variations on the oscillator.

Failure Analysis.

No Output. Lack of output from this type of oscillator may be due to a fault in either the oscillator portion or the amplifier portion of the circuit. Thus, it should first be determined whether the crystal oscillator is oscillating, using the failure analysis discussion of the basic oscillator as a guide. If the oscillator is operating, then lack of output is caused by lack of plate voltage due to an open or short-circuited condition. An open suppressor bypass capacitor may cause a virtual cathode to be formed between screen and plate and reduce the output almost completely. A defective electron tube may oscillate, but have insufficient emission to supply any appreciable output in the plate circuit. Usually, the cause of a no output condition can be quickly localized to a particular part by a resistance check of the few components involved.

Reduced Output. This condition is more likely than no output and may be caused by low plate voltage, by the presence of a high resistance in the plate load circuit due to poor connections, particularly in tuned tank circuits, and by excessive bias. Short-circuiting of the cathode bias voltage-dropping resistor connected to the supply source (R_i in Pierce circuit) would produce cutoff-bias conditions and the

tube would not operate; an increase in this resistance would minimize the fixed bias and allow the cathode bias alone to prevail, causing class A operation of the plate section, so that reduced output and a reduction of harmonic content would occur.

Incorrect Frequency. Since the frequency is determined by crystal operation, any basic frequency changes will occur solely in the oscillator section, except when the circuit employs a plate output tank. If this tank becomes tuned (either accidentally or by component faihrre) to the wrong harmonic of the crystal frequency, the circuit" will produce an output of incorrect frequency. Any changes caused by load fluctuations or supply voltage fluctuations will be so small that they may go unnoticed unless precision measuring equipment is available.

OVERTONE CATHODE-COUPLED (BUTLER) CRYSTAL OSCILLATOR (ELECTRON TUBE)

Application.

The cathode-coupled (Butler) crystal oscillator is used primarily for overtone crystal operation on high or very high radio frequencies. It is used in receivers, transmitters, test equipment, and other equipment which requires the use of a stable crystal-controlled high-frequency oscillator.

Characteristics.

Uses an overtone crystal to provide operation on frequencies which are not integral harmonics of the fundamental crystal frequency.

Employs two triodes coupled by the crystal operating all series resonance.

Normally operates class A, but may be operated class C for greater power output.

Provides an approximate sine-wave output of relatively constant amplitude.

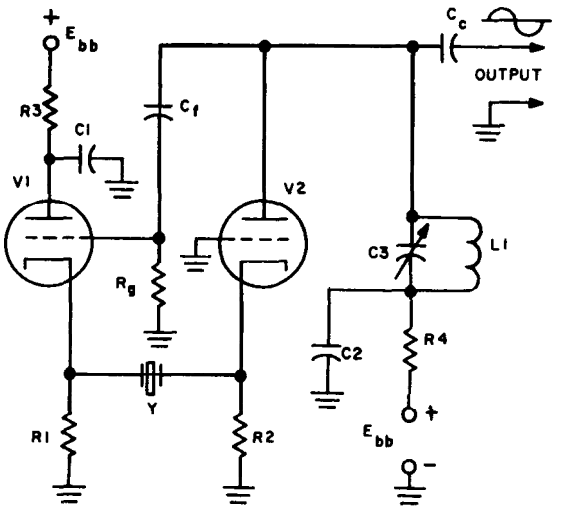
Circuit Analysis.

General. The Butler cathode-coupled two-stage oscillator is one of the most widely used of the ***series mode*** oscillators because of its simplicity, versatility, frequency stability, and comparatively high reliability. This circuit seems to be the least critical to design and adjust for operation at a given harmonic with any type crystal. The balanced circuit, plus the fact that twin triodes within a single envelope can be used, contributes to a saving in space and cost and provides for short leads. The cathode-coupled circuit can also be used for operation on the lower radio frequencies, provided that the resistance of the crystal unit is not greater than a few hundred ohms. However, the power output is less than that of the Miller circuit for the same crystal power, and the broad bandwidth of operation without tuning as provided by the Pierce circuit is not possible.

At series resonance, the crystal element appears as a resistance, so that in the normal circuit it can be short-circuited or replaced with a comparable resistor without stopping oscillations. Although circuit operation of the series-mode oscillator is less complicated than that of the parallel-mode oscillator, the circuit design becomes increasingly critical at the high frequencies and higher overtones. It is vitally important to keep stray capacitance at a minimum, and all leads must be as short as possible to eliminate unwanted resonances. It is sometimes necessary to nullify the shunt crystal capacitance by paralleling the crystal with an inductor which is antiresonant with the shunt crystal capacitance at the operating frequency. It may also be desireable to connect a capacitor in series with the crystal to tune out the stray inductance of the crystal leads, and tuned output circuits must be provided to select the proper overtone. For maximum frequency stability, the effective resistance of the circuit facing the crystal unit should be as small as possible. At the higher frequencies, stray capacitances limit the impedances obtainable with tuned circuits, making them more selective, and more effective in influencing the frequency and increasing instability.

Usually, the output is taken from the plate or cathode of either tube. Sometimes the cathode follower is a pentode tube utilizing the cathode, screen, and grid elements as the basic oscillator, which is electron+ oupled to the plate load. This provides greater stability and affords the possibility of tuning the plate circuit to a higher harmonic.

Circuit Operation. The accompanying illustration shows the basic cathode+ oupled circuit using triodes.



Basic Cathode-Coupled Crystal Oscillator

Tube V2 is a grounded-grid amplifier whose output is fed back to the cathode (input circuit) through cathode follower VI and the series-connected crystal. Cathode bias is supplied through RI and R2, and VI Normally conducts more heavily than V2 (both tubes are identical triodes). The feedback voltage is coupled capacitively through C_f to the grid of V1, and grid resistor R_g provides conventional grid-drive bias which varies with the excitation supplied. When operated class A, no grid current is drawn, and there is no grid-drive bias produced across R_g. In this instance R_g acts solely as the grid-return resistor in a conventional R-C coupling network, and the bias is produced by R1 alone. In class C operation, grid current is drawn, and grid drive bias is produced exactly as in the conventional r-f driven amplifier. In this case, the total bias consists of the self-bias produced through cathode resistor RI, plus the drive bias in the grid circuit. The tuned tank circuit (L_1 and C_3) in the plate of V2 offers maximum impedance at the frequency to which it is tuned. The maximum output voltage (and feedback) occurs at this point, neglecting crystal operation. The crystal is normally an overtone type, and is ground for maximum acitvity at the overtone frequency (fundamental frequency crystals are occasionally used with this circuit, but this fact does not materially affect the theory of operation of the circuit). Usually the circuit will oscillate when the crystal is short-circuited or replaced with an equivalent resistance, operating at the frequency of the tank circuit. Resistor R4 and capacitor C2 are a conventional plate voltage dropping and decoupling network provided for series plate feed of V2. Resistor R3 and Cl perform a similar function for V1 with sufficient capacitance to effectively ground the plate of VI for rf at the frequency of operation. The output is taken from the plate of V2 through coupling capacitor Cc, but it could also be taken from VI or from the cathode without materially changing operation.

Off resonance, the crystal exhibits a high resistance, which effectively reduces the feedback and prevents oscillation. At the series resonant frequency, the crystal exhibits a low resistance and the circuit oscillates vigorously. Since the gain of the cathode follower tube cannot exceed unity, there is partial control of excitation because V] cannot amplify the feedback from V2; as a result, greater feedback is provided for a weak crystal than for a strong crystal. This action enhances overtone operation, since the strongest oscillations are at the fundamental frequency, with successively weaker oscillations being obtained as the numerical value of the overtone increases.

Now consider one cycle of operation. When plate voltage is applied to V1 and V2, since no initial bias exists there is a heavy flow of plate current. The flow of plate current through RI and R2 produces a cathode bias on each tube which reduces the plate current flow. At the same time, the flow of plate current in V1 through plate resistor R3 drops the supply voltage to the proper value. Any a-c variations in voltage produced by changing plate current through R3 are bypassed to ground by C 1, and tube V1 operates as a cathode follower. The initial flow of current shock-excites the crystal so that it vibrates at its series-resonant frequency. At resonance the drystal appears as a low value of resistance, while on either side of resonance it appears as a large resistance. In the off-resonance, high-resistance state, the crystal attenuates any feedback from the plate of V2 through V1 and thus prevents oscillation. In the series-resonant state, the low crystal resistance permits practically all the feedback to be applied across R2. (The crystal resistance, R, and the cathode bias resistor, R2, form a voltage divider connected in parallel with R 1.)

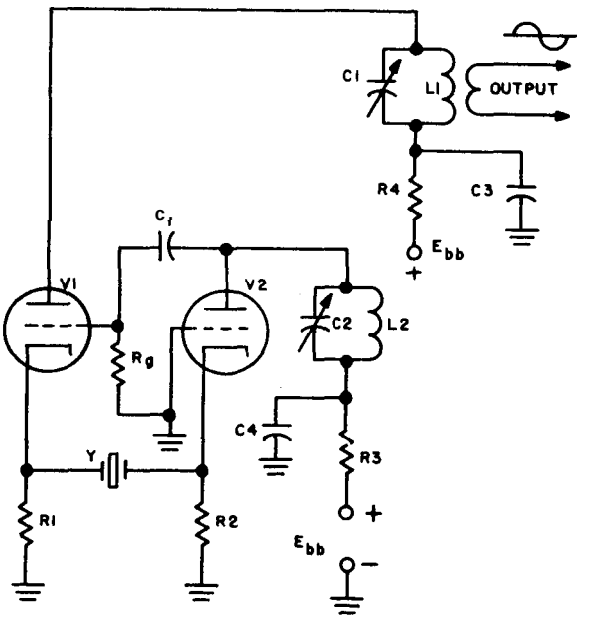
With the crystal oscillating on the positive half-cycle, assume that a positive voltage produced by

piezoelectric effect is applied to R2, and increases the bias. The plate current of V2, therefore, is reduced. Since the output voltage is developed across the impedance of the plate tank circuit, a reduction in plate current produces less drop across the tank, and the plate voltage approaches the source (goes positive). Thus, a positive-going voltage is fed through coupling capacitor C_f to the grid of VI. The positive-swinging grid voltage produces an increase of plate current in V1 and a positive increase across cathode bias resistor RI. Since the gain through cathode follower V1 is less than unity, no amplification of the signal occurs through V1. Sufficient feedback occurs, however, to replace the small circuit losses; thus oscillation is sustained.

On the negative half-cycle of operation the crystal develops a negative voltage which is applied to R2. The bias on V2 is thus reduced, and the plate current increases. The output voltage produced across the tank circuit is now negative-going, and is fed back to the grid of V1 to reduce plate current flow. Consequently, the voltage drop across cathode resistor R1 is decreased, and a negative-going voltage is applied through the crystal to maintain oscillation.

Although it might appear that the feedback voltage is such as to oppose crystal oscillation, it must be realized that this circuit will operate with the crystal removed if the equivalent resistance (or an ohmic connection) is placed across the crystal terminals. Operation without the crystal, however, is never as stable as with the crystal.

Circuit Modifications. As with all other oscillator circuits, there are numerous variations of the basic circuit. A typical variation is shown in the accompanying illustration.

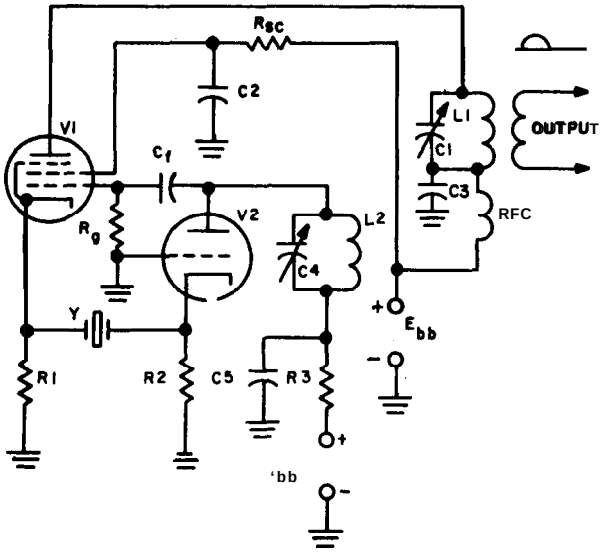


Frequency Multiplying Overtone Oscillator

This circuit is essentially identical with the basic Butler overtone oscillator, except for the insertion of a tuned tank in the plate circuit of the cathode follower. Thus, the cathode follower stage becomes a cathode-coupled stage. The effect on over-all operation is to make available an output which can be tuned to a harmonic of the overtone frequency (instead of being bypassed to ground as in the basic circuit) and provide effective frequency multiplication.

As far as the basic oscillator is concerned, the operation is the same as described for the basic circuit. Although amplification occurs in the plate circuit, since the plate load of VI is tuned to a different frequency, any coupling effects through the plate-grid capacitance do not affect the basic frequency.

An electron-coupled version is formed by connecting VI as a conventional pentode amplifier which is resistance-capacitance coupled to V2, with the frequency multiplying tank in the plate circuit of Vl, shown in the following illustration. This version is identical with the basic Butler circuit except that the screen of V1 acts as the anode of the cathode-follower stage. With the screen ac grounded through C2 and the suppressor tied back to the cathode, the plate is coupled solely through the electron stream between screen and plate. The rfc and C3 form a conventional series plate feed decoupling network, and R_{sc} is the screen resistor. All other components function as in the basic oscillator. In this circuit VI is usually operated class C, and has a high applied plate voltage. Thus, the plate output is considerably higher than in the previous triode type of frequency-multiplying circuit, and the tank L_1 and C_1, may be tuned to either the second or third harmonic of the oscillator frequency. The basic tank C_4L_2 is tuned to the fundamental frequency.



Electron-Coupled Overtone Oscillator

Although other versions of the Butler circuit exist, they are similar to the versions described above. The identifying feature of the Butler oscillator is the connection of the crystal as a series feedback arm between two cathode-coupled stages. Overtone oscillators with grid-cathode or grid-plate comected crystals are special versions of the Miller and Pierce circuits.

Failure Analysis.

No Output. A primary cause of inoperation is a defective crystal or poor holder connections; the crystal and holder resistance should not exceed 500 ohms for proper operation. Since two tubes are involved, a defective tube is also a possible cause of no output. An open circuit in the feedback path, either in the coupling capacitor or crystal holder, will rdso stop operation. In addition, short-circuited components will cause the affected tube to draw greater than normal current and stop oscillation. A short circuit across the crystal will not stop oscillation; depending on the design, it is possible for oscillation to continue at the tank frequency. Lack of supply voltage will also stop operation, but low supply voltage will primarily affect only the output amplitude. Because of the few components involved, a quick voltage and resistance check should isolate the defective part. If all parts and voltages appear normal, the cause of trouble is in the crystal, or the tank tuning capacitor is shorted or tuned' to the wrong frequency. If other crystals oscillate in the circuit, cleaning the defective crystal may restore activity. (Return crystal to repair activity for cleaning.)

Low or Unstable Output. Excessive bias on one or both tubes will reduce the output. Such bias could be caused by heavy current through the cathode bias resistors due to defective tubes or short-circuited components in the plate circuits. A change in the grid-leak resistor and in the coupling capacitor constants may cause blocking and motorboating or intermittent operation. A weak or dirty crystal may also produce low output. (Replace the crystal.) Too low or too hi&a plate voltage can cause instability.

Incorrect Frequency. The series-resonant crystal oscillator is the most stable kind. Therefore, a change in frequency will probably be due to crystal caused effects. Cleaning the crystal should restore proper operation (cleaning to be done only at repair activity); if not, there is a possibility that changes in stray capacitance between cathode and ground (perhaps

491-044 0 - 73 - 43

from a change of lead dress) have caused a slight detuning. Though operation at a frequency above the series frequency can occur, it is rather unlikely because the limits of series resonance do not permit as much detuning as those of parallel resonance.

OVERTONE CRYSTAL OSCILLATOR (SEMICONDUCTOR)

Application.

The overtone type oscillator is used as an oscillator in receivers, converters, frequency synthesizers, and test equipment, and as an exciter in low-power transmitters. Its use is restricted to the high-frequency ranges (above 20 mc) where fundamental mode crystal operation is not practicable.

Characteristics.

Uses piezoelectric effect of a quartz crystal operating on an odd overtone to provide stable high-frequency oscillations.

Has at least one tuned circuit at overtone frequency and may have two; it is never untuned.

Operates class C to help produce harmonic operation.

Regenerative feedback is usually provided through a tapped coil (Hartley principle).

Always operates as a crystal-controlled oscillator to avoid spurious frequencies.

Circuit Analysis.

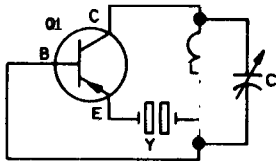
General. Overtone circuits are basically of two types: one type uses. a crystal which is ground for fundamental frequency operation, and the other uses an overtone ground crystal. Since the circuits that use overtone crystals are usually designed for specific types of crystals, this discussion will be restricted to circuits which can use either type of crystal.

Basically, the overtone crystal oscillator uses an inductive form of feedback, but it is not necessarily limited to that type. It just happens that at the present state of the art the inductive type is more popular. Although the tapped coil is primarily a Hartley feedback arrangement, it is closely similar to the tickler coil feedback arrangement. At the frequencies used, the tighter coupling of the Hartley arrangement and the ease of construction make it a more natural choice.

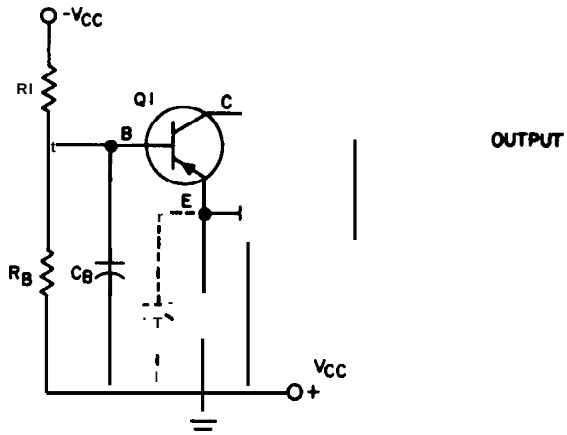
For operation of an overtone circuit, regenerative feedback must be provided to assist in the starting of oscillations, but the feedback must not be strong enough to cause free-running oscillations. Most circuits of this type are first designed to operate as free-running oscillators, and the amount of feedback is then reduced by the manufacturer until only the crystal controls the oscillation. Oscillation is usually vigorous, and the output at the third and fifth overtones (using a fundamental crystal) is almost as large as that at the fundamental; at higher overtones, the output falls off quickly. The output depends so much upon the processing and manufacture of the crystal, however, that the highest overtone at which practical operation is possible is rather indefinite. Designers have produced satisfactory outputs on overtones above the 11th, but mostly with patented circuits and special components. In the transistor crystal oscillator, for example, overtone operation has been improved by the use of special transistors designed to minimize phase shift at very high frequencies. When this type of transistor is combined with an overtone crystal or a specially processed crystal, the results equal or surpass similar electron-circuit tube achievements, but the power output is less.

Circuit Operation. A simplified schematic of the basic overtone semiconductor oscillator, using the common-emitter configuration, is shown in the accompanying illustration, It can be seen at a glance that this is the basic Hartley Oscillator circuit with a crystal in series with the emitter feedback connection. For simplicity, bias and supply arrangements are not shown. It is assumed that the collector is reverse-biased and the base forward-biased, and that PNP junction transistors are used. The crystal can be either a fundamental or an overtone type. The tank circuit, consisting of L and C, is tuned to the overtone frequency desired. The principle of operation is exactly the same as the principle of operation of the basic Hartley oscillator, with proper polarity of feedback between the oppositely polarized collector and base being obtained by means of the tapped-coil arrangement. The difference in operation is primarily in the amount of feedback, with the portion of the coil between emitter and base producing just enough feedback for easy starting with the crystal in place. In the self-excited Hartley, the tap on the inductor is normally at or near the center of the coil, the number of turns between emitter and base being selected for strong and stable feedback. In the overtone oscillator the feedback coil usually consists of a few turns (no more than 3 or 4), approximately 10% of the total

number of tank coil ,turns. This corresponds very closely to the tickler coil oscillator arrangement used in regenerative receivers, where it is possible to just produce oscillation with the regeneration control all the way on. The overtone oscillator regeneration, however, is adjusted so that the circuit will not quite oscillate with the crystal out of the circuit, but will produce, strong stable oscillation at the crystal frequency only (no spurious self-oscillation) with the crystal in the circuit.



Simplified Overtone Circuit



Overtone Crystal Oscillator

A typical overtone circuit with bias and supply connections is shown in the accompanying figure. The common-emitter circuit is used, and the crystal is in series with the feedback loop as in the basic schematic. Voltage divider bias is obtained through R1 and R_B, and the base resistor is bypassed for rf by C_B. An unbypassed emitter swamping resistor (R_e) is used for stabilization. Actually, at the high frequencies used, it is probable that the distributed capacitance (shown in dotted lines in the schematic) across R_E and the resistor itself form a grid-leak bias arrangement for amplitude control, and that some designs may use a bypassed emitter. In the circuit shown, the collector supply is bypassed by C_2, with the RFC connected in series between the negative collector supply terminal and L_1, as a conventional series-feed arrangement.

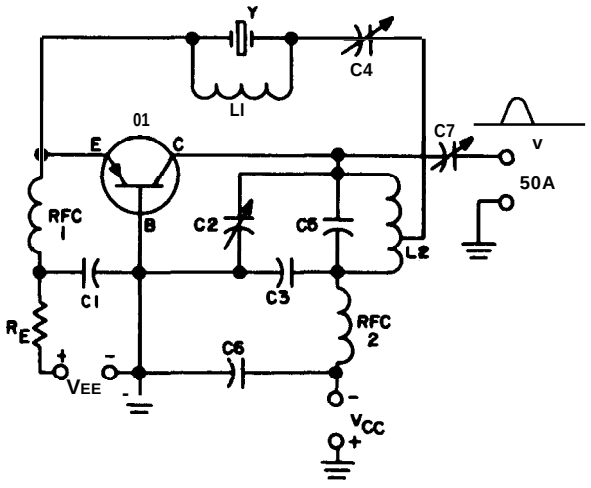
Now consider one cycle of operation. When collector voltage is applied, bias divider R_1R_B supplies class A bias to the base, and collector current flows as in a conventional amplifier circuit. Assume that a noise pulse causes the collector current to increase and that a voltage is developed across the tank circuit (L_1C_1), which offers a high impedance at the resonant frequency. The voltage developed across the tank is positive with respect to the supply end. The crystal offers a low-impedance path to the emitter at series resonance. With the crystal connected near the supply end, that electrode is negative, and the electrode connected to the emitter is positive. Therefore, a voltage exists across the crystal, causing it to deform in one direction. The base of the transistor is connected for rf through C_B and C_2 to the supply end of the tank coil. Thus the tank is essentially connected between collector and base, with the emitter

tapped to the tank. This is equivalent to a typical Hartley-type of grounded-base feedback oscillator, which is effective only for the series-resonant frequency of the crystal. On either side of resonance the increasing crystal impedance quickly stops any feedback, and the circuit will not oscillate.

As the noise pulse causes the collector current to increase, the feedback to the emitter is positive and the base end of the coil becomes more negative. Both the more negative base and the more positive emitter cause an increase in forward bias and a greater I_c. The collector current increases until the supply voltage bottoms (cannot go any lower). During this time the tank capacitor, Cl, is charging. The tank circuit now discharges and the polarity of the base and emitter feedback voltages change to produce a reduced forward bias and a lowering of I_C. This causes the collector voltage to rise toward the supply voltage and become more negative. At the same time, since the polarity across the crystal changes, the crystal flexes in the opposite direction as a result of piezoelectric action. This state of operation continues until the collector current cutoff point is reached; at this time a small flow of I_{CEO} (reverse current) occurs, but it has no effect on operation other than to cause a lowering of efficiency. When the feedback ceases, the crystal flexes back toward its original resting condition and generates a piezoelectric charge that starts collector current flowing again, and the cycle repeats. Emitter resistor R_E is affected only by the dc current flow, and operates as a simple swamping resistor for thermal compensation and stabilization. In some circuits the distributed capacitance across R_E is considered to cause it to operate in a manner similar to that of the electron-tube grid leak. That is, the charge across this capacitance holds the circuit inoperative until the charge leaks off; too large a capacitance will effectively short the crystal. The capacitance is shown in dotted lines in the above illustration because it is not considered necessary for operation. The output is taken capacitively through Ccc between collector and ground, or, if desired, by inductive coupling to the tank circuit. The tank circuit is tuned to the overtone frequency, and the crystal also operates at the overtone frequency.

Circuit Variations. A typical practical operating design used in a satellite transmitter is shown in the following figure. The grounded-base arrangement is employed. The tank circuit is connected between base and collector, and the emitter is connected to the tap on the tank coil through the series crystal and capacitor C_a. Separate bias supplies are shown because their use provides almost perfect stabilization; however, voltage divider bias can be used if only one supply is available. RFC 1, in the emitter circuit, is used to keep the emitter above ground, and R_E, which is bypassed by C 1, provides emitter swamping (and also controls output). Forward bias is applied between the emitter and base by battery supply V_{EE}. Conventional series collector feed is provided through RFC2, which is bypassed for rf by C6. The output is taken capacitively from the collector through C7, which is adjustable to match of 50-ohm load. Capacitor C3 is a base blocking and coupling capacitor (it also affords a reduced tuning range for C2); it connects the base to the tank circuit for rf and isolates it from the dc collector supply; otherwise, the supply would be short-circuited. Capacitor C5 is a trimmer across the tank, and variable capacitor C2 is the tank tuning capacitor. Feedback is obtained from the tap on L2, and applied through C4 and the series crystal to the emitter. In this circuit, C4 adjusts the phasing to ensure feedback of the proper polarity and to compensate for the phase lag in the transistor at high frequencies. It acts as a variable regeneration control to permit the use of various types of crystals and replacement transistors. Inductor L1 is used to resonate out the effects of excessive crystal holder shunt capacitance at the frequency of operation. At the series resonant overtone the crystal offers minimum inpedance and supplies maximum feedback from collector to emitter. Although the emitter and collector are of the same polairty, or phase, L2 and C4 provide the necessary phase rotation to insure oscillation, since the feedback is taken from the end of the tank coil opposite the collector.

4



Grounded-Base Overtone Oscillator

Now consider one cycle of operation. When voltage is applied, the fixed bias, which is less than cutoff, permits collector current to flow. Assume a noise pulse which causes an increased I_c. Since the tank is connected between collector and base, with the emitter tapped onto the coil, it is basically a Hartley-type oscillator. In this circuit L2 acts as an autoformer, with the emitter-base turns coupled to the emitter-collector turns. However, the emitter is not directly connected to the coil; it is connected through crystal Y and capacitor C4 in series. The capacitor offers only a small capacitive reactance to the oscillator frequency; the crystal offers a high impedance off-frequency, and a low inpedance at its series-resonant frequency. Thus, feedback is permitted at the series-resonant frequency, but is stopped on either side of resonance.

The increased collector current induces a feedback pulse in the emitter-base portion of L2 in a direction which increases the forward bias, and, hence, the collector current. Capacitor C4 provides a phase-delay adjustment which can reduce the amount of feedback (or increase it, as desired) so that various types of crystals and transistors may be used. For the purpose of this discussion it carI be considered as short-circuited, since it is only a production type or compensator, and is not necessary to basic operation. Since the feedback action is regenerative, the collector current continues to increase until the collector saturates and no further change can occur. At this time the crystal, which was initially deformed by the feedback potential between the emitter and collector, flexes in the opposite direction. The polarity across the crystal produced by piezoelectric action also reverses, and the flow of emitter current is reduced; since the collector current is also reduced, and the feedback is regenerative, the collector is driven to cutoff. At this time a small I_{CEO} (reverse current) flows, but it has no effect on operation except to lower the over-all efficiency. At this time C 1, which was charging during the conduction period, now discharges through R_E. When the bias drops below cutoff, current again flows and the cycle repeats. During the reducing collector current period, the crystal is flexed in a direction opposite the initially caused deformation, and at cutoff it again flexes oppositely and resumes its original shape. Thus, the crystal is caused to oscillate, and in oscillating it provides a low-impedance path for the feedback. Because of its inherent stability, the crystal controls the frequency by permitting operation to occur at only one frequency. The basic tank circuit (L2, C2) functions in the conventional manner to supply energy during the nonconducting half-cycle, so that the negative output alternation may be completed. This flywheel effect provides a sine-wave output through coupling capacitor C7, instead of the distorted pulse which otherwise would occur.

The circuit described above is capable of providing an output of 15 to 30 milliwatts at an efficiency of 30 to 35% to a 50-ohm load, and a maximum output of 100 milliwatts at an efficiency of 40 to 45%. Under constant loading and controlled temperature, the short time frequency stability is plus or minus one part in one hundred million. The circuit uses a fifth overtone crystal operating on 108 MHz and a diffused base transistor.

Failure Analysis.

No Output. Loss of output will result from the loss of bias or supply voltage due to an open- or short-circuited component; this condition is easily determined by checking for the presence of voltage. An incorrectly tuned tank circuit will prevent the crystal from operating and could result from shorted turns or a shorted tuning capacitor, but at low voltages used, troubles of this kind are rather unlikely with ordinary components. In miniaturized circuits where the current-carrying capacity is low, there is the possibility that an overload can cause the induc-

tor or leads to open. It is important, therefore, to use a meter having a very low full-scale current requirement, preferably in the microampere region. A VTVM is preferable to the standard 20,000-ohms-per-volt meter, although with care both can be used interchangeably. A check of the forward and reverse resistances of the transistor will quickly determine whether it is at fault. Because of the low potentials involved, a high resistance or poor soldered joint can introduce excessive resistance and stop the circuit from oscillating. A defective, partially fractured, or dirty crystal can also prevent oscillation.

Reduced Output. Since the output amplitude is primarily controlled by the emitter swamping resistor and bias voltage, changes in these parameters can cause reduced output. Opening of the bias ground return resistor will place a higher bias voltage on the transistor, and, depending upon the internal base-to-emitter resistance of the transistor, oscillations may be blocked entirely or hard starting may result. Hard starting is usually a clear indication of a dirty or defective crystal. The value of the emitter resistance and its bypass capacitor will determine the output amplitude to a great extent; therefore, a partially shorted capacitor or increased resistance in the emitter circuit will reduce the amplitude. Such troubles can be easily located by making a resistance check of the few components in the circuit. A reduction of output may also be caused by short circuiting of the transistor elements or by mismatching of the transistor due to a change in the circuit values. This too is easily checked by making a resistance analysis and by measuring the forward and reverse resistances of the transistor. A combination of low foreward resistance and high reverse resistance indicates a satisfactory transistor. If the forward resistance is high or nearly the same value as the reverse resistance, the transistor is defective. If both resistances are zero, the transistor is short-circuited.

Incorrect Frequency. Since the crystal is the frequency-determining component, an appreciable change in frequency indicates a defect or a change in the crystal, except where the tuned circuit is actually tuned to another overtone. Under normal conditions it is practically impossible to tune the tank to resonance at a different overtone unless the tank circuit components are defective. Although a fimdamentrd type crystal will operate within the tolerances marked on the holder, it must be kept in mind that for overtone generation of the crystal the tolerances will be multiplied by the overtone number (1, 2, 3, etc); hence, the tolerance range at the overtone will be much larger. Oscillation will occur, not over the entire range of tolerances, but at a specific frequency within the range. On the other hand, overtone crystals are rated for their actual tolerance at the overtone frequency; therefore, operation outside this range indicates a defective crystal or spurious oscillations. As a result of changes in circuit components and transistor parameters with age, excessive feedback may occur at certain resonant frequencies and produce free-running oscillations. Usually these signals have a much rougher or more raspy sound and are less stable than the controlled oscillations. In the case where calibration capacitors or feedback controls are provided, it is normal for them to control the frequency slightly so as to permit the crystal to be operated on its exact frequency. When no controls are provided, a change in ambient temperature can place the crystal in another class of temperature compensation and change the actual overtone frequency. The temperature tolerance is shown on the crystal holder and is stan&rd for a MIL type crystal. Minute imperfections or partial fractures can also cause the crystal to operate at another frequency. Return defective or dirty crystals to the crystal repair activity for servicing.

TICKER COIL FE EOBACK CRYSTAL OSCILLATOR (SEMICONDUCTOR)

Application.

This oscillator is used to provide an approximate sine-wave r-f output that is extremely stable under crystal control, and operable over the low-, medium-, and high-frequency r-f ranges. It is universally used where a transistor oscillator is required; typical applications are local oscillators in receivers and heterodyne converters and oscillators in test equipment.

Characteristics.

Uses piezoelectric effect of a quartz crystal to control oscillator frequency.

Uses a feedback (tickler) coil to provide the proper phasing for oscillation and control of regeneration.

UsuaIly has the primary coil tuned to the crystal fundamental frequency, with the secondary (tickler) coil being untuned. Not restricted to a particular configuration; may be **CE, CB,** or CC as desired.

Can operate on a fundamental, harmonic, or overtone frequency if proper tuned circuit and crystal are selected.

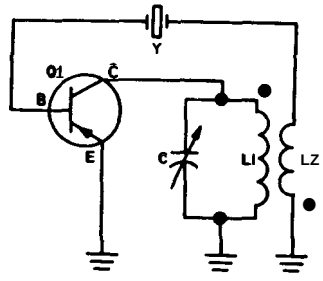
Circuit Analysis.

General. The semiconductor tickler coil crystal oscillator is basicrdly a transformer< oupled oscillator. It may be either tuned or untuned, or partiaIly tuned by stray and distributed capacitance. When the circuit is tuned, it is possible to operate the crystal on a fundamental frequency and tune the tank circuit to a harmonic, thus obtaining frequency multiplication, or to use overtone crystals for the same result. Like the electron-tube crystal oscillator, it may be crystal-stabilized or crystal-controlled. However, this circuit discussion will be restricted to the crystal-controlled type of oscillator. The ease of obtaining the feedback and controlling it makes the tickler coil feedback circuit popular. Since the polarity of each coil with respect to the other is easily changed by reversing the windings (at the time of manufacture), and since the coupling may be made tight by spacing the coils close together, or loose by spacing them apart, it is easy to obtain the proper amount and polarity (or phasing) of feedback. With the use of inductors to provide a low dc resistance, the dc resistance losses are minimized, and more output is obtained from the circuit with better efficiency. Since the transistor requires a certain amount of stabilization against bias and temperature changes, it is usually necessary to add stabilization resistors or reactance.

The use of a crystal operating in the series-resonant mode is more common with transistor oscillators because the crystal serves as a convenient means of permitting feedback at the resonant frequency by virtue of its low impedance series resonant circuit, but offers a hi@ impedance to feedback at all other frequencies. When placed in series with the feedback loop, the crystal effectively controls the feedback. Use of the parallel-resonant mode is not obviated, however, since sufficient flexibility exists in the placement of the crystal in either the collector, base, or emitter circuit to match circuit conditions. For example, since the common-base circuit has a high output impedance, the crystal could be placed in the collector-to-base (or ground) loop and operated effectively as a parallel resonator. Actually, the possibility of three different basic circuit configurations, together with placement of the crystal in either the input or output circuits, poses a problem in the circuit discussion because of the numerous circuit variations that can be formed. The discussion will, therefore, be limited to a typical circuit considered most likely to represent present day use. It is assumed that placement of the crystal or choice of circuit configuration does not materially change the basic stability, but that it does affect the power output and efficiency of operation to some extent.

Since the crystal power oscillator practically does not exist in the semiconductor field (most outputs are on the order of milliwatts), the crystal is not restricted in its placement by power requirements or heat dissipation, but it may be placed so as to produce the best performance.

Circuit Operation. The basic common-emitter circuit configuration for the tickler coil crystal oscillator is shown in the accompanying illustration. For the sake of simplicity, bias and collector supply voltages are not shown and will be discussed later. It is assumed that forward bias is applied to the emitter-base junction and that reverse bias is applied to the collector junction. The discussion is based upon the use of PNP junction transistors, although the basic principles also apply to point-contact transistors. From the discussion of basic transistor operation in the Amplifier Section of this Handbook, it will be recalled that the inputs and outputs of the common-collector and common-base circuits are of the same polarity, or in-phase, and that those of the common-emitter circuit are oppositely polarized, or out-of-phase. Thus, to ob tain the desired polarity (phase) of feedback in the common-emitter circuit, the two coils are oppositely phased. In the illustration the feedback is from collector to base, with the input being considered from base to emitter. Since the polarity is reversed in the transistor collector circuit, the tickler coil, L2, is connected so that it also reversed the polarity, and feedback through the crystal (series-mode operation) arrives at the base properly polarized (or phased) to produce regeneration. Removal of the crystal, which is in series with the feedback loop, will prevent the occurrence of feedback; therefore, the circuit will not oscillate with the crystal removed. However, the circuit is normally designed to operate as a self-excited oscillator with the crystal short< ircuited.



Basic Tickler Coil Crystal Oscillator, Common-Emitter Circuit

The operation of the circuit is similar to the operation of the electron-tube Tickler Coil LC Oscillator described earlier in this section. When the oscillator is switched on, current flows through the transistor as determined by the biasing circuit. Initial noise or thermal variations (initial current) produce a feedback voltage from collector to base through the crystal which is in-phase with the initial noise pulse. Thus, as the emitter current increases, the collector current also increases, and additional feedback through L1 and L2 further increases the emitter current, until it reaches saturation (or the collector voltage bottoms) and can no longer increase. When the current stops changing, the induced feedback voltage is reduced until there is no longer any voltage fed back into the base-emitter circuit. At this time, the collapsing field around the tank and tickler coils induces a reverse voltage into the base-emitter circuit which causes a decrease in the emitter current, and hence a decrease in the collector current. The decreasing current then induces a reverse voltage into the feedback loop, driving the emitter current to zero or cutoff. At this time a small reverse saturation current (I_{CEO}) flows, representing a loss of efficiency, but having no other effect on circuit operation. The discharge of tank capacitor C through L_1 then causes the voltage applied to the base-emitter circuit to rise from a reverse-bias value through zero to a forward-bias value. Emitter and collector currents flow, and the previous action repeats itself, resulting in sustained oscillations.

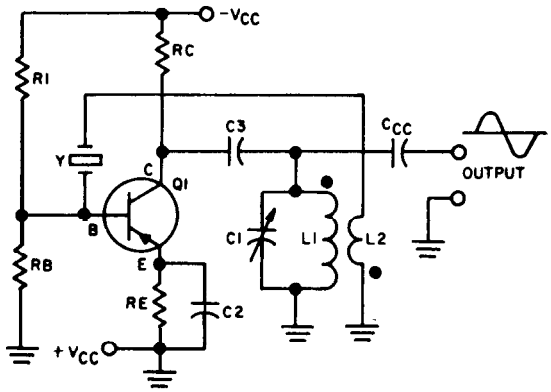
While this oscillatory action is going on, piezoelectric action occurs in the crystal; that is, as the feedback voltage is increased, the strain on the crystal is increased with maximum strain (and maximum crystal deformation) occurring at the peak of the cycle. Upon reversal of the feedback voltage the strain on the crystal is reduced; since the crystal is now changing shape back to its original form, a piezoelectric charge (potential) is produced across the crystal. This charge is opposite to that which produced the deformation of the crystal. For example, if the original charge which caused the deformation was positive, the crystal causes a negative potential to appear across itself when the strain is released. This potential is in the direction of the feedback (decreasing) so that alternate positive and negative charges are induced across the crystal as it vibrates. These potentials add to the feedback voltage; as a result, the crystal enhances the feedback, and the feedback increases the strength of the mechanical vibrations.

Since the feedback and piezoelectric action are regenerative the transistor quickly reaches its saturation and cutoff points. By correctly proportioning the turns and coupling between the tank circuit and the tickler coil, it is easy to obtain the proper amount of feedback, although with the low potentials involved there is no danger of fracturing the crystal as in the vacuum-tube oscillator. The amount of feedback is adjusted to produce maximum stability. The crystal current is not nearly as great as the crystal current in an electron-tube circuit; in fact, the total transistor collector current is usually less (depending on the type of transistor) than the electron-tube crystal current.

Although the collector-emitter capacitance of the transistor is in parallel with the tank circuit, the use of a low L/C ratio (high-C) produces effective capacitance swamping so that variations in the collector supply voltage, which produce a change in this capacitance, have a minimal effect. For good stabilization, a Zener diode placed across the supply provides excellent regulation. By careful design, the short time stability of the semiconductor crystal oscillator can be made as high as 2 or 3 parts in ten million, which is better than the stability of the equivalent electron tube oscillator. The power output is, of course, very small; however, this fact increases the stability since any change of output load or tuning results in a smaller over-all change. Thus, the frequency stability of the circuit is less affected by load changes than that of the electron-tube (triode) circuit. The output may be taken from the emitter or collector, or even the base circuit, by means of either capacitive or inductive coupling.

The circuit operates at the natural or fundamental frequency of the crystal for the series mode; hence, the operating frequency is slightly lower than the tank resonant frequency. It is also possible to operate this circuit using the parallel mode (antiresonant operation) of the crystal by proper choice of circuit parameters. Although the crystal offers a high impedance at the antiresonant frequency, sufficient feedback can be obtained to sustain oscillation in this mode. In this case, the crystal appears as a high-Q inductor which is tuned by the total shunt capacitance (self, stray, and distributed) across it, and the tank is tuned to a higher frequency. This type of operation is particularly applicable to the higher frequencies, where the shunt crystal capacitance is appreciable. For operation in the parallel mode, the frequency stability is slightly degraded and the output is slightly less than the output in the series mode. Both types of operation are in use.

Bias and Stabilization. In practical circuits, bias and stabilization are usually combined. Bias is usually provided by a freed voltage divider (RI and RB), as shown in the accompanying illustration of a typical tickler coil crystal oscillator. Note that the base in this case is not bypassed for rf, although in some circuits it may be. When it is unbypassed, there is presumed to be a slight amount of degeneration, which enhances the circuit stability.



Tickler Coil Tuned Collector Crystal Oscillator

Collector resistor R_C serves two purposes, to drop the collector voltage and to provide resistance stabilization. If the dc losses are serious, the resistor can sometimes be replaced by an r-f choke. Emitter resistor R_E, which is bypassed by capacitor C_2, provides the major stabilization by emitter swamping action, as explained in the Amplifier Section of this handbook. The tank circuit consists of L1 tuned by Cl, with tickler coil L2 untuned, and is coupled to the collector through C3 in a shunt-feed arrangement. The crystal is in series with the feedback circuit with the tickler coil polarized so as to produce regenerative feedback. In similar circuits of this type using the tuned base configuration, the crystal is connected directly between base and collector, and the tank between base and ground. In this case, the operation is identical to the operation of the circuit described above; however, the feedback is basically controlled by the capacitance between base and collector, thus making the circuit more suitable for the parallel mode of operation.

Taking the output across the tank through capacitor Ccc effectively places the load across the tank and reduces the operating Q, but provides a good waveform because of the smoothing action of the tank circuit. Without the tank circuit, since the oscillations consist essentially of clipped pulses, the waveform would be quite distorted unless the circuit were operated with class A bias. The class of operation is usually class C, with the emitter resistor and capacitor R_EC2) acting similar to a grid leak in tube oscillators. In the circuit shown, the initial bias is class A for easy starting, with the operating bias being determined by the values of the emitter RC circuit. With large values of capacitance for C2 fixed bias alone is provided, but as the capacitance is reduced to a small value the self-bias developed across R_E increases.

Failure Analysis.

No Output. In addition to failure of the transistor, no collector voltage or excessive bias can cause a no-output condition. Transistor failure is not very likely under normal conditions, and the transistor should be replaced only after all other checks have been made. Lack of collector voltage can occur because of opening of the series collector resistor or short-circuiting of the tank coupling capacitor, which-provides a path to ground through the tank inductor. An open emitter resistor will also cause lack of output. A short-circuited coupling capacitor will place the output load directly across the tank and could change the resonant frequency sufficiently to prevent feedback at the crystal frequency, and stop oscillation.

Reduced Output. Although aging of the crystal may cause a change in the resonant frequency, it is more likely to cause a drop in output as the crystal becomes less active. This condition usually results in a gradual change over a long period of time and is most easily determined by comparison with a known good crystal operating in the same circuit. A change in bias conditions or in the emitter RC network will probably reduce the output because of the amplitude regulating effects of these components. This condition could be caused by an increase in emitter resistance value or by a reduction in capacitance of the emitter bypass capacitor. These conditions are most likely to occur in miniaturized circuits where new component fabrication techniques have not been perfected. If a resistance analysis shows all circuit values normal, there is a possibility that the crystal is dirty and requires cleaning; however, this condition is not very likely to occur in sealed holders, and certainly will not occur in evacuated holders. Do not attempt to clean the crystal yourself. Return it to the crystal laboratory for servicing.

Incorrect or Unstable Frequency. Placement of the equipment so that it is subjected to a change in ambient temperature will cause a change in frequency if the change is not within the range of the temperature characteristic for which the crystal is cut. Likewise, small capacitance changes in the crystal circuit (particularly when the crystaI is operated in the parallel resonant mode) will cause slight changes in frequency. Detuning of the tank circuit, if sufficient, may cause the crystal to pop in and out of oscillation with a slight change in frequency. Voltage variations will produce a change in the collector capacitance and cause a slight change in the operating frequency. At very low audio frequencies or at high frequencies near f_{max}, phase shift within the transistor csused by transit time effects may produce instabilities (such trouble is not encountered in properly designed circuits). In the crystal-stabilized circuit (which is not used in the Navy), changes in component values may cause oscillation at undesired frequencies outside the range of the crystal, but in the crystal-controlled circuit they cannot cause this effect because the circuit can oscillate only over a very narrow range about the resonant frequency or at an overtone. This can easily be determined by observing whether the circuit oscillates with the crystal removed. If the crystal is short-circuited, it is possible in the series mode of operation for the circuit to oscillate at the tank frequency, but not in the parallel mode of operation. Frequency changes can sometimes be traced to a defective crystal, but more often to varying supply voltages. If a crystal oven is used to keep the crystal temperature stabilized, a defective oven may cause the frequency to shift.

COLPITTS CRYSTAL OSCILLATOR (SEMICONDUCTOR)

Application.

The Colpitts crystal oscillator is used mostly at the higher radio frequencies as an extremely stable oscillater in receivers, transmitters, and test equipment. However, it may also be used at low and medium radio frequencies.

Characteristics.

Uses piezoelectric effect of a quartz crystal to control oscillator frequency.

Feedback is provided through a capacitive voltage divider arrangement, which is usually external, but it may be provided through the transistor element capacitances.

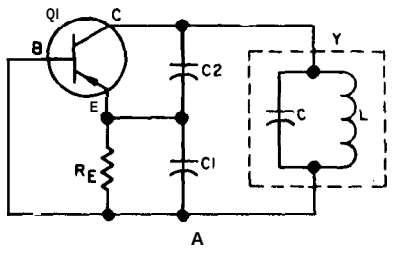
Normally does not use a tuned tank circuit adjusted to the crystal fundamental frequency (but may employ a tuned circuit for special applications).

Operates class C if waveform is not important, and class A if good waveform is required.

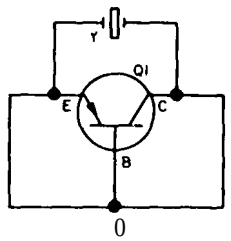
Circuit Analysis.

General. The Colpitts type crystal oscillator is usually used at the higher radio frequencies where the difficulty of tightly coupling the inductors in the inductive feedback circuits makes their use problematical. Actually, the so-called Colpitts version uses three basic feedback arrangements: (1) the external capacitive voltage divider with the crystal in shunt (or in series) (2) the crystal acting as a high-Q tank inductor similar to that in an ultraudion arrangement (parallel mode operation), and (3) the in-phase capacitive feedback arrangement, which is included in the Colpitts group solely becuase the feedback is capacitive (some texts may not regard this as a Colpitts, but as a special type of its own). The basic circuits of each type are shown in the accompanying illustration. Part A of the illustration employs the common-emitter configuration, and parts B and C use the common-base configuration. Actually, the circuit of part B can also use the CE configuration, and that of part C can use only the CB or CC arrangements, because the

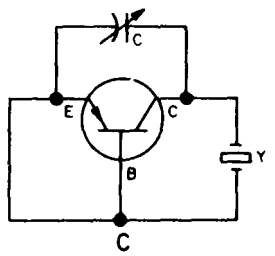
feedback must be between elements of the same phase of polarity. In the case of part C, the circuit is unique with semiconductors, since in electron tubes there is always a polarity inversion between input and output (except when used as cathode followers). The circuit of part B is analogous to the Pierce electron tube crystal oscillator.



External Voltage Divider Arrangement (Parallel Mode)



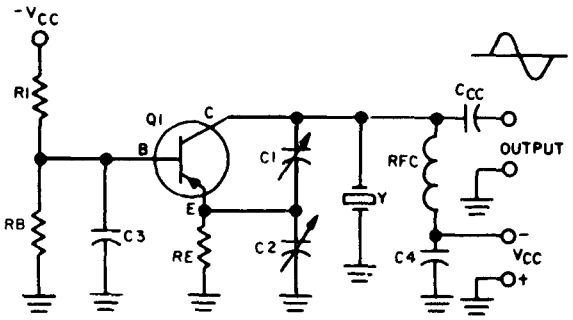
U1 **tra-audion Arrangement**



Basic Capacitive Feedback Circuits

For maximum power output, the input and output closely as possible; this requirement accounts to a great extent for the numerous variations in circuitry, since it is usually possible to sue any of the three basic circuit configurations and to ground any element. With the crystal determining the frequency stability of the circuit it is only necessary to arrange the proper polarity of feedback and provide a small amount of excitation to start the crystal oscillating. Although in a few cases the phase relationships within the transistor may require tight coupling to provide oscillation, it is usually easier to obtain stable crystal oscillations than to obtain stable self-excited oscillations, because of the assistance of the piezoelectric effect. The Colpitts semiconductor crystal oscillator, like its electron-tube counterpart, is usually a vigorous oscillator in the high-frequency range. However, the use of a quartz crystal does not extend the maximum frequency of oscillation, although it sometimes does provide better performance in the region between the alpha cutoff frequency and f_{max}. Thus good design makes it mandatory to use a transistor capable of oscillating strongly m the desired radio-frequency region of operation regardless of crystal control, Although there are a number of circuits in use, there is not much evidence at the present state of the art that the Colpitts is much (if any) more stable than the tickler coil crystal oscillator. Its main use is to improve operation at the higher frequencies.

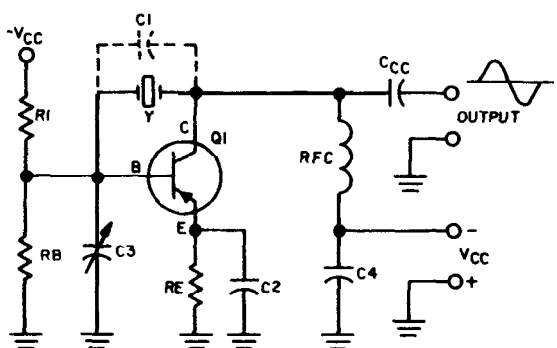
Circuit Operation. A typical common-emitter Colpits circuits using the external capacitive divider feedback method is shown in the accompanying schematic. Voltage divider bias is used for easy starting and is supplied by RI and R_B, with R_E providing emitter swamping resistance for stabilization of the transistor. Feedback is provided from collector to ground. With the base effectively bypassed by C3, the capacitive voltage divider consisting of C 1 and C2 is effectively connected between collector and base for rf. Both feedback divider capacitors are variable to permit adjustment and control of feedback. Capacitor Cl also serves to bypass rf around emitter swamping resistor R_E. Capacitor C2 is the primary feedback control, and is usually made variable to facilitate operation with more than one type of transistor and crystal. The crystal is connected between the collector and ground and operates in the parallel mode. The collector is series-fed through the RFC and conventional bypass capacitor C4. The output is taken capacitively through Ccc from the collector.



Untuned Colpitts Crystal Oscillator

The operation of the Colpitts type of oscillator basicaMy depends upon the action of the voltage divider consisting of Cl and **C2.** Assume that the oscillator is first turned on. With fixed class A bias supplied by bias voltage divider R1, R_B, collector current flows, and a voltage appears across the Cl, C2 divider. The voltage appearing across Cl is in parallel with emitter resistor R_E. Assume that a noise pulse caused by thermal action in the transistor causes the collector current to increase. A portion of the noise pulse voltage is then fed back through C2 to the emitter, causing the collector current ot increase further (this is a regenerative action). At the same time, this increase in noise voltage at the collector also appears across crystal Y. Thus, the crystal is slightly strained mechanically by piezoelectric action. When the collector current reaches satr.tration, no further change in I_c occurs, and the regenerative action ceases. At this time, the electrostatic strain across the crystal begins to reduce as capacitor C2 discharges (the heavy current flow from collector to emitter effectively shunts the capacitor). Thus, the emitter to ground voltage is reduced, the forward bias is reduced, and the collector current starts to fall. This action is also regenerative, and the transistor quickly reaches cutoff. As the collector current reduces, the voltage across the crystal approaches that of the supply (becomes more negative), and the crystal is now strained in the opposite direction. As a result, as each cycle of this action continues, the crystal oscillates at its parallel-resonant frequency. Since oscillation of the crystal produces a voltage across it, once started into vibration, the crystal continues to oscillate Since the crystal is connected in shunt from collector to ground, it effectively functions as a parallel-resonant tank circuit, and smooths out the pulses of oscillations into approximate sine wave-forms. On the conducting portion of the transistor operating cycle, it is effectively reinforced by the ensuing pulse of collector current, and during the nonconducting portion of the cycle, it supplies what would otherwise be the missing half-cycle of oscillation by flexing in the reverse direction. Emitter resistor R_E and capacitor Cl form an amplitude limiting device similar to that of the electron tube grid leak. The output is taken from across the crystal, with CCC acting as a dc blocking and ac coupling capacitor. It is evident that the crystal must be capable of handling the power developed, since if driven too hard it will fracture. However, at the normally low milliwatt outputs obtained with transistors, this is no problem. It does indicate, however, that the transistor crystal oscillator requires additional stages of amplification to produce the same r-f drive as an electron tube crystal oscillator.

A typical Colpitts crystal oscillator of the ultraudion form is shown in the following illustration and may be compared with the basic version. This circuit is analogous to the Pierce type crystal oscillator, and is more easily recongnizable because the crystal is connected directly between collector and base. The common-emitter configuration is also used in this version, and feedback is provided directly through the crystal. Voltage divider class A bias is obtained by means of **R1** and R_B for easy starting, with emitter swamping being provided by R_E, bypassed by C2.



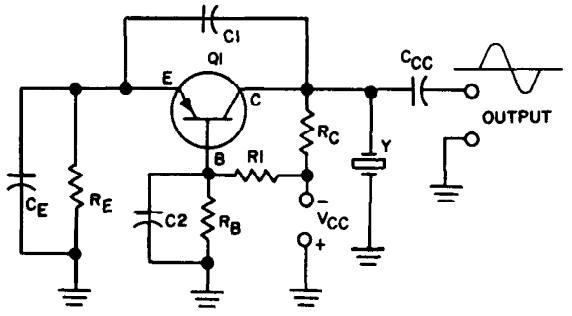
Ultra-audion Colpitts Crystal Osci11 ator

4

The output is taken capacitively from the collector circuit through Ccc. In this instance, C3 isa variable control which permits adjustment for feedback and transistor variations. Both this circuit and the Pierce electron-tube circuit operate almost identically. The feedback capacitive divider in this case consists of the total shunt capacitance across the crystal (including holder and stray wiring capacitance, plus the internal collector-base capacitance, shown dotted as Cl) and external capacitor C3 to ground. In this circuit version, the crystal and feedback network appear to be in the base circuit, rather than the collector circuit as in the other version. The difference is that, like the ultraudion electron-tube oscillator, the crystal is considered to be a tank circuit operating in the parallel mode, and since the capacitance of Cl and C3 is usually less than that of Cl and C2 in the previous circuit version (the emitter-collector capacitances is much larger than the base-collector capacitance), the ultraudion circuit tends to be operable at higher frequencies than the external capacitive-divider circuit. Also, phase shifts within the transistor due to transit time effects are such that they aid in producing the correct feedback polarity.

Now consider one cycle of operation. Assume that crystal Y at rest and the circuit, as illustrated above, is inoperative with no collector voltage applied. At rest, the crystal is unstressed and there is no charge on either plate. When the collector voltage is applied, since the circuit is fixed biased for class A operation by voltage divider Rl, R_B, collector current flows similarly to that in a conventional amplifier. With the base connected to one plate of the crystal and the collector connected to the other plate, when one plate is negative the other plate will be positive. This is the same condition as when the crystal produces a piezoelectric voltage; it is also the same as the polarity for base-collector operation in the common emitter circuit (base polarity is opposite to collector polarity). Therefore, the instant the collector appears negative at turn-on time, the piezoelectric voltage across the crystal causes the base electrode to be positive; this small positive voltage, in turn, causes a reduction in I_c, producing a decrease in collector current. Thus, the collector voltage (of a PNP transistor) becomes more negative. This action is regenerative, and quickly drives the collector to cutoff. During this time the crystal is being deformed in the same direction. During cutoff a small I_{CEO} current flows which only affects the efficiency of the circuit. Since the value of I_{CEO} is steady, there is no change in feedback from the collector. Meanwhile, the small charge developed on C2 by the flow of emitter current through R_E leaks off, reducing the emitter bias and permitting the class A bias to again cause normal current flow. The increase in collector current now causes a reduction in collector voltage, in effect producing a positive swing. The crystal now changes polarity and flexes back toward its original shape. As a result of piezoelectric action, a negative charge now appears on the base electrode. This causes a further swing of collector voltage in the positive direction (this action is also regenerative), and at full current flow the crystal is equally deformed in the opposite direction. At this time the flow of I_c is again steady (corresponds to saturation current flow with self-bias). Since the emitter current flow through R_E produces a bias voltage, C2 now charges and the emitter bias is added to the fixed bias. Once again the collector current is reduced by the increasing bias, and the cycle repeats. Thus, in flexing back and forth in accordance with the changes in collector voltage, the crystal is caused to oscillate; in turn, it produces an in-phase piezoelectric voltage which enhances circuit action. The crystal oscillates at some frequency between that of series and parallel resonance. Actually, the phase shift of the feedback voltage from collector to base, which is necessary to produce oscillation, is produced by the crystal acting as a high-Q inductor which produces an initial 90-degree shift. An additional phase shift is caused by the base-emitter capacitance, which is sufficient to cause an effective feedback large enough to overcome any of the resistive losses in the circuit. Thus, continuous oscillation under control of the crystal is assumed. Although the basic oscillation consists of distorted pulses of collector current, the effective tank circuit action of the crystal helps smooth out these pulses into approximate sine-wave oscillations. The output is taken through coupling capacitor Ccc, and appears as a resistive load in shunt from collector to ground.

The common-base arrangement of the Colpitts crystal oscillator using in-phase capacitive feedback is shown in the following illustration. Voltage divider



Colpitts Common-Base *Crystal* Oscillator

bias is supplied by R_1 and R_B, and the base resistor is bypassed for rf by C2. Emitter resistor R_E, which is bypassed by C_E, provides conventional swamping of the emitter circuit, and R_C provides resistance stabilization in the collector circuit. The crystal is connected between collector and ground, but is effectively connected between the collector and base for rf by means of C2. The output is taken capacitively from the collector (across the crystal) through Ccc.

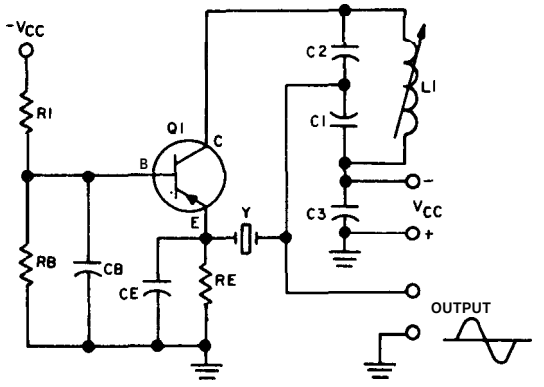
Since the emitter and collector in the common-base circuit are of the same polarity (in-phase), feedback is obtained by using Cl to apply a portion of the collector voltage to the emitter.

Now consider one cycle of operation. Fixed class A bias is supplied by voltage divider Rl, R_B. When collector voltage is applied, Q1 conducts as in a conventional amplifier. Assume that a noise pulse occurs in the base circuit, which causes the collector current to increase. The voltage drop across collector resistor R_c appears as a positive-going puke, which is applied through Cl to the emitter. This increase in emitter bias is in the forward direction, causing a larger flow of collector current. Thus, a regenerative in-phase feedback exists. The positive-going noise pulse is applied to crystal Y, which is in shunt from collector to ground, causing the crystal to be distorted in one direction by piezoelectric action. When the collector voltage bottoms (becomes almost zero), no further feedback occurs and the crystal flexes in the opposite direction. By piezoelectric action the crystal polarity is now reversed and a negative charge appears at the grounded electrode. Since the base is connected to ground through C2, the base now has a negative voltage applied and thus operates to reduce I_C. As the collector current reduces, the drop across R_C becomes negative-going and approaches the source voltage.

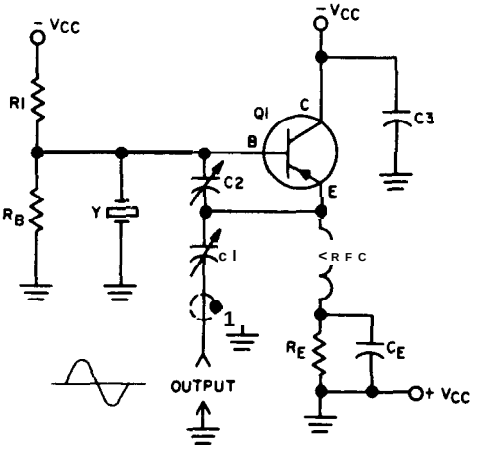
The feedback through capacitor Cl is also negative and reduces the forward emitter bias, causing a still smaller I_c to flow. This action is also regenerative and continues until cutoff is reached. At this point a small flow of reverse current (I_{CEO}) exists, but it has no effect other than to reduce the over-all efficiency of the circuit. Once the feedback stops, there is no further change in current, and C_E (which was charged negatively during this half-cycIe) starts to discharge through emitter resistance R_E. When the emitter voltage drops to a value which again starts I_c flowing, a positive-going voltage is produced across R_C, and a positive voltage is again fed back through Cl, and the cycle repeats. During this time the crystal is now flexing in the opposite direction and the polarity across it again changes, so that the crystal-induced piezoelectric voltage is in phase with the collector-base voltage. Actually, the crystal acts as a tank circuit, smoothing out the rough pulses of current into approximate sine-wave variations. By appearing as a high-Q inductance, the crystal insures that the proper feedback phase relationship is maintained, and, since it is a low-loss tank, the feedback through Cl need only be sufficient to supply the small tank losses to sustain oscillation.

By properly proportioning C_E and R_E, the bias can be made to reach the region of class C operation for best efficiency, as in regular gridleak operation, while the fixed class A bias makes certain that starting occurs easily. The output is taken from across the crystal through coupling capacitor Ccc. Therefore, the load is in shunt with the crystal and tends to reduce the output somewhat as in the electron-tube Pierce circuit.

Circuit Variations. Because the Colpitts crystal circuit has so many variations, a few representative circuits are shown in the following illustrations to facilitate identification of this type of circuit. Parts are labeled as in previous illustrations where they serve the same function, and the discussion is limited to the basic differences between these circuits and those considered previously.



Tapped Cdleetor Crystal Oscillator

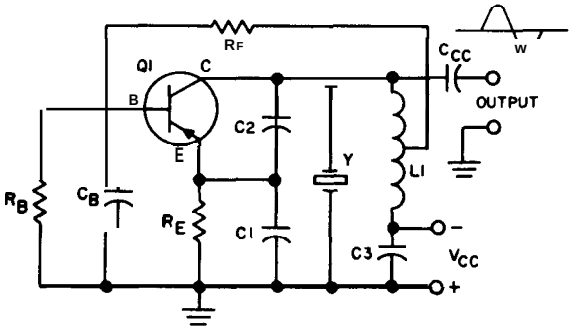


Grounded-Collector Colpitts Crystal Oscillator

In this circuit version, conventional voltage divider bias and emitter swamping are used for stabilization. The crystal is series-connected between the emitter and the collector by the voltage divider, consisting of Cl and C2, connected across L1. The operation of this circuit is based on a combined matching of impedances and a feedback connection. Connecting the crystal to the emitter through the capacitive voltage divider provides the proper feedback polarity, and the capacitances of Cl and C2 together with L1 form a tuned tank circuit which is resonant to the crystal fundamental (series-resomnt) frequency. The input and output impedances of the transistor are matched by the proper capacitance ratios, producing the same effect as though the collector were tapped across L1. The output is taken between the tap and ground, that is, across the crystal. This type of circuit is usually used at the lower r-f frequencies. The use of a tuned tank helps provide a good waveform and permits frequency doubling or the use of an overtone crystal.

A grounded-collector common-emitter version in which the voltage divider and crystal are located in the base circuit shown previously. Conventional voltage divider biasing and emitter swamping are used for stabilization. The collector is grounded for rf by C3. Thus in effect the crystal is connected between base and collector similar to the Pierce grounded-plate electron-tube version. However, the crystal, although isolated from collector voltage, is still subject to the small bias voltage from base to ground. Feedback is provided through capacitive divider Cl and C2, with primary control of feedback being provided by C2. Capacitor Cl is used to tune (match) the output, which is taken between the tap and ground. This type of connection offers a low output impedance suitable for coaxial line matching. The RFC is used to keep the emitter above ground; otherwise, the load or output would be short-circuited through C_E. ***No*** particular claims are made for this version other than its output matching feature.

The inverse feedback type of crystal oscillator shown in the following illustration, utilizes a conventional Colpitts with an external feedback capacitive voltage divider and with the crystal in the collector circuit. Bias is obtained by a conventional voltage divider, and emitter swamping is used for stabilization. The bias is provided in conjunction with feedback by tapping R_F on L1. Thus, dc bias is obtained through R_F and R_B, r-f feedback is obtained through R_F and L_1. The basic feedback path is through the capacitive divider, Cl and C2, and the secondary feedback path is through L_1 via R_F. Placing the tap at the lower end of L_1 produces regenerative feedback, and placing it at the upper end produces degenerative feedback, because the polarization of the collector is opposite that of the base. Thus, by placement of the tap, the feedback can either enhance oscillation by regenerative action or stabilize operation by degenerative action. The possibility that unwanted resonances of parts in this circuit may tend to cause free-running operation makes this version of dubious value. With the output being taken from the collector, it is more likely that the feedback tap provides better input and output matching to the transistor, similar to the tapped collector circuit previously mentioned.



Inverse Feedback Crystal Oscillator

Failure Analysis.

No Output. In tuned circuit oscillators, the loss of output can be due to improper tuning. Also, a defective crystal will prevent operation, in either tuned or untuned circuits. A suspected crystal can easily be checked by the substitution of a crystal known to be good. A simple resistance check will indicate continuity and general parts condition. A defective bias resistor producing a high bias voltage (in the divider arrangement) can prevent starting, and will be made evident by a resistance or voltage check. An open bias arrangement can prevent operation by causing a lack of bias, or by causing excessive internal bias due to feedback within the transistor. An open r-f choke, collector resistor, or coil will also stop operation. A shorted coil in the tuned circuit can stop oscillation, but the short will not be revealed by a resistance check. This condition is checked (after all other components have been eliminated from suspicion and a crystal known to be good has been substituted) by grid-dipping the tank for resonance. A defective transistor should be suspected only if all other parts check satisfactory and bias and supply voltages are normal.

Reduced Output. A low supply voltage or increased collector resistance can cause a reduction of output. A reduction of bias from class B or C to class A will also result in reduced output. Both of these conditions can be determined by a simple voltage check, preferably with a vacuum-tube voltmeter or a high-resistance voltohmmeter. Reduced crystal activity, due to aging or semi-fracture, or a dirty crystal can also be a prime cause. In this case, substitution of a crystal known to be good will restore normal operation. A change in the value of the emitter swamping resistor or bypass capacitor can cause excessive bias, and consequent squegging or motorboating due to intermittent blocking of oscillations. In circuits designed for the higher frequencies, changing the lead dress or parts wiring during repair may change the distributed wiring capacitance sufficiently to detune the circuit and cause a reduced output. In the tuned tank versions of this circuit, reduced output can also be caused by a high-resistance tank circuit connection or a shorted turn.

Incorrect Frequency. A defective or dirty crystal can cause an abrupt change from one frequency to another; this can sometimes be corrected by adjusting the tank tuning, if an adjustment is provided. Aging of the crystal can also cause a slow change over a long period of time; this change can sometimes be compensated for by means of a small trimmer capacitor, if the frequency is higher than normal. (Do not add an unauthorized modification to accomplish this. In most circuits a trimmer is included to permit calibration to the exact frequency for which the crystal is ground.) Failure of the collector supply regulation (as well as the bias supply regulation) can cause the effective element capacitance of the transistor to change

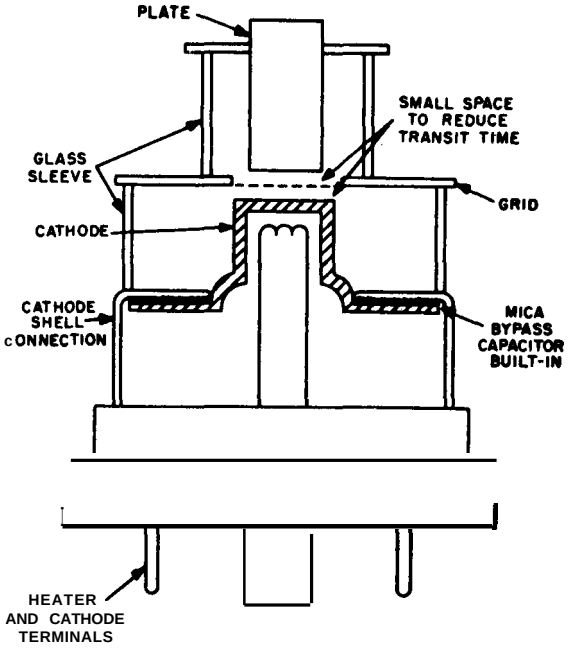
and cause slight off-frequency operation. In this case, check the supply voltage with a high-resistance voltmeter and observe whether there are occasional fluctuations of the voltage when the crystal is suddenly removed from its socket and reinserted into its socket or when the load is suddenly removed and replaced. If all components check normal and trouble is still present, the crystal is probably defective.

PART 6-3. TUNED-LINE OSCILLATORS

TUNED-LINE OSCILLATORS

General.

As the frequency of operation extends into the VHF and UHF regions and into the microwaves, it becomes more and more difficult to produce oscillations using conventional electron tubes. At the extremely high frequencies even the best oscillators are not very efficient. The difficulties of high-frequency operation involve the construction of the electron tube. As the frequency increases, the transit time between electrodes must be considered. Also, the tube electrodes have capacitance between each other and ground, and their leads have inductance. At the lower frequencies these capacitances and inductances are negligible as compared with the other lumped circuit components, but at the very high frequencies they become the major part of the circuit, and often must be minimized to extend the upper frequency limit. To minimize lead inductance, electron tubes are debased (no base is used), they use large leads to minimize skin effect, and sometimes have their grids or plates brought out through the envelopes. To reduce interelectrode capacitance, tubes are miniaturized to make their elements smaller (this also reduces their power-handling capability), and special construction in the form of a planar triode or tetrode is used. (The planar type of construction uses a single flat grid (or plate) through which the electron stream passes, instead of grids or plates made up of wires or screens, which are "wrapped" around the emitter as in conventional tube construction.) The original derivation of the planar tube was the well known lighthouse tube (also called ***disc seal*** tube), which is so named because of its physical resemblance (three or more stepped cylinders) to a lighthouse. These tubes utilize coaxial and planar elements, or rings, with direct physical connection to the electrodes themselves. There are two forms of oscillator used. One form, which operates in the VHF region, uses a special socket and its operation is similar to that of a conventional LC oscillator. The other, which is used in the UHF region, incorporates a series of coaxial cylinders into which the lighthouse tube fits as an integral part, forming a tuned line coaxial oscillator. Tubes used for low power and receiving purpose are usually provided with conventional pin type sockets, and those used for transmitting are either provided with a special socket and plate cooling fins or are inserted into the cavities or lines to form a compact unit. The construction of a typical tube is illustrated in the accompanying figure.



Lighthouse Tube

In addition to the coaxial line oscillators, tuned transmission line, or Lecher line, oscillators are also used. The tuned lines in these oscillators are arranged parallel to each other, instead of being arranged coaxially. At the lower frequencies the lines are used as inductances and are tuned with a shorting capacitor. At the higher frequencies they are tuned with a

491-044 0 - 73 - 44

shorting bar and operate essentially as a quarter wave transmission line.

The tuned line can be substituted for an LC tank circuit because it possesses the same properties as the tuned tank. When the line is exactly a quarter wavelength long electrically, and is shorted at the far end with the input open, it presents a high impedance at the input and a low impedance at the far end. When it is coupled to a source of energy, a heavy current will flow in the line at the shorted end, but only a small current (or no current) will flow at the open or input end, because of the high input impedance. This effect is exactly the same as that produced by the conventional LC tank; therefore, the quarter-wave line can be substituted in its place.

Use of the transmission line tuned circuit provides a higher Q and lower losses than is possible with conventional lumped inductance and capacitance. The higher Q is obtained because the resistance of the line is low for a given value of reactance, since Q is equal to XL/R. The low resistance is obtained by using relatively large diameter tubing, since at radio frequencies current flows on the outside of the conductor because of *skin effect*. For UHF applications this loss is made even less by silverplating the outside of the conductor, so that the r-f current flows through a highly conductive path of silver. For single-tube oscillators the concentric type line is frequently used, and for push-pull circuits a balanced two-wire line offers a convenient arrangement (two concentric lines may also be used). The concentric line has the additional advantage that the outer conductor shields the inner conductor and thus reduces unwanted radiation from the tank to a minimum.

An incidental feature of the quarter-wave transmission line tank results from the use of the high-impedance property at the open (input) end and the low-impedance property at the output end to insulate the line as far as rf is concerned. Thus the shorted end of the line may actually be attached to the chassis without affecting the operation. This helps to reduce dielectric losses, which otherwise would be introduced if an actual insulator were used. Unfortunately, this feature cannot be used where dc is applied to the line as in series plate feed arrangements, but it can be used in shunt-feed arrangements.

The tuned lines and circuits discussed in this section are confined to negative grid oscillators; that is, to oscillators where the average grid voltage is always negative, since there are other special oscillators (such as the Barkhausen-Kurz and Gill-Morrell oscillators) which use positive grid operation to obtain UHF oscillations. This classification is necessary to avoid confusion, as both groups appear to be identical schematically at first glance, since both employ tuned lines. The positive grid voltage is the major identifying feature of the positive grid oscillator and the circuit operation is entirely different from the operation described below.

Because the reactance of the tube interelectrode capacitance and distributed circuit capacitance is small at ultra high frequencies, the circulating (or charging) current in these capacitances is large. It is on the order of many amperes for large power tubes. This high current adds nothing to performance, and may cause damage. Because of skin effect, the current follows the surface of the metal electrodes of the electron tube, and causes localized heating of the seals, sometimes causing cracks and tube failure. Thus, in UHF oscillators the tuned circuit is designed to have a high inductance and the minimum capacitance that will resonate the tank to the operating frequency. Tuned-line tanks provide the required high inductance with a minimum of capacitance. The trend in present day tube manufacturing is to employ ceramics instead of glass as dielectrics, because of their better heat resistance and easy machining properties, in addition to the reduction of inter-electrode capacitances. The push-pull circuit effectively reduces these capacitances to half their normal value since they are in series in push-pull operation. Although an open transmission line has some eddy current and radiation losses, close spacing to less than one hundredth of a wavelength (a few inches) causes the field around one conductor to neutralize the field around the other, Radiation and eddy current losses are thereby minimized, but not as completely as with the shielded coaxial line.

The Q of the quarter-wave short-circuited section of line is much higher than that of the conventional tank circuit because larger diameter conductors can be used than in the conventional coil, making the skin effect less. Specially constructed (planar) tubes extend the transmission line as a part of the tube leads. Thus, the interelectrode capacitances and lead inductances of the tube are all incorporated as a part of the tuned circuit.

Transit time produces two different effects at UHF. (1) it causes the plate current to lag the grid voltage by a small angle, so that the phase difference

between the plate current and plate voltage is greater than 180 degrees. As a result, the power output is decreased and the plate dissipation is increased. (2) The transit time permits an accumulation of electrons on the grid and causes grid current flow, even when the grid is negative. This produces a grid loss which is similar to the loss incurred by shunting the grid with a resistor. At extremely high frequencies this loss is so great that the effect is as though the shunting resistor produced a short circuit between grid and cathode and prevented proper excitation of the tube. The grid loss also results in the development of heat, which can exceed the tube ratings.

Therefore, while tuned lines, together with special tube construction, offer a partial solution to the transit time problem, a different kind of generator other than the simple ultraudion feedback arrangement is required to operate at UHF with resonable power output. The lighthouse tube provides efficiencies on the order of 48% at 500 MHz to 10% at 2100 MHz for CW operation, and 52% to 35%, respectively, for pulsed emissions. The present day trend is to use klystron generators for UHF, plannar tubes for VHF, and either klystron or magnetron generators for microwaves and beyond.

LIGHTHOUSE-TUBE OSCILLATOR

Application.

The lighthouse tube oscillator is used as an r-f source in the UHF range for recievers, test equipment, and low-power oscillators or transmitters. The planar type triode or tetrode is used for transmitters where more than a few watts are needed.

Characteristics.

Use special tube construction to overcome high-frequency limitations.

At frequencies of 300 to 1500 MHz uses external lines, and at frequencies of 1500 to 2500 MHz uses coaxial cylinders, into which the tube is inserted as an integral part.

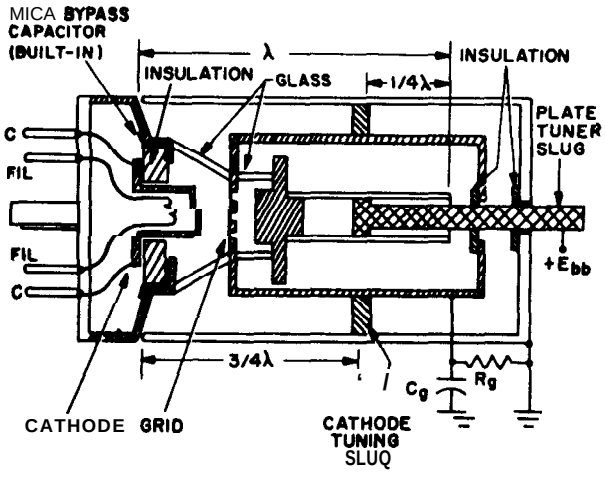
Tuning is accomplished by means of shorting bars or plungers.

Has low output and low efficiency (10-30%).

Circuit Analysis.

Generel. The so-called lighthouse tube oscillator is operable over a large range of frequencies, and the frequency of operation basically determines the final form of the oscillator. At frequencies up to about 1500 MHz, the size of the coaxial elements that would be required is so great that external open-wire line or tubing must be used. When the frequency approaches 2500 MHz, however, coaxial elements become small enough for practical use, and the tube itself can be inserted into them to form part of the line. Since the design of the lighthouse tube provided the necessary means of overcoming the difficulty of obtaining oscillations at the high frequencies above 300 MHz, there have been a number of similar designs. Thus, the basic lighthouse tube evolved into the co-planar type of triode and pentode. In this tube the elements are coaxial cylinders, with the outside of the rign forming the electrode contact. Planar tubes using plane rings instead of coaxial cylinders can be used in coaxial lines, or separately with a special socket. The receiving type (or low-power type) has a conventional octal socket using only cathode and heater pins. The transmitting type requires the special socket and is usually equipped with radiation type cooling fins connected to the plate and normally requires forced air cooling. Where coaxial construction is used, the coaxial line itself acts as the heat radiator. Since the basic lighthouse coaxial unit is representative of this type of design, all discussion will be confined to the original type of lighthouse tube. Although now replaced by tubes of planar design, the original lighthouse tube may still be encountered.

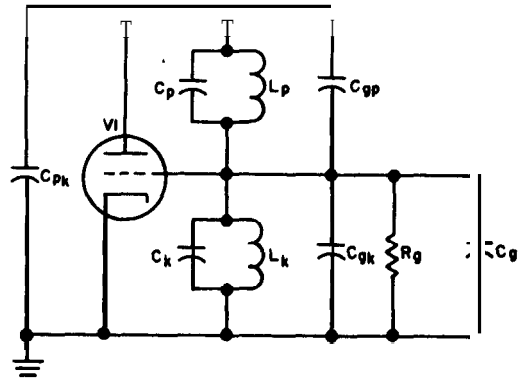
Circuit Operetion. The construction of a typical self-contained lighthouse tube oscillator is shown in the accompanying illustration. The tuner assembly consists of three concentric tubes, or coaxial lines. The inner tubing is connected to the plate, the center tubing to the control grid, and the outer tubing to the shell or base envelope of the tube. The outer tube is effectively shorted to the cathode for rf by a built-in mica capacitor connected between the metal envelope and the cathode.



Coaxial Cavity Tuned Oscillator

The cathode (outer) and control grid cylinders form a coaxial cathode line which is effectively short-circuited by a capacitive non-conducting plunger at a point approximately 3/4 of a wavelength from the point of connection to the tube elements. The position of this plunger is adjusted for the proper amount of feedback. The capacitance between the plunger dielectric and the grid conductor of the coaxial line effectively shunts the rf to the cathode, but does not short-circuit it for dc. The dc path between the cathode and control grid is provided by grid-leak resistor 1$, bypassed by grid capacitor C_g, which produces grid-leak operating bias. A shorting plunger is inserted into the plate line 1/4 wavelength from the open end (3/4 wave from plate end) to tune the plate circuit. Plate voltage is supplied by connecting B+ to the plunger. The short circuit provided by the shorting plunger offers a high impedance to r-f energy a quarter wavelength away, so that no rfc is needed to isolate the plate supply. Since the grid is located approximately one wavelength from the open end of the line and a high impedance is reflected there by the plate tuning plunger, the grid is also placed at a point of high impedance with respect to plate. Thus the open wavelength-long plate conductor and the shorted three-quarter-wavelength cathode conductor both act as parallel resonant tank circuits. The tuning of the plate circuit determines the operating frequency of the oscillator, and the tuning of the cathode circuit determines the proper amount of feed-back for stable oscillation. Since there is a certain amount of interaction between the plate and cathode circuits, it is necessary when changing frequency to adjust both plungers for optimum operation.

Detailed Analysis. The r-f equivalent circuit of the lighthouse tube oscillator is shown in the accompanning illustration.



Lighthouse Equivalent Circuit

The interelectrode capacitance of the lighthouse tube, plus the capacitive effect of the open ends of the grid conductor, is represented in the diagram as C_{pk}. The net reactance of the parallel tuned circuit containing C_k and L_k, shunted by C_{gk}, must be capacitive to ensure that the voltage divider which they form with C_{gp} supplies alternating voltage of the proper polarity to the grid. This means that the frequency of the cathode tank circuit must be lower than the output frequency of the oscillator. The operating frequency of the oscillator is determined primarily by the resonant tank in the plate circuit (C_p, L_p), which is in parallel with C_{gp}, and the effective input capacitance of the voltage divider network; consequently, it is lower than the resonant frequency of the plate tank alone, and slightly higher than the frequency of the cathode tank. To provide the proper feedback to sustain oscillation, it is necessary that the resonant frequency of the cathode tank circuit be less than the resonant frequency of the plate tank circuit. This is accomplished by careful tuning of the lines. Particular care is necessary in adjusting the cathode line; if the line is too short, it appears inductive and

oscillation stops. On the other hand, if the line is too long, the effective feedback divider capacitance is increased, and the amplitude of the feedback voltage becomes too low to sustain oscillation. Consider now one cycle of operation. When the plate voltage is applied, heavy current tends to flow in the plate circuit since the tube is self-biased and the initial bias is zero. The initial rush of current shock+ xcites both plate-grid and grid-cathode tanks into oscillation. Since the grid-cathode tank (C_k L_K) is tuned to a lower frequency than the oscillator output, it appears as a capacitive reactance shunting the grid-cathode interelectrode capacity, C.&. Neglecting the plate tank for the moment, it is seen that C_{gp} will charge due to momentary grid current flow, since C_{gP} and C_{gk} form a capacitive voltage divider between plate and cathode, or ground. Assuming that the charge is in such a direction as to make the grid more positive a momentary and amplified increase in plate current will occur. This action is regenerative. Since the plate tank is tuned to a higher frequency than the r-f output, it appears as an inductive reactance shunting C_{gP}. The result is to produce a negative grid input resistance which overcomes grid circuit losses and permits oscillation to occur. This negative resistance occurs primarily from the tank circuit which, in effect, returns energy to the circuit through its flywheel effect. When the grid pulse reaches its maximum, the plate tank appears as a high inductive impedance across which the plate voltage is dropped. During this time the tank absorbs energy from the circuit. As the grid swings negative plate current is reduced and eventually cut off. During this time the tank is returning energy to the circuit. The feedback is now in an opposite direction to the initial charging current (C_{gp} is discharging), is likewise regenerative, and quickly drives the tube to cutoff. Once oscillatory action is started it continues until the plate voltage is removed, or until the grid tank is detuned too far from resonance to retain the proper phasing. If tuned too high in frequency it appears inductive and the feedback is opposed and oscillation stops. Conversely, if tuned too low in frequency it acts as a heavy capacitive shunt from grid to cathode and also stops oscillation.

Grid bias is provided by grid-leak resistor R_g and capacitor C_g, which are connected between the open (high-impedance) end of the grid line and ground. After a few oscillations are built up, a small charge is put on C_g each time the lower end of the tank circuit swings positive. During the time the grid is not positive with respect to the cathode part of the charge leaks off through grid leak R_g. The voltage to which the grid capacitor is charged ultimately makes the grid sufficiently negative so that only a small amount of charge is added to the capacitor at the peak of each cycle, and all of this small increase of charge leaks off through R_g during the remaining time of the cycle. Thus the grid is maintained at the proper bias for good operation. If the high negative bias required for proper operation were applied at the time the oscillator was turned on, the tube would be completely cut off and oscillations could not start. It can be seen from the schematic that this circuit is essentially a simple tuned-plate, tuned-grid oscillator with the basic feedback being supplied through the plate-to-grid capacitance.

Failure Analysis.

No Output. Since the unit is of integral construction, loss of output may be caused by failure of the cavity to tune properly, a defective tube, or an open or shorted supply. Where contact fingers are used for the shorting plunger, as in the plate line, poor contact will cause improper tuning and lack of oscillation. Also, poor contact will cause a reduction or complete lack of plate voltage, and produce 1oss of oscillation. The presence of voltage maybe determined by a voltmeter. Poor contacts will be indicated by fluctuations of the plate current as the plunger is tuned, and sometimes by burnt spots on the lines. A defective tube is usually indicated by lack of normal plate current when due to lack of emission, or by abnormal plate current when short-circuited. **Because** of the inherent solid construction of the coaxial tuner, poor contacts or tube failure are the most common troubles. At radio frequencies any additional resistance in contacts produces losses which are serious in the UHF range. Therefore, effects which are not very noticeable at the lower frequencies can produce complete lack of oscillation at UHF. Since the inner cavities are inaccessible until disassembled, the only practical check is a test for voltage on the heaters and plate, and between grid leak and ground, if accessible. Observation of the plate current while tuning and a check of the voltages should be made first. The unit should then be disassembled and the tube and coaxial tuner checked.

Reduced Output. Reduced output is usually due to low plate voltage or improper tuning. Low plate voltage can be the result of poor contact resistance in

the tuner or a defective supply, which can be easily located by making a voltage test. Improper tuning can be quickly verified by slight readjustment of the controls to see whether the output improves. With normal plate voltage and correct tuning, if the output remains low, either the tube or the grid leak is probably defective.

Incorrect Frequency. Since the frequency is determined by the adjustment of the plate tank, small frequency changes can be corrected by tuning. Plate-voltage and load changes will also affect the frequency to a small extent; these can be checked by changing the load and measuring the supply voltage. Normally the high Q tank afforded by the coaxial cavity results in a highly stable frequency. In cases of high ambient temperature, however, the line and cavity dimensions may change and produce a drift in frequency, depending upon the metal used. For temperature-caused changes, adequate ventilation by means of forced-air cooling is necessary. If the cavities and lines are made from temperature-compensated alloys, the cause of frequency changes will be limited to supply or tube defects.

Instability. Unstable oscillations may be caused by erratic plate supply voltage, lack of regulation, or improper tuning.

LECHER-WIRE OSCILLATOR

Applications.

Lecher-wire oscillators are used in the VHF and UHF regions to generate rf for the receiver oscillators, test equipment, and transmitters.

Characteristics

Uses a pair of lecher wires, or tuned lines, in place of conventional LC tanks.

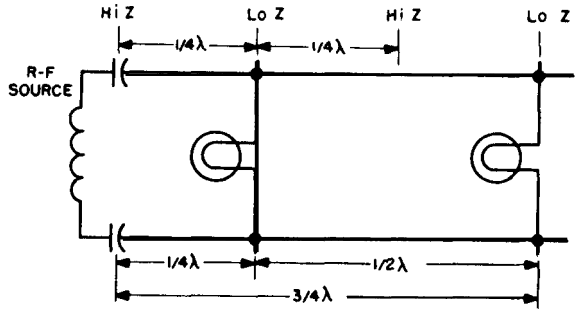
Frequency of operation is such that use of quarter-wave or half-wave lines are practical.

Has better stability and efficiency than a conventional LC circuit.

Usually used with the planar type of high-frequency tube, but not restricted to any type (can be used with any tube that will oscillate).

Circuit Analysis.

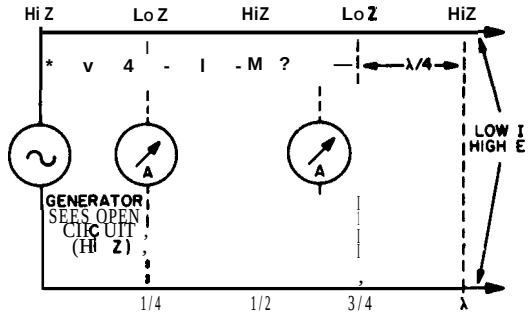
General. The lecher-wire, or transmission-line, oscillator is derived from the lecher wire wavelength measuring principle and the application of transmission line theory. The lecher-wire principle is shown in the accompanying illustration, in which two parallel wires a few inches apart are capacitively coupled to an r-f source. Assuming that the coupling is loose, the wires are in effect open-circuited. The length of the wires should be at least one full wavelength at frequency of the r-f source. When a shorting bar is series with a current indicator, such as a lamp or r-f ammeter, is placed across the lines, it will be observed that at a point 1/4 wavelength from the source maximum current is obtained. If the shorting bar is left at that spot and another one is moved along the line, an identical maximum indication (but not the same value) will be obtained at a point 1/2 wavelength from the first indication (3/4 wavelength from the source). This demonstrates that standing waves exist on the line. Such a device can be used to measure the frequency of operation in wavelengths. When the lecher wire is coupled through a single-turn loop to the r-f source, the line is considered closed at both ends; in this case, the first indication will be obtained at the half wavelength point.



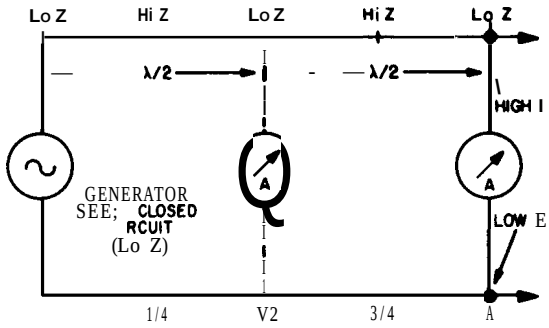
Lecher Line

Transmission line theory predicts that a half-wave line repeats, or reflects, the input conditions at the output.

If a transmission line is open-circuited, it will have maximum impedance at the half-wave points, as shown in the preceding figure. If the transmission line is shorted, it will have the lowest impedance at the half-wave points as shown in the following figure. Conversely, a quarter-wave line (if open) will see a high imput impedance (at its source) when shorted at a point a quarter wave from the input end, and if



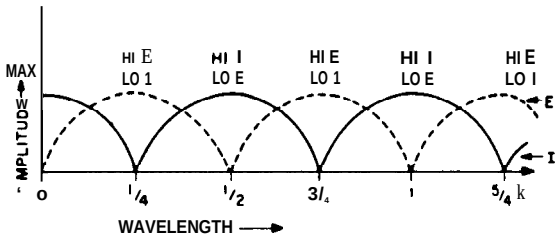
Open-End Line



Closed-End Lines

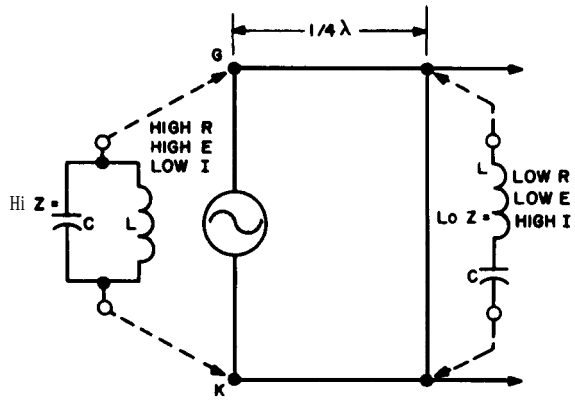
shorted at the input, will have a maximum impedance one quarter wave from the short as shown in the preceding illustrations of open and closed lines.

When standing waves exist on the transmission line, the current and voltage are out of phase. That is, at a point of maximum current, the voltage is at a minimum and, conversely, at the point of maximum voltage, the current is at a minimum as shown in the accompanying illustration. Thus either voltage or current indications may be used in the lecher wire.



Relationships of Standing Waves

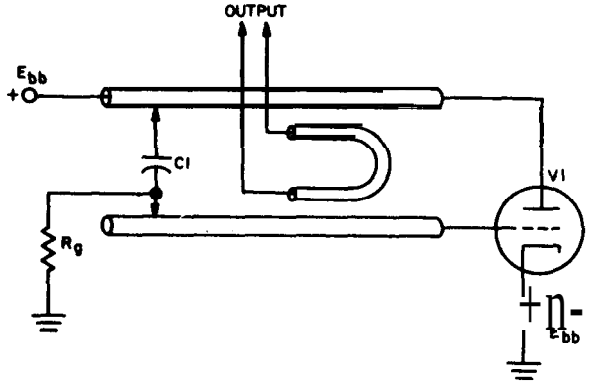
If the lecher line is attached to the grid and cathode of an electron tube and ground, and is tuned to a quarter wavelength, the current through the line will be heavy since it is limited only by the resistance in the line at the short; this is the equivalent of a series resonant circuit formed by an LC tank. At the grid and cathode (one quarter wavelength away), the impedance will be high and only a minimum current will flow between cathode and grid. Thus the line simulates a parallel resonant circuit, with a heavy circulating line current and minimum external current as shown in the following illustration.



Shorted Line Equivalents

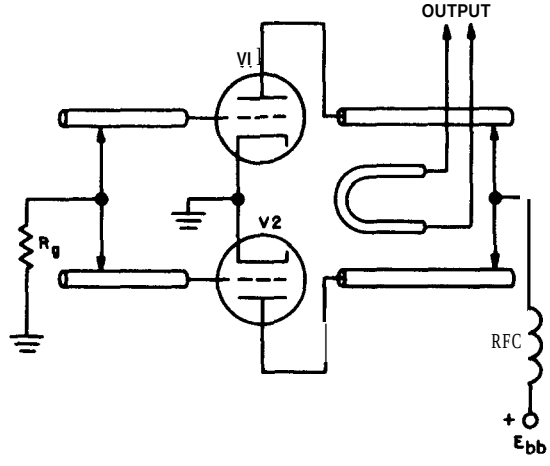
Circuit Operation. When the lecher line is connected between the grid and plate of an electron tube, a simple ultraudion oscillator results, with the line forming the tank connected between grid and plate of the tube, as shown in the following illustration. In the illustration a capacitive shorting bar is employed; since plate voltage is present on the plate bar, it would be applied to the grid if a direct shorting bar were used. At the frequencies used, the capacitor has such a low reactance that it is effectively a short circuit for rf, but it will block dc. Grid-leak bias is obtained through the action of R_g, and the total effective grid-cathode circuit capacitance acts as the grid-leak capacitor. The r-f output can be taken from

the circuit with a hairpin coupling loop or capacitively from the grid or plate bar. Tuning is accomplished by moving the shorting bar along the lecher line. The amplitude is controlled by the grid-leak value and the applied plate voltage, by the spacing between the bars, and by the tube electrode capacitance. See the ultraudion oscillator circuit discussion in another part of this section for an explanation of the feedback operation of this type of circuit.



Simple Lecher Line Oscillator

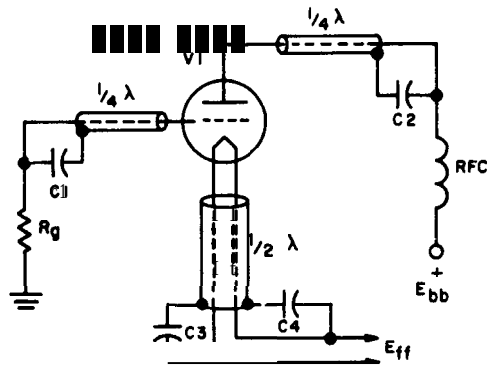
Although the simple oscillator just discussed is operable, it has been found advantageous at UHF to utilize circuits which minimize the circuit capacitance. This allows the lecher lines to act more like lumped components, and thereby serve as the controlling factor in the circuit, permitting tube replacement with minimum effect on circuit operation. The tubes may be any type that will operate at the desired frequency of operation. In this circuit all elements are balanced. Since the interelectrode capacitances are in series in a push-pull oscillator, the effective capacitance shunting the circuit is half that for a single tube. (See following illustration,) Thus, the charging current for this amount of capacitance is reduced with a consequent reduction of capacitive circulating currents. As a result, tube seal heating effects and circuit losses are also reduced. Since the tubes operate alternately and the currents are opposite, losses resulting from eddy currents and radiation from the lecher lines are reduced. Such reduction is due to the complete balance in the circuit and the close line spacing which causes the electromagnetic field around one line to almost completely cancel that around the other. Since the same voltages are present on both grid bars and on both plate bars, shorting bars can be used. 4



Push-Pull Lecher Line Oscillator

For best efficiency and stability at ultra high frequencies, not only the tube losses but also the losses in associated circuits must be kept as low as possible. On the other hand, both the loaded Q and the unloaded Q must be kept high as possible. For this reason, the tuned circuits associated with UHF oscillators use resonant sections of transmission line, rather than coil and capacitor tank combinations.

Since the coaxial line is a form of transmission line, it has properties similar to the open-wire type. At high frequencies it has the further advantage of shielding the line, because the center conductor is entirely surrounded by the shield. As a result, coaxial lines reduce radiation and eddy current losses to an absolute minimum, and for this reason are used extensively. A typical coaxial type of lecher line oscillator is shown in the following illustration.



Coaxial Line Oscillator

In this type of oscillator, the grid and plate coaxial lines are shorted by small capacitors, Cl and C2, and have an effective length of one quarter wave each. This oscillator corresponds to a tuned-plate, tuned-grid LC oscillator with series plate feed and grid-leak bias. The filament type of tube shown utilizes the transforming action of a half-wave line section to bypass the filament to ground. At low frequencies the filament would be directly bypassed to ground with a capacitor. At the UHF region, however, this method of bypassing proves ineffective because the filament leads are long enough to offer a large inductive reactance. As a result of the transformer action in the half-wave line, connecting C3 and C4 to the far end of the line provides an effective shunt at the filament *inside* the tube, which ordinarily is inaccessible. Since the length of the line includes the filament leads, the physical length of the external line is slightly shorter than a half-wavelength.

Failure Analysis.

No Output. Lack of supply voltage, a defective tube, an open circuit, or improper tuning can cause loss of output. Resistance and voltage checks will quickly reveal lack of circuit continuity or incorrect voltage conditions. The trouble then may be either in the tube or tuning. If the circuit will not tune and the plate current is excessively high or low, the tube is defective. Lack of contact in the shorting bar is then most probable, since it is possible to have a low dc resistance or continuity indication and a high r-f resistance which will not show on an ohmmeter. The usual troubles in this type of unit are open or high-resistance circuits due to poor solder joints or defective components. Most line sections are mechanically and electrically of excellent construction. It is possible, however, for silver-plated components to develop a heavy oxide film which effectively open-circuits them at UHF, particularly in areas where corrosive vaports react with the silver. In this case, frequent cleaning is necessary, or gold plating may be required.

Low Output. Low plate supply voltage, together with reduced tube emission, is the primary cause of low output. A check of voltages will detect this type of trouble. Improper tuning can also result in reduced output; it can be eliminated by a slight readjustment of the shorting bars for maximum output. Defective contacts in the shorting bars are usually obvious, causing erratic indications as the bars are moved slightly back and forth. A high-resistance grid leak can also reduce the amplitude of oscillations, but it is easily located by a resistance check. In the open-wire unshielded line, it is also possible for nearby objects to produce capacitive unbalance and mistuning. If this effect is present, the plate meter will show a change in current as the hands or other objects are moved near the tuning controls.

Incorrect Frequency. This type of **oscillator is** adjustable over a sufficiently broad range that normal plate voltage changes or slight emission changes may be compensated for by tuning. Since the stability is determined by the tuned lines, any large frequency change indicates a defect in the tuning of the lines. This can be caused by poor contact resistance of the shorting bar and by defective shorting capacitors. Reflected load reactance can also affect the circuit operation; this condition is normally indicated by a return of the frequency to original value as the load is adjusted. A lecher line circuit is usually so stable that calibration markings ruled on the line itself can be used to accurately determine the line frequency. Normally, a resistance analysis and voltage checks should quickly reveal the component at fault.

MAGNETRON OSCILLATOR

Applications.

The magnetron oscillator is used in the region of 100 MHz to 30 GHz and beyond, to develop r-f energy. It is used in test equipment, in low-power CW transmitters, in beacons, and particularly in radar equipment, as a source of high-power pulsed r-f energy.

Characteristics.

Utilizes a specially constructed tube with a resonator surrounded by a permanent magnetic field to produce the r-f energy.

Operates with grounded anode.

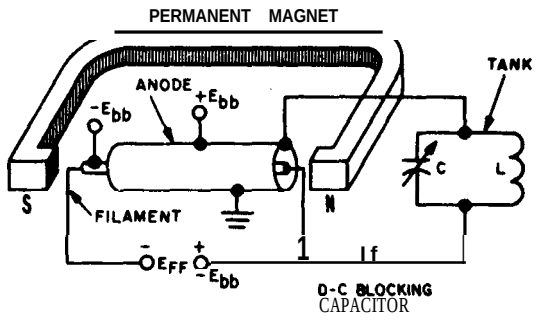
Is usually operated by a negative pulse applied to the cathode.

Has either coaxial or waveguide output, depending upon the frequency of operation.

Circuit Analysis.

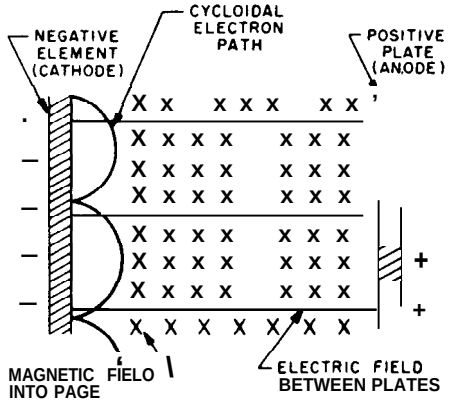
General. There are, generally speaking, two types of magnetrons: the split-anode negative resistance (or dynatron) type, and the transit-time (or electronic) type. The negative resistance type uses the principle of negative resistance between the two anodes to produce oscillation, and operates only at frequencies which are low with respect to the transit-time frequency (on the order of 100 MHz to 1000 MHz). The efficiency is low in comparison with the efficiency obtainable with transit-time operation; therefore, it is not very popular, being more or less supplanted **by the** power type klystron at these frequencies. The frequency of oscillation in this type of magnetron is controlled entirely by the resonator with which it is used, as in conventional LC oscillator On the other hand, the transit-time type of magnetron depends entirely upon the transit time to determine the frequency, with the resonator(s) providing greater efficiency and proper phasing for maximum output. A short treatment of the negative resistance type of magnetron is given below for the sake of completeness, with the remainder of the discussion devoted to transit-time magnetrons, which are in greater use.

Circuit Operation. Before discussing the two types of circuits, it is necessary to establish the fundamentals of operation. The accompanying figure shows a simple magnetron. As can be seen, the tube is a diode with a cylindrical plate surrounding a coaxial



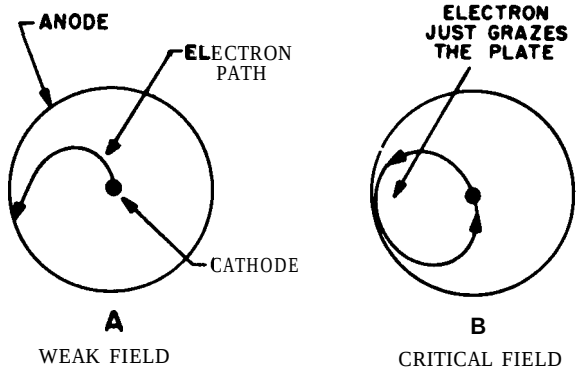
Elementary Magnetron

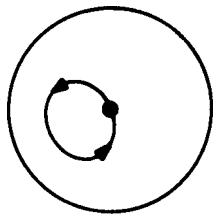
cathode or filament. A negative voltage is applied to the cathode, in addition to the heater voltage needed for fdament emission or heating of the cathode, depending upon whether direct or indirect heating (fdament) is used. Because the plate is positive with respect to the cathode, an electrical field exists between cathode and plate (anode); an external dc magnetic field is placed perpendicular to the electric field, and is produced by a strong permanent magnet. See the following illustration. (While an electromagnet could be used and the magnetic field could be alternating, as well, this is done only on the low frequencies for special effects, and will not be discussed further.) In these discussions it is assumed that the magnetic field is produced by a permanent magnet. The tuned tank circuit in which the oscillations take place is connected between the plate and the cathode. This can be a tuned LC circuit, a coaxial cavity, or a special cavity resonator built into the tube.



Motion of Electron in Electric and Magnetic Fields

Consider now the effect of the electric field on the electrons emitted from the cathode. In the absence of the permanent magnet field there would be a continuous electron flow in all directions, radially, direct from the cathode to the plate. But with the magnetic field applied, as the electrons are attracted toward the plate they encounter a force (due to the magnetic field) that tends to push them in a direction perpendicular to the forces applied. Since two fields are involved, the plate-to-cathode-voltage induced electric field and the permanent magnet field, and since they are at right angles with respect to each other, the electrons are affected by the vector sum of these forces; with a strong enough field the electrons are deflected in a cycloidal path as shown in the above illustration. Thus they are effectively bent back toward the cathode. The following illustration shows the path followed by a single electron as the external magnetic field is increased. At some low value of field (A in the figure), the electron travels in a slightly curved path, but reaches the ancde. At the critical value of field (B in the figure), the electron just grazea the plate and returns to the cathode. When the field exceeds the critical value (C in the figure), the electron follows a smaller-diameter circular path and returns to the cathode without getting near the plate.





c
STRONG FIELD

Electron Path with Increasing Magnetic Field

The current flow of the magnetron for the previous conditions is shown, perhaps more clearly, by the following graph. With the low value field a constant flow of current occurs between anode and cathode until the critical field value is reached, whereupon the current abruptly ceases and drops off to zero, since the electron can no longer reach the plate. The useful point of operation is where the electron is just prevented from reaching the plate by the critical

field value. Oscillation is then produced by the current induced in the cavity or resonator by the electron movement.

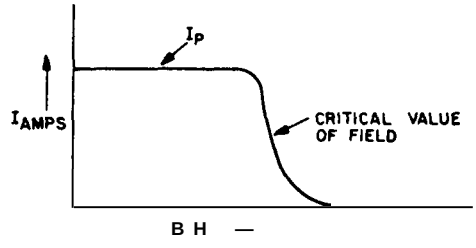


Plate Current vs Field Strength

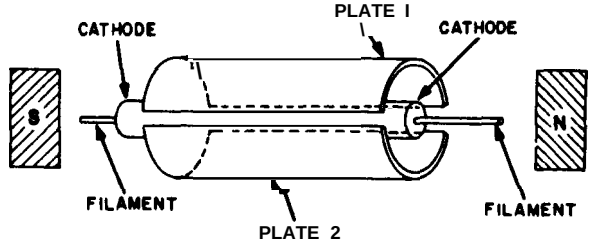
on the other half-plate is decreased by an equal amount. This results in a different electron trajectory.



Split-Anode Magnetron

While the actual electron flow in a magnetron is complicated, it is evident that since an electron is basically a negative charge of electricity, as it approaches an electrode it will change the field distribution around the electrode, inducing a positive charge and causing current flow within or on the electrode by electrostatic induction. As it recedes, a negative change will be induced. If the electron reaches the electrode it will be absorbed, and current will cease. When positive and negative charges are induced in a resonator, current flows alternately back and forth within the resonator, at the frequency to which it is tuned (resonant), and r-f oscillations are thereby produced. This is the simple basic principle by virtue of which the magnetron operates.

Negative Resistance Magnetron. The negative resistance magnetron is a variation of the basic magnetron using a split anode. It is capable of operating at a higher frequency (than the single plate magnetron) and with higher output. Its general construction is similar to the basic magnetron, except that it has a split plate, as shown in the accompanying figure. These half-plates are operated at different potentials by connecting them to opposite ends of a tuned tank circuit (or cavity). When the tank circuit is oscillating, the voltage on one half-plate is increased, while that

A graph of the plate current versus plate voltage characteristics of one segment of a two-segment magnetron, showing four different vahres of voltage applied to the other segment, is shown in the accompanying figure. Note that for each voltage there is a negative slope to the curve where the current is reducing as the voltage applied to the segment is increasing. Likewise, a curve of the difference current to the two segments of a split-anode magnetron as a function of the difference in the potential of the two segments when the voltage on one segment is raised as the other segment potential is lowered a like amount shows the same effect, that is, a negative slope. From the earlier discussion on negative resistance oscillators (see contents list under Electronic Oscillators for location), it can be seen that this curve bears a resemblance to the typical lazy “S” type curve that indicates negative resistance. Therefore this tube will produce oscillations of the negative resistance type if a parallel-tuned tank is series connected, either from one segment to the cathode or between the two segments. A schematic showing the tank connected between the two segments is shown in the following figure; this is a typical so-called push-pull nrugnetron circuit (from its resemblance to the push-pull type electron tube circuit.)

4

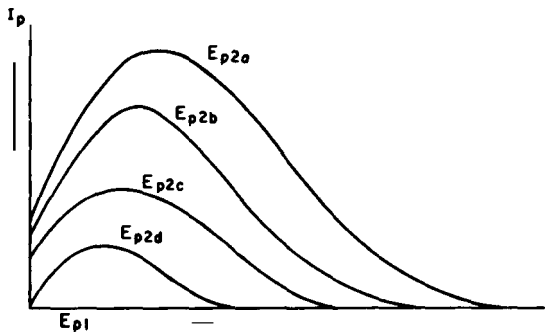


Plate Current vs Plate Voltage Characteristic

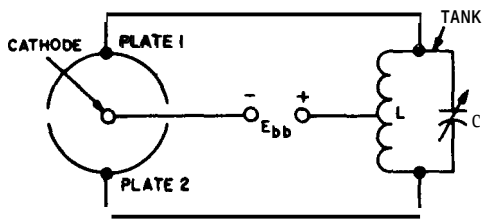
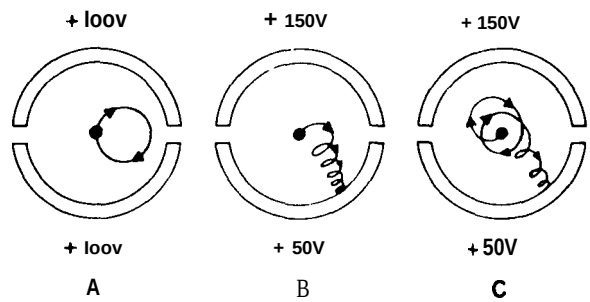
Consider now the effect of the different potential fields between the segments and the cathode. In the quiesent or static condition, since the plate potential is applied equally through the tank coil, as shown in the following illustration, the dc field



Push-Pull Magnetron Circuit

between the cathode and either segment is of equal strength. Once shock-excited (by application of B+), a transient oscillation is produced to increase the potential on one segment and decrease the potential on the other segment by a like amount. Thus the field is stronger in one half of the area around the cathode than in the other half. By applying the external permanent magnet field so that it is perpendicular to the cathode, a cycloidal motion is imparted to the single electron in a manner similar to that described in the basic magnetron discussion. The effect of the distorted field, however, is to cause the electron to make a number of revolutions before eventually being attacted to the segment with the lower potential as explained below. This action occurs because after the initial deflection by the field in a particular path of motion, the electron passes the split between the two plates and enters the electrostatic field set up by the lower-potential plate. Here the magnetic field has a stronger effect on the electron (since the electric field is weaker), and causes it to be deflected with a smaller radius of curvature. As the split is passed again (on the opposite side of the cathode) and the electron once again enters the higher-potential field area, it is again caused to deflect with a change in the radius of curvature. Thus the electron continues to make a series of loops through the magnetic and electric fields until it finally hits the low-potential plate and is absorbed. The following figure shows the effects of different potentials on the motion.



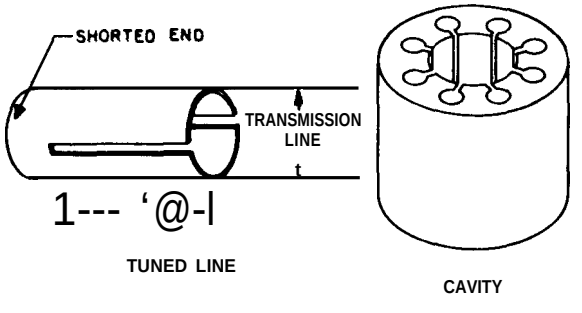
Electron Transit Paths

In part A the fields are equal, with the permanent magnetic field below the critical value. In B and C the field is above the critical value and current flows because of the action just discussed. Two different electron paths are shown for clarity. Actually, it has been found that optimum efficiency is obtained when the electron makes approximately 10 revolutions before contacting the anode. Since oscillation is produced by the negative resistance effect, the tank frequency governs the path of the electron and transit time is maximized. Naturally, this can happen only at the lower frequencies. As the frequency of operation is increased, the transit time eventually becomes the important limiting parameter, and the negative resistance oscillation is ineffective. Since a very concentrated field is required for the negative-resistance magnetron oscillator, the length of the tube plate is limited to a few centimeters for a magnet of reasonable dimensions. In addition, a small-size tube is required to make the magnetron operate efficiently at

UHF. Therefore, the plate size (area) is limited, and produces a serious limitation on the permissible plate heat dissipation. For this reason, heavy-walled plates are necessary to increase the heat radiating properties, and artificrd air or water cooling is necessary for high-power operation. These parameters, in effect, are the limitations which restrict its use to the low-frequency end of the UHF spectrum and cause the transit-time magnetron to be in greater demand.

With the electrons traveling in numerous loops, there are bound to be collisions between electrons and bombarding of the filament (or cathode), producing secondary emission and in some cases even destruction of the fdament or cathode. This action is cumulative, and sometimes results in fdament burnout before the current can be reduced to a safe value. To minimize this effect, and to prevent unstable operation, the tubes are operated with reduced plate and filament voltage. In some tubes it is possible to use the electron bombardment of the cathode element to provide the heat for emission, once oscillation is started.

Transit Time Magnetron. In this type of magnetron the plate or anode block is usually constructed so that it functions as a tank circuit resonant to a particular frequency. The construction may be that of a simple shorted quarter-wave line resonator, as shown in the accompanying illustration, or as a multicavity resonator also illustrated.



Magnetron Tank Circuits

In either case there are no external tank circuits to be tuned, and the output of the magnetron is picked up by a transmission line with coupling loop (or aperture for waveguide) built into the tube. Usually, the anode is composed of more than two segments; as many as eight or more are often used (while as many as 64 cavities have been used). While this type of magnetron has a reasonably high efficiency (30 to 60 percent) and large output, it is limited in that the frequency of oscillation is fixed by the resonator. Thus it tends to be supplied as a single-frequency unit which usually has provisions for tuning over a limited range (on the order of 1% at 9 GHz), and is operated at a fixed frequency. The average power is limited by the fdament emission, and the peak power is limited by the maximum voltage it can safely withstand without damage. Actually, during initial operation the high-power magnetron arcs from plate to cathode, and must be properly adjusted by a process known as seasoning, after which it can handle the high voltage properly without damage (within limitations).

New magnetrons require an initial break-in period or seasoning because violent internal arcing occurs when they are first put into operation. Actually, arcing or sparking in small magnetrons, and in high power magnetrons is very common. It occurs with a new tube or after long periods of idleness once a tube has been seasoned. One of the prime causes is the liberation of gas from the tube elements during idle periods. Arcs are also caused by the presence of sharp surfaces in the tube, mode shifting, and by overworking the cathode (drawing excessive current). While the cathode can withstand considerable arcing for short periods of time, if continued excessively it will shorten the useful life of the magnetron and can quickly destroy it. Hence each time the excessive arcing occurs, the tube must be seasoned again until the arcing ceases and the tube is stabilized.

The seasoning procedure is relatively simple. The magnetron voltage is raised from a low value unit until arcing occurs several times a second. The voltage is left at that value until the arcing dies out. Then the voltage is raised further until arcing again occurs, and is left at the value until the arcing again dies out. Whenever the arcing becomes very violent and reassembles a continuous arc the applied voltage is excessive and is reduced to permit the magnetron to recover. Once recovered the procedure is again continued. When normal rated voltage is reached and the magnetron remains stable at the rated current value, the seasoning is completed. It is good maintenance practice to season magnetrons left idle either in the equipment, or held as spares, when long periods of non-operating time have accumulated. Follow the

recommended procedures and times for seasoning specified in the equipment technical manuals. The preceding information is general and of an informational nature only.

The outputs of pulsed magnetrons are on the order of megawatts, with an average power of not much more than 1000 to 2000 watts being usable for CW operation (a typical 3-megawatt pulsed radar has a 6-kw average rating). However, as the state of the art changes, these limitations also change; thus where 50 kw was once high power, 5 to 10 megawatts now represents high power.

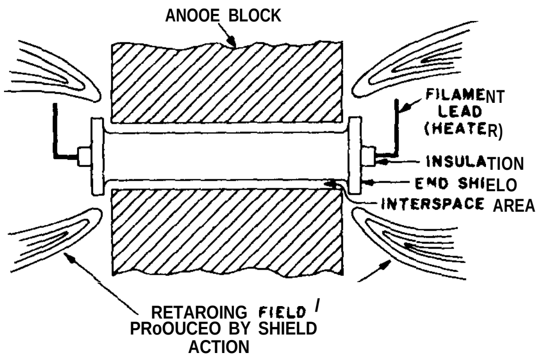
The construction of transit-time magnetrons is varied; they operate in the VHF, UHF, and SHF regions. Some are not tunable, while others are voltage tunable (anode potential is varied), mechanically tunable by hand or by motor, or are fixed-tuned. They provide power outputs of 50 to 100 milliwatts for receiver operation, and in the megawatt region for high-power radars, with all ranges of in-between powers. They are provided with integral built-in permanent magnets or with external magnets. They are supplied with transmission line outputs or wave-guide outputs, or with transition type coaxial-to-wave-guide outputs. They are of glass-metal or ceramic-metal construction, with advantages claimed for each. Cooling is achieved directly by natural air draft for low powers, by forced air or liquid air-convection, or by heat exchangers for the high-powered types. It is evident, therefore, that the subject or magnetrons covers a large field, with a complexity far beyond the scope of this technical manual. Thus, in the following discussion sufficient detail is provided to insure a basic understanding of the general principles of operation, with the important principles emphasized or expanded as needed. For details on a specific type of magnetron, consult the manufacturer's specifications, and refer to a more comprehensive text for further information.

Detailed Analysis. The magnetron, while capable of generating continuous-wave oscillations, is particularly suited for pulsed power applications, as in radar. That is, the magnetron is capable of producing pulsed powers of more than 1000 times greater than the best c-w output at the same frequency. Basically, there are three factors which produce the favorable conditions for pulsed powers; the magnetron is more efficient at very high levels of power and voltage; an oxide cathode under pulsed operation produces currents over 100 times greater than that obtainable under dc (non-pulsed or CW) conditions; and finally, by pulsing with small duty cycles, anode heat dissipation is less of a problem, so that greater powers can be handled. On the other hand, a new problem is posed, where the build-up of oscillations from noise to full power must occur reliably for every pulse in a time that may be as short as one-hundredth of a microsecond. Failure of this build-up produces misfiring or mode changing, and often occurs under the proper conditions.

From the preceding discussion it is clearly seen that the understanding of pulsed operation involves new concepts, some entirely different from those in CW operation. Since the magnetron consists basically of an emission system involving electron flow, plus resonators (or cavities) which modify the electron flow, and a means of extracting the r-f output, a discussion of the functioning of each of these items logically leads to a better understanding of the magne tron oscillator.

First consider the emission system, which may be a straight filament, a coiled filament, or an oxide-coated cathode cylinder. Magnetrons using thoriated tungsten or pure tungsten filaments are generally operated at high temperature; because of their ruggedness, these filaments are suitable for c-w type tubes, but consume considerable fdament power. The low-temperature, oxide-coated filaments operate best for pulsed-type tubes, producing much larger emissions than the high-temperature type (for a given filament power). However, since they are not as rugged, they are more susceptible to damage from electron bombardment and deterioration effects. The oxide coated cathode cylinder provides the most practical construction for low-temperature operation; keeping the heater fdament independent of the operating circuit avoids any fdament inductance effects which might adversely affect the frequency of operation. Another type of operation is also possible with the cathode sleeve, namely, cold-cathode operation. Because of the extremely high secondary emission produced by electron bombardment of the cathode by electrons out of the useful orbit, once started by heated-cathode operation, cold-cathode operation may be obtained by lowering the heater voltage or by removing it entirely. Such operation is commonly used in high-powered magnetrons, operating with extremely high plate voltages and heavy electron bombardment of the cathode.

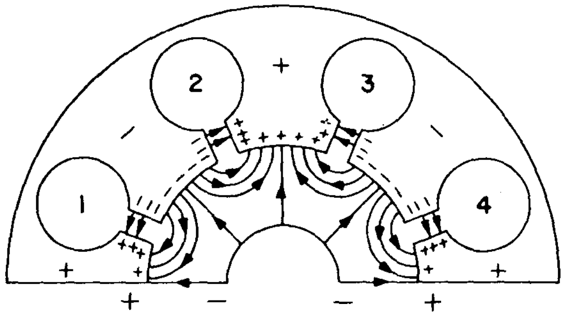
Since it is desired that the electrons travel in the interspace area between the anode and cathode of the cavity block and thus contribute to the excitation of the various cavities, end shields are placed at the ends of the cathode. These shields, which are of various designs (some may be only small protuberances at the ends of the cathode), minimize the electron leakage paths at the ends of the cathode. These cathode end shields are considered to operate by producing a retarding electrostatic field at the ends of the inter-spacial area. By distorting the equipotential lines at this point in such a way as to produce an inwardly directed force upon the electrons attempting to leak out of the area, they simply urge the electrons toward the center plane of the anode block. While in some cases secondary electrons may also be emitted from the end shields, through bombardment by partially controlled electrons in orbit, the useful electron emission is usually restricted to the cathode alone. An exaggerated illustration of end shields and the retarding field they produce is shown in the following illustration.



Cathode End Shields

With the cathode emitting a stream of electrons into the interaction space, let us examine the method by which the electrons produce oscillation. A half-section of a typical eight-cavity anode is shown in the following illustration, with the fields and current flow as indicated.

Assume for the initial operation that the cavities have been excited by an r-f field so that each cavity is oscillating. In the capacitive space between the walls of the entrance to the cavity (slot) a charge exists, with one wall negative and the other wall positive. By construction, the segments are placed 180 degrees apart electrically (pi mode), so that when traveling from one cavity to the other in the interaction space, each cavity is oppositely polarized. Thus the original negative-to-positive charge in cavity 1 is now a positive-to-negative charge in cavity 2, and likewise for the other cavities around the interaction space. A complete cycle of rotation around the anode block is produced in 360 degrees of rotation or some multiple thereof. In the case illustrated, since there are eight cavities (only half are shown) and the phase shift between the cavities is 180 degrees, there is a total of 8 pi radians shift which, when divided by 2 pi (for one full 360° of rotation), gives a number of 4. This arbitrary number is called a mode number. As might be surmised, magnetrons can be constructed so that they will operate at a different number of modes for the same frequency.



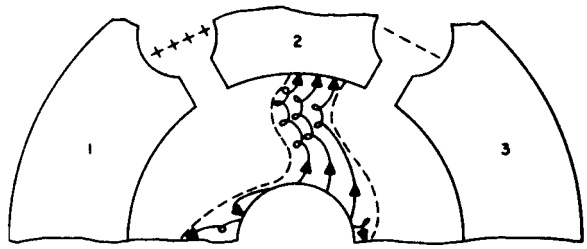
Development of Internal Fields

Examine the illustration and observe the effect of the fields produced. First the r-f field at the entrance to the cavity is strong at the lip but weaker as it extends into the interaction space, as shown by the widely separated lines. Arrows indicate field direction. The straight lines between the anode and cathode represent the dc field produced electrostatically by the anode-to-cathode potential. The dc field is steady except where reinforced or reduced by the changing r-f field. The permanent magnet field is at right angles to it (into the page), and is not shown. Thus two fields are always present in the cavity, and the resulting field affecting the electrons is the vector sum of the two.

Recalling from basic magnetron theory that when an electron approaches an anode it induces a positive

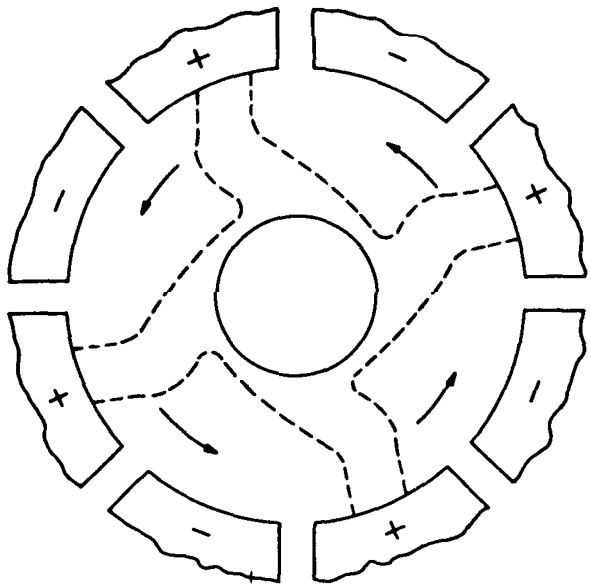
charge, and as it recedes from the anode it induces a negative charge. It is evident that as an electron approaches an anode which is going positive (because of the r-f cavity field), that segment is made more positive, aiding cavity oscillations. If the electron recedes from the anode as it is going negative, oscillations also will be aided. On the other hand, if the electron approaches the anode as it is swinging negative, or recedes as it swings positive, the electron tends to oppose oscillations. If sufficient electrons were so phased, oscillation would stop. Therefore, to sustain oscillation the phasing must be such as to produce more aiding than opposing electrons, or to remove those that oppose the oscillation, retaining only those that aid.

In addition to the r-f fields existing because of cavity resonance, assume that the magnetic field is just slightly greater than the cutoff value. Therefore, if the r-f oscillating field did not exist, or were zero at a point in the interaction space, the electron emitted at the cathode would be returned by the effect of the dc magnetic field. On the other hand, when r-f field is going positive, the electric field is enhanced, and an electron emitted at a point affected by this field would be attracted toward the anode. Because of the effects of the two fields, the electron is forced to travel in a cycloidal path instead of straight, and around the interaction space in a clockwise or counterclockwise direction (depending on the polarity of the magnet). If the distance between the cavity segments is such that the electron traverses the space between adjacent slots in a time equal to one-half cycle of r-f oscillation, when the second slot is reached the electric field will be reversed (the next half-cycle of r-f oscillation is now starting) and will be in an aiding direction. Because of the curved path, however, the *working* electron is traveling in a long path and through a decreasing potential (since the potential through which it falls is less as it approaches the anode). The result is a change in phase of such a mture that by the time the electron approaches the third slot the polarity is opposing and repels the electron. Thus the electron is forced to curve back upon itself, and, by the time it is traveling towards the direction from whence it started, the field in segment 2 is again attracting it, and it again curves toward the



Electron Path

anode. Likewise, because of the curved path it enters the number 1 segment field when the field is in a direction that pushes it back toward the number 2 and 3 segments. In this way the working electron follows a series of looped paths between two segments, as shown in the preceding figure until it reaches the anode. During the time it is being attracted by the field, it effectively aids oscillation in that cavity just as if an additional charge were induced into it. Because of the curved path it is in an aiding condition longer than it is in a position where it removes energy from the cavity; therefore, the net result is to enhance the oscillations. Since the distance traversed between segments is effectively 180 degrees, the electron is operating in the pi mode. Thus in an eight-cavity magnetron, four pairs of segments are operating simultaneously, and the effect is the same as that existing in a polyphase motor; that is, an effective traveling field is produced which rotates around the circumference of the interaction space, and oscillation is successively enhanced in each cavity as the field rotates past the slot. The effect is as though a wheel of four spokes were being rotated, as shown in the following figure.



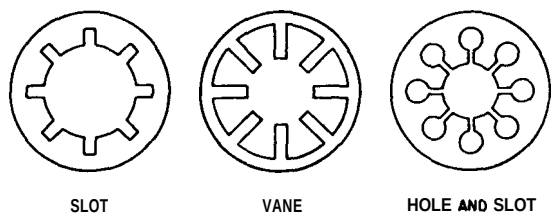
Rotating Electron Field

Conversely, the non-working electron is emitted at a time during which the r-f field opposes it and is quickly directed back to the cathode. This is a harmful electron in that it strikes the cathode with considerable force and tends to destroy it. Since the back radiation cannot be eliminated, it is used to produce secondary electrons and economize on filament heating.

Since there are electrons emitted from all points on the cathode, there are electrons which start at intermediate points of changing field, and are not attracted or repelled as strongly as the working electron; therefore, their paths are of different orbits. However, since the r-f field varies sinusoidally with time, the result is that the electron emitted before the working electron is retarded until the electron emitted after the working electron catches up. For this reason there is an effective electron density grouping (or bunching) about the working electron, or a *velocity* modulation effect similar to that in the klystron. Thus standard waves similar to those on traveling wave tubes are caused to exist in the inter-action space.

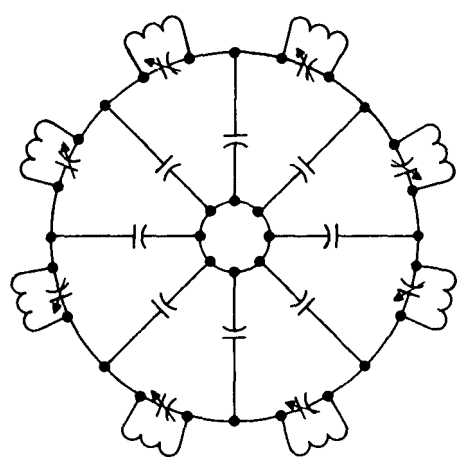
While the r-f filed was initially assumed, it is produced by application of the anode voltage or negative cathode driving pulse, which is sufficient to shock-excite the cavities, and with the proper phasing oscillations are built up. This proper phasing is produced through construction and by the proper selection of anode voltages and field strength. Since the phasing of magnetrons is a highly technical subject and of concern only to the designer, it is beyond the scope of this technical manual and will not be discussed.

Types of Cavities and Modes. There are basically, three different types of cavities used in unstraped resonant systems; these are the slot, the vane, and the hole-and-slot types of side resonators shown in the following figure.



Types of Resonators

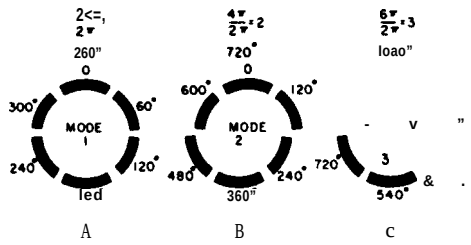
Regardless of the type of resonator used, it is primarily the simple equivalent of a parallel LC tuned circuit, which can be represented schematically by a series of tank, as shown in the following illustration, the interaction space is represented by capacitance between the anode and cathode; inductive effects are neglected for simplicity.



Resonator Equivalent Schematic

While the resonators are shown connected in series, actually each one is independent and is dimensioned and shaped so that all are resonant to the same frequency (identically shaped resonators are used). They are coupled together by the interaction space between the cathode and anode. The spacing of the cavity entrances is approximately a half-wave at the desired frequency of operation (assuming the pi mode of operation). Therefore, the smallest number of cavities that are operable is two (2x 180 equals 360 degrees), corresponding to split-plate usage. The maximum number of cavities is limited only by construction since multiplication by two produces the same result (2, 4, 8, 16, 24, and up to 64 as a practical limit).

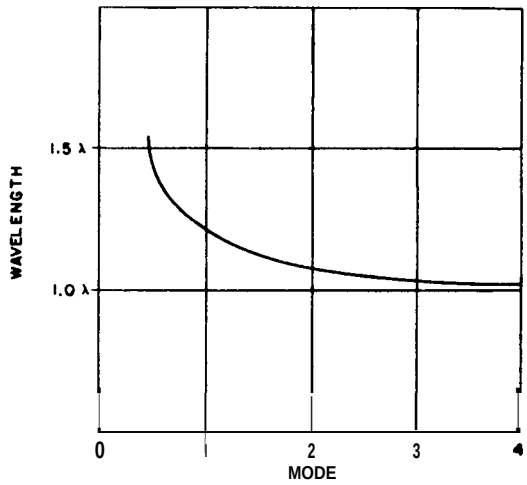
Consider now the mode of operation. Assume a basic six-cavity magnetron, as shown in the following illustration; operation is possible in three types of modes, as shown.



Examples of Various Modes

In part A of the figure there is a phasing of 60 degrees between adjacent segments. Therefore, six segments must be traversed before a total phase rotation of 360 degrees (one cycle) is obtained. Since there are 2 Pi radians in 360 degrees by angular measure, this represents a rotation of 2 Pi radians divided by 2 Pi, or mode 1. In part B of the figure the segments are separated 120 degrees, and only one-half as many segments (three segments) need be traversed to produce a complete cycle of operation. When the complete cycle around the magnetron is traversed, a total of 720 degrees of ratation is completed (two complete cycles of operation), or 4 Pi, giving mode 2. In part C of the figure adjacent segments are oppositely polarized, so that only two segments need by traversed to complete a cycle. Therefore, in a complete rotation of the magnetron cavity, 1080 degrees of rotation is produced, or 6 Pi radians divided by 2 Pi, giving mode 3.

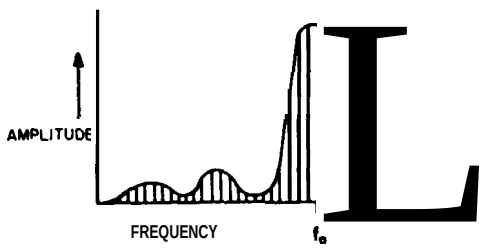
Since a six-cavity magnetron can operate in at least three modes (with either leading or lagging phase, this represents 2 x 3 modes, or a total of 1 mode for each cavity), there is a frequency for each of these modes at which the output is a maximum. Thus the magnetron generates a series of discrete frequencies arranged symmetrically (in the ideal case) around a center frequency of maximum amplidude for each mode. A typical plct of wavelength variation with mode for typical magnetron is shown in the following graph.



Wavelength vs Mode Variations

The c-w magnetron provides a different output from that of the pulsed magnetron, in that a steady anode voltage is supplied, and the output is mainly concentrated at the mode chosen by the plate voltage and current applied. It still does not consist of a single frequency, however, since the cavity at microwave frequencies can support a number of different types of oscillation. This concept is diametrically op posed to the normal concept of a tuned tank being responsive to only one frequency. It is true, however, because the magnetron consists not of a single cavity, but of a number of cavities, each coupled to the other. As in coupled circuits at the lower frequencies, it is possible to achieve a response curve having a main lobe with numerous side lobes, depending upon the interaction and amount of coupling between the

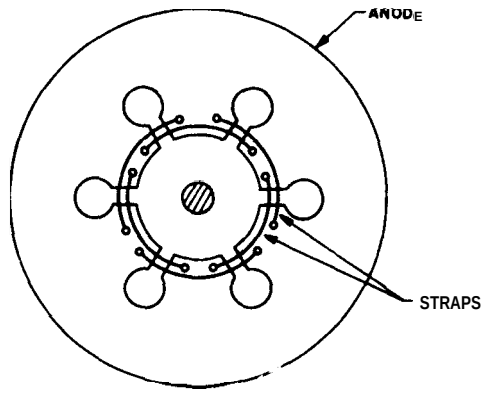
cavities. This condition is further complicated by the possibility of phased bunching of electrons in the interaction space; thus it can be clearly seen that a single pure frequency output is rather unlikely. In the tunable types of magnetrons, the main spectrum can be shifted to the desired frequency by tuning. In the fixed-tuned magnetron, operation consists mainly of operating at the proper current, which for a pulse of a particular shape produces the desired main lobe at the proper frequency with a minimum of side lobes (other modes). A typical output spectrum for a pulsed magnetron is shown in the accompanying figure.



Typical Magnetron Spectrum

The broad spectrum shown is caused mainly by pulsing. Because the pulse is a rectangle with steeply sloping sides, it approximates a square wave with a similar harmonic content. Thus, in effect, many frequencies are induced into the cavities, and all those to which it responds will be present. The shape of the anode pulse is important, since it can cause a distorted output and place the main output energy in an unwanted portion of the spectrum. It should also be understood that this discussion is necessarily general since it concerns actions mostly of interest to the designer. The technician is concerned with making the magnetron perform as designed. He can control only the voltages applied and the currents at which it is operated, plus any cavity tuning which may be possible. Therefore, the preceding discussion of modes and spectrum effects is intended to indicate, in a very limited manner, internal operation effects which are highly complex and beyond the scope of this circuit analysis. The interested reader is referred to standard texts such as the Radiation Laboratory volume on Microwave Magnetrons, from which much of this material was selected.

Since the unstrapped magnetron presents a number of modes of nearly equal outputs, it has been discarded for the sfrapped type, and for a special type known as the rising sun magnetron because of the design of the cavity. Strapping consists of connecting together alternate segments with short, heavy conductors, as shown in the accompanying figure. Thus

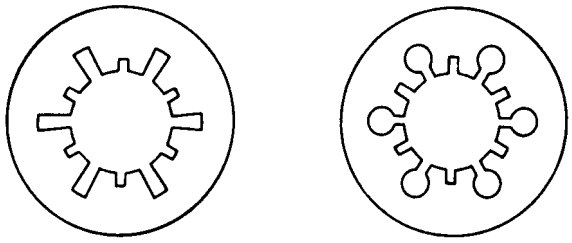


Double Ring Strapping

strapping favors mode 3, the Pi mode, and places alternate segments at the same potential (which corresponds to a shift of 2 Pi radians). Operation at mode 2 is impossible, since it would require a shift of 4/3 Pi radians between alternate segments, and cannot occur with the segments short-circuited. While the straps are essentially simple short circuits, at the frequencies used they have inductance; moreover, since the straps pass near the segments which they connect, they also have capacitance. As a result, the frequency of the mode of operation is slightly altered. At the Pi mode the straps are at the same potentirds at the ends, and carry no current (except for a slight capacitive current between them); therefore, the inductance is negligible and the capacitive effect predominates, lowering the basic frequency of the Pi mode. When the magnetron is excited in a different mode, there is a difference in potential between the segments, causing the straps to carry more current between them because of the difference in potentials. Thus both inductive and capacitive

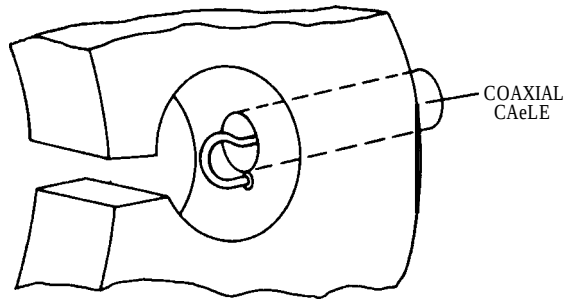
effects operate on the other modes, changing their operating frequency. The result is to further separate the modes and eliminate the possibility of simultaneous operation on two closely spaced modes. Suppression of the unwanted modes increases the over-all efficiency of the magnetron. While it might appear that the symmetry of strapping is essential, this is not so in practice. Actually, by omitting certain straps (usually the ones at the output resonator and adjacent to the input cathode), even greater discrimination is obtained.

The rising sun magnetron design evolved from the fact that symmetry is not required for best results in strapping. The typical design of alternate cavities of the same shape, with adjacent cavities of dissimilar shape, produced the so-called "rising sun" des'ign. Since the sizes of the cavities in the two groups are different, the mode frequencies of this type of magnetron tends to form into two groups as though there were only two resonators. Thus the respective mode frequencies are well separated from the Pi mode, and this unit is suitable for Pi mode operation without the use of strapping. The rising sun design is used at the higher frequencies (above 10 GHz), while strapping with the conventional design is used at the lower frequencies to provide a smaller assembly. A typical rising sun design is shown in the following illustration.



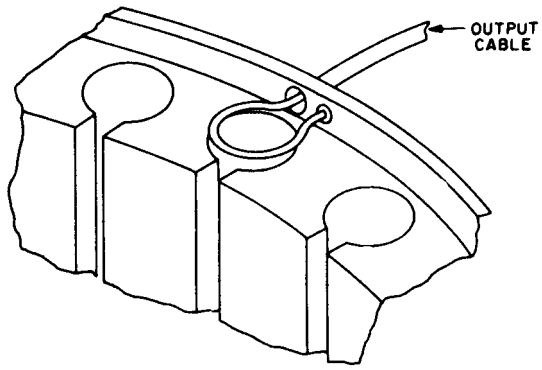
Rising Sun Magnetron

Coupling Methods. F-R energy is usually removed from the magnetron by means of a coupling loop. At frequencies lower than 3 cm the coupling loop is made by bending the inner conductor of a coaxial line into a loop (center-fed coupling) and soldering the end to the outer conductor, so that the loop projects into the cavity, as shown in the following figure.



Coaxial (canter-fed) Coupling Loop

At the higher frequencies to obtain sufficient pickup the loop is located at the end of the cavity (halo loop), as shown in the accompanying illustration.

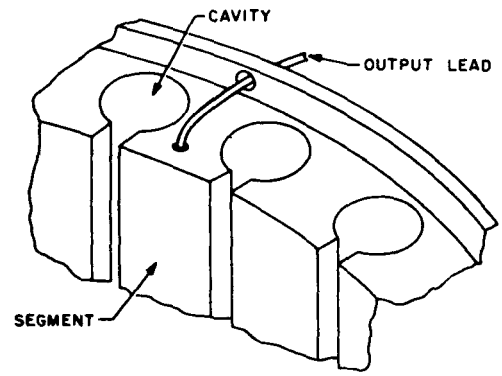


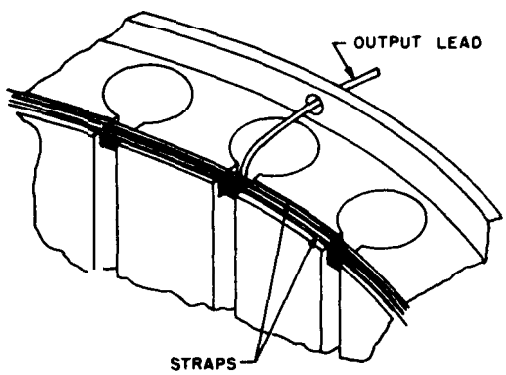
External (halo) Coupling Loop

Other forms of inductive couplings are shown in the following illustration.

In the segment-fed loop it is presumed to intercept the flux passing between cavities, while the strap-fed loop intercepts the energy picked up between the strap and the segment. On the output side, the coaxial line feeds another coax line directly, or it feeds a waveguide through a choke joint, with the vacuum seal at the inner conductor helping to support the

line. Direct waveguide connection is usually through a slot in the back of the cavity, with an iris feeding into the waveguide connector through a window.





Segment-Fed Coupling Strap-Fed Coupling

Tuning. The magnetron is basically fixed-tuned. It is pretuned by adjusting the straps, pressing them in or out to resonate with a test voltage inserted into the cavity from a klystron at the desired operating frequency; the adjustment is made for maximum response on a detector-indicator. Some magnetrons have a flexible plate arranged to move in or out by means of a screw adjustment. Still other magnetrons have pins or rods that screw in or out of the cavities (as in the klystron), and some low-powered types are voltage-tuned. Usually, pretuning is necessary before the magnetron is placed in operation; therefore, some form of mechanical tuning which can be externally performed over a small range tuning which can be externally performed over a small range is used to adjust it to the desired operating frequency. (Of course, this frequency must be within a specified band of frequencies over which the magnetron is designed to be operable.) Thus in most cases the magnetron output frequency is essentially fixed, with the receiver having its bandpass and frequency automatically centered and maintained in synchronism with the transmitting magnetron.

Failure Analysis.

No Output. Lack of output can be caused by nonoscillation of the magnetron, or by oscillation on an undesired mode which will not couple to the output circuit; it can also be caused by a short circuit or an open circuit. Use of the ammeters and voltmeters supplied with the equipment will usually pinpoint the trouble. A steady high current with low applied anode voltage usually indicates a loss of magnetism which allows the electrons to pass directly from cathode to anode. In this case, remagnetization or replacement of the magnets will generally restore operation. (Sometimes insertion and reinsertion of the small soft iron bar placed between the magnet poles during storage, known as the keeper, a few times will restore the magnet.) An anode-to-cathode short will produce heavy plate current and blow fuses or operate protective circuits immediately after the plate voltage is applied. Such a condition will be indicated by a simple ohmmeter check between the anode and cathode, with the voltages removed.

An erratic heavy plate current, usually accompanied by noise and internal flashes within the magnetron (seen through the coupling ports or at visible portions of the glass envelope), particularly in high-power magnetrons, indicates arcing. This is a common occurrence after periods of long idleness or after exceeding the permissible ratings; it can also be caused by land changes or discontinuities in choke or rotating joints, producing excessive r-f reflections. Immediate reduction of plate voltage is imperative to prevent damage to the magnetron or modulator equipment. Then, by following the normal seasoning process, the arcing should occur less frequently until the magnetron stabilizes and resumes normal operation.

If there is no output until a number of starting attempts have been made and the output then builds up slowly, this is a possible indication of an open filament. Particularly with extremely high-powered tubes using very high voltages, the phenomenon of

cold cathode operation can occur through the back bombardment effect. Checking the filament for continuity with the plate voltage removed will quickly determine whether this condition exists.

Since magnetrons are expensive and usually do not plug in as conveniently as common receiving tubes, replacement of the magnetron should be resorted to only after all other checks have been made. Where the current meter indicates zero, it is most probably an open circuit caused by cathode burnout, an open anode or cathode lead, or failure of the modulator or power supply. Checking with the voltmeters provided on the equipment will quickly determine whether the power supply and modulator are normal; if they are, the open must be between these units or within the magnetron. A resistance check for continuity of connections will indicate whether the condition is external to, or within, the magnetron. Do not overlook resetting any overload relays or replacing open fuses in the search.

Reduced Output. Reduction of output below normal is usually more difficult to analyze than lack of output, since the magnetron is very susceptible to variations in the strength of its magnetic field, anode voltage, and load impedance. Such variations cause a loss of output power and efficiency to a large extent, and usually affect the frequency of operation. A shift in the mode of operation can usually be caused by any of the previously mentioned items, and, since the magnetron is normally designed to operate at a particular frequency with maximum output, reduced output may indicate such a condition. Perhaps the best method of trouble shooting is to use a spectrum analyzer such as the echo box, detector, and meter, or by direct observation of the r-f envelope on an oscilloscope. Since the shape of the high-voltage modulator pulse is important, using a portable spectrum analyzer connected via a directional coupler to the magnetron output will save time. Double moding will be indicated by the presence of two or more maximum lobes. A jittering pulse which changes in amplitude or wiggles back and forth is immediately apparent. Changes in load can be made and the effect observed and evaluated. Likewise, the anode voltage can be varied and its effects observed; any frequency instability will be evident. The effect of reduced output will be obvious from local meter indications in the case of c-w magnetron type of operation, but they are not as accurate and are sometimes actually misleading in pulsed operation. A change in current or voltage will show immediately in the steady voltage type of c-w operation. However, in pulsed operation, where the pulse width and duty cycle govern the average value of the current and voltage, a change in pulse width may compensate for a change in duty cycle (or vice versa); thus the pulsed indications may appear normal, when actually there is a reduction in efficiency and output power. Low power output usually results from a weak magnetron or low modulator output. If the modulator pulse is normal, the trouble lies in the magnetron. A weak magnet will cause a loss of power, by reducing the efficiency of operation, and also a change in the spectrum, which is usually obvious on the oscilloscope. For further information, test, and typical waveforms, refer to Test Methods and Practics, NAVSHIPS 0967-000-0130, of the EIMB.

Incorrect Frequency. While magnetron troubles may be divided into three general classifications, namely, wrong frequency, poor spectrum, and low output, they are usually interlinked. For example, a magnetron operating off frequency will most probably show a poor spectrum and produce a lower output, as compared with previously recorded data obtained when the magnetron was known to be operating correctly. In the case of wrong frequency operation for fixed-tuned magnetrons, there are three possible causes. The magnetron may be defective, or frequency pulling or pushing may be present. Frequency pulling may be present because of some fault in the r-f system, such as varying impedance, faulty rotating joints, or be caused by a strong reflection from a nearby object. A change in magnetron frequency due to a change in load impedance is known as “pulling”. The effect of pulling is greatest at high output powers. The operating point of a magnetron is usually a compromise between high output power and good frequency stability, and is usually chosen for a matched load condition. Magnetron performance is often summed up in what is called the pulling *figure*. This figure is the total change in frequency (usually in MHz) which occurs when the load is adjusted to produce a voltage-standing-wave ratio of 1.5: 1, and the phase of the reflection is varied through 360 degrees.

When off-frequency operation occurs and another magnetron is substituted, satisfactory operation of the replacement does not necessarily indicate that the

original magnetron is defective. In some cases a magnetron may be in good condition, but because of individual difference it may be more easily pulled outside the operating band by externrd conditions (such as a change in load impedance) than another magnetron of the same type number. Blind replacement of the magnetron when off-frequency operation occurs, therefore may result in the discarding of a perfectly good tube. The VSWR of the r-f system should first be checked to determine whether it is high or low. With a low VSWR, normal operation of the r-f system is indicated, and the fault is most likely the magnetron. Sometimes the effects of pulling are not noticed if the frequency is within the operating band, so that occasional off-frequency operation is possible without any visible external indications. Frequency pushing (indicated by waveform distortion) may be present because of improper anode or filament voltage. Magnetron pushing, caused by a change in dc anode voltage, is frequently indicated by a poor spectrum shape; this condition results from improper modulator pulse amplitude or shape. The frequency of operation may be slightly altered, or may change from pulse to pulse. Although such operation maybe indicated by a changing anode current, a more definite check can be made by use of an oscilloscope.

Magnetron pushing is usually produced by a change of input conditions. The pushing figure is usually expressed in terms of megacycles per second per ampere. In most cases pushing can be neglected for the longer wavelengths where it is slight. It cannot, however, be neglected at the shorter wavelengths. Regardless of the cause of the frequency change, in the case of the tunable magnetron, only a slight adjustment of the tuning control to establish the desired frequency may be all that is required.

When frequencies appear and disappear in the spectrum, the cause is usually arcing, which produces temporary transients. If this condition occurs frequently, seasoning is necessary; there is also the possibility that the magnetron is becoming unstable and approaching the end of its useful life. If it occurs infrequently, operation can be considered normal, but there is the possibility of incipient magnetron failure.

REFLEX KLYSTRON OSCILLATOR

Applications,

The reflex klystron is used as a low-power r-f oscillator in the microwave region (from 1000 MHz to 10,000 MHz) in receivers, test equipment, and low-power transmitters.

Characteristics.

Uses special tube construction to produce r-f feedback and oscillation.

Operates as a positive grid oscillator.

Uses a tuned cavity, either integral (built-in) or external, to determine the basic range of operation.

Uses negative anode (repeller-plate) voltage.

Circuit Analysis.

General. A klystron tube is a specially constructed electron tube using the properties of transit time and velocity modulation of the electron beam to produce microwave frequency operation. It can be used as an oscillator or an amplifier. The amplifier employs two or more cavities to produce the proper bunching of electrons, upon which its function and amplifying properties are based. The amplifier type of klystron can produce a large amount of power (up to megawatts) and can be used as an oscillator if proper feedback arrangements are made. However, the reflex klystron offers a simple type of feedback arrangement and performs specifically as a special tube designed for oscillator operation alone. Although the power output of the reflex klystron is limited, it is adequate for receiving and test equipment functions and for low-power transmitters. Where high power is required, it can be achieved by using the reflex klystron as a master oscillator and the conventional amplifier type klystron as a power amplifier. Since microwave radiation is limited to line-of-sight distances, the reflex klystron usually furnishes sufficient power for these relatively short rf transmission paths.

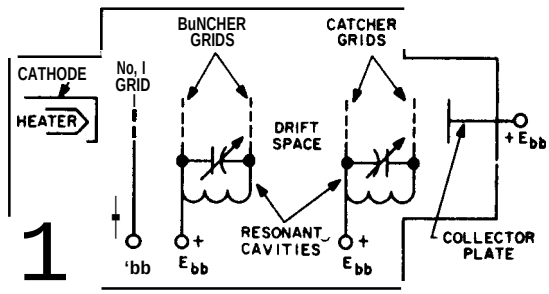
Generally speaking, although the efficiency of the klystron is low as compared with efficiencies obtainable with conventional tubes at the lower frequencies (on the order of 30% as compared with 60%), it is

more efficient than the other types of high-frequency generators in the microwave region. The negative grid tetrode provides approximately the same efficiency at 500 MHz, but its output drops to zero around 1500 MHz; similarly, the lighthouse tube covers a range of from 800 MHz to 2500 or 3000 MHz with comparable efficiencies and then its output drops off; the multicavity klystron, however, is operable up to 10,000 MHz and beyond with efficiencies not less than 1 0%. In this respect, the reflex klystron offers the lowest efficiency (on the order of 2 or 3 percent) mostly because of its simplicity of construction. For example, the use of more cavities to provide better bunching would give higher efficiency. Actually, the klystron is the only device other than the magnetron (and perhaps the traveling wave tube) which offers practical operation on the microwave frequencies; it is simpler and cheaper than the magnetron (or TWT) and more flexible in its applications, which is the reason for its popular use. Present trends indicate that the reflex klystron will be replaced for high-power operation by the two- or three-cavity klystron, but for simplicity and economy for low-power applications the reflex klystron is more practical.

The klystron has a large power gain than the negative grid tube at the higher frequencies because the tetrode primarily has a smaller cathode area, is limited in the amount of plate voltage that can be applied, and has greater r-f losses. The advantages of the klystron accrue because the cathode is not limited in size but can be made as large as necessary, and, being outside the rf field in the tube, it is unaffected by radio-frequency bombardment or other deleterious effects. Although the negative grid tube has a closely spaced grid and plate (to reduce transit time effects), and distance between the anode and the cathode in the klystron is large (on the order of one inch), permitting larger applied plate voltage before breakdown occurs. Since there is no grid structure in the klystron to heat and cause losses (actually, grids are sometimes used, but are very rugged) and the collector is located outside the r-f field and designed solely to dissipate heat, better efficiency results. The major loss in the klystron is dielectric loss (such as the loss produced by windows in cavities for waveguide couplings), as well as wall absorption. Thus, the r-f gain is limited only by the small r-f input cavity loss and by beam loading of the output cavity. Normally there is no negative feedback to be overcome by virtue of interelectrode couplings, as in the negative grid tube, since the input and output cavities are isolated. In the case of the reflex klystron, positive feedback is obtained by the use of a repeller electrode so that only one cavity is required.

In the preceding discussion, a number of generalities were made to bring out the inherent differences between negative grid tubes and the klystron. Since the subject of klystrons and their design considerations cover a large field, which is beyond the scope of this text, and since there are so many variations between different products, it is possible that exceptions to some of the generalities can be made. In fact, considering reflex klystrons alone as a small branch of a large family of klystron tubes, there are a number of variations in design from type to type. Therefore, the interested reader is referred to other texts for specific data on a particular type or design, and the generalities made herein should be viewed broadly. The discussion that follows will be restricted to basic principles which can be applied to any type of tube.

The operation of the klystron is predicated upon the development of velocity modulation of the electron beam; that is, the velocity of the electron beam is controlled to produce a grouping or bunching of electrons. These bunches of electrons are then passed through grids or cavities to produce oscillations at the desired frequency by direct excitation of the cavities. A basic klystron (not reflex type) is shown in the following illustration to establish the fundamental principle of operation. As shown in the figure, a



Basic Klystron

heater is used to produce electron emission from a cathode. The electrons from the cathode are attracted to the accelerator grid (No. 1), which is at a postive

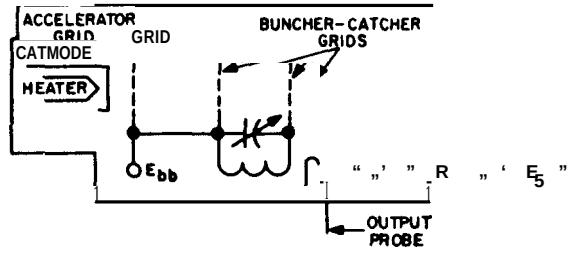
potential with respect to the cathode. The accelerator grid may be a flat grid structure or an annular ring (cylinder or sleeve) through which the electrons pass unhindered. Assume that this attraction produces a constant-velocity electron beam, which is further attracted to the next electrode, the buncher grids (or cavity), and then to the next electrode, the catcher grids (or cavity), also at a higher positive potential. If the output from the catcher is fed back to the buncher, and if the proper phase and energy relations are maintained between the buncher and the catcher, the tube will operate as an oscillator. The collector plate, which is also at a positive potential, serves only to collect the electrons which pass the catcher. Successful operation requires that the energy needed for bunching be less than that delivered to the catcher. Amplifying action is obtained because the electrons pass through the buncher in a continuous stream and are effectively grouped so that they pass through the catcher in definite bunches or groups as explained in the following paragraphs.

Bunching is produced by applying an alternating voltage to the buncher grids (produced by excitation of the buncher resonator by the passing electron beam). Assuming that a sine-wave voltage is produced and applied between the buncher grids, it is evident that on the positive alternation the buncher grid nearest the catcher effectively has its positive potential increased, and therefore further accelerates the electron flow. On the negative alternation, the same buncher grid voltage is made less positive and the electron stream is slowed down. Since a continuous stream of electron enters the bunching grids, the number of electrons accelerated by the alternating field between the buncher grids on one half-cycle of operation is equalled almost exactly by the number of electrons decelerated on the negative half-cycle. Therefore, the net energy exchange between the electron stream and the buncher is zero over a complete cycle of alternation, except for the losses that occur in the tuned circuit (cavity) of the buncher.

After passing through the buncher grids, the electrons move through the drift space in the tube with velocities which have been determined by their transit through the buncher grids. Since in a conventional klystron the drift space is free of any fields, at some point in this drift space the electrons which were accelerated will catch up with these which were previously decelerated (in a prior passage) to form a bunch. The catcher grids are placed at this point of bunching (determined by frequency and transit time), to extract r-f energy from the bunched electrons.

At the catcher a different situation exists. Since the electrons are traveling in bunches, spaced so that they enter the catcher field only when the oscillating circuit is in its decelerating half cycle, more energy is delivered to the catcher than is taken from it. The remaining electrons in the beam pass through the grid and travel to the collector plate, where they are absorbed.

In the *reflex* klystron, the catcher grids are replaced by a repeller plate, to which a negative potential is applied, as illustrated in the accompanying figure.

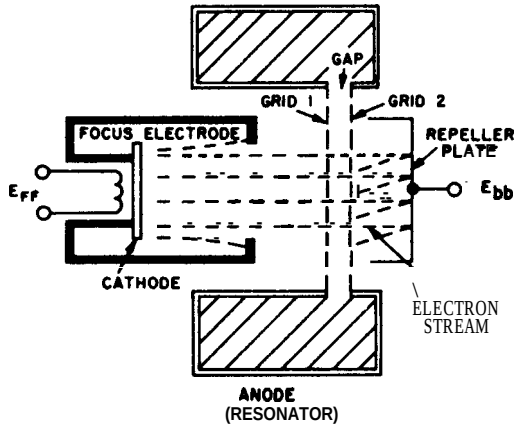


Reflex Klystron

In this type of klystron, the electron beam is also velocity-modulated, and, by proper adjustment of the negative voltage on the repeller plate, the electrons which have passed the bunching field may be made to pass through the resonator again (in the reverse direction) at the proper time to deliver energy to this circuit. Thus, the feedback necessary to produce oscillation is obtained and the tube construction is simplified. Spent electrons are removed from the tube by the positive accelerator grid (when used) or by the grids of the positive buncher cavity. Energy is coupled out of the cavity by means of a one-turn hairpin coupling loop. The operating frequency can be varied over a small range by changing the negative potential applied to the repeller, because this potential determines the transit time of the electrons between their first and second passages through the resonator. Since maximum output depends upon the fact that the electrons must return through the resonator at just the time when they are bunched and at exactly the decelerating half-cycle of oscillating resonator grid voltage, the output is more dependent

than the frequency upon the repeller potential; therefore, the amount of tuning provided by varying the repeller voltage is limited. Usually the volume of the resonator cavity is changed (by mechanical tuning) to make a coarse adjustment of the oscillator frequency, and the repeller voltage is varied over a narrow range to make a fine adjustment of the frequency (electronic tuning) consistent with good output. Since the same grids perform the dual function of bunching and catching in the reflex klystron, they are frequently referred to as the buncher-catcher grids. Because of the variation of frequency with accelerating voltage, it is difficult to achieve linear amplitude modulation with a klystron. Frequency modulation may be readily accomplished, however, by introducing a small modulating voltage at the cathode or repeller. The tuned circuit used in the reflex klystron is a cavity resonator, which has a very high Q. Depending upon the tube type, the cavity may be an integral cavity (built into the tube) or an external cavity (clamped around the tube). Several methods are used to tune cavity resonators. Capacitive tuning is provided by mechanical varying the grid gap spacing; inductive tuning is provided by moving screw plugs in or out of the cavity (this changes the volume, making it either smaller and tuned to a higher frequency, or larger and tuned to a lower frequency). In some instances thermal tuning is used by applying heat to grid gap to produce capacitive variations. Several types of output couplings are used, but the coupling loop is the most popular type. Capacitive probe coupling is often used with the external type of cavity because construction difficulties do not readily permit the use of coupling loops with this type of cavity. At frequencies above 10,000 MHz waveguides are employed, and the output is coupled to the waveguide through a window or aperture.

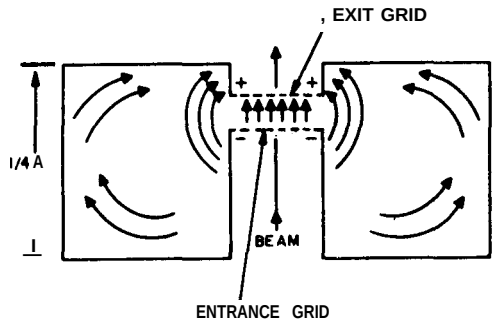
Detailed Analysis. In the practical klystron, the function of the accelerating grid is provided by the cavity, which is maintained at a postive potential sufficiently strong to produce the initial effect of accelerating the electrons to a constant velocity. A focus electrode, in the form of a cyclinder connected to the cathode, is also provided to confine and effectively focus the electrons into a narrow beam. Focusing is achieved electrostatically without any external control. Any electrons which travel outside the beam are intercepted and removed, while those within the beam are attracted by the strong positive cavity field and accelerated uniformly. A typical reflex klystron, showing the focusing electrode and the cavity structure, is illustrated in the accompanying figure.



Practical Reflex Klystron

Note the particular shape of the cavity, which has a post-shaped center hole. As a result of this construction, the cavity is very narrow at the point (the gap) where the electrons pass through it. The narrow gap is necessary for proper operation since the transit time through the cavity must be much less than the time for a complete cycle at the frequency of operation. Beyond the center hole the cavity is much larger. The portion of the cavity at the gap where the ends are close together may be considered capacitive in effect, and the remaining portions, where the capacitance is small, may be considered inductive in effect. Consider now the operation of velocity modulation. Since the cavity is developed as a quarter wave coaxial resonator, the input and output ends are at opposite polarities. Also, the current distribution is approximately uniform at the center, where the beam passage takes place. Hence, in the gap a uniform electric field is produced. The passage of the electron beam through this field will distort the field and cause energy to be absorbed from the beam. Thus, the cavity is excited, and it oscillates at a frequency determined by its dimensions. These oscillations produce opposite polarities at the entrance (grid 1) and exit (grid 2) grids, because the sides of the cavity are exactly one quarter wavelength apart at the operating frequency. By virtue of resonance and the use of a high-Q cavity, the r-f oscillations develop a large

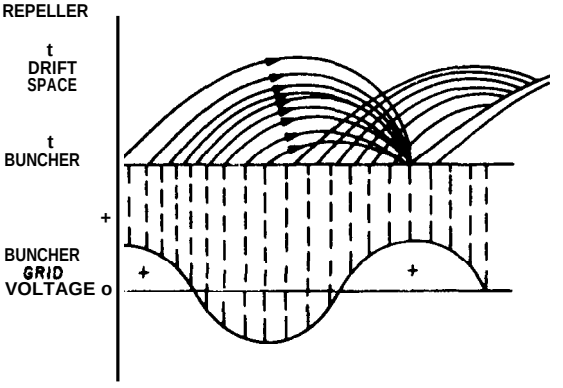
instantaneous voltage, which on the positive alternation places the exit grid at a more positive potential than the entrance grid. As a result, the exit grid is polarized in the proper direction to attract the electron beam and increase the electron beam velocity. See the following illustration for a representation of the cavity action.



Cavity Action

On the negative alternation the beam is opposed and effectively slowed down. At and near the changeover points, the ac oscillation voltage is practically zero so that the beam is not affected and it passes through with the initial velocity. The alternate acceleration and deceleration of the beam, together with the ineffective period of no change produces a bunching of the electrons. (In effect, the bunches of electrons occur at a period equal to the frequency of oscillation. Thus, actual density modulation is produced, resulting in an alternating current varying in strength at the frequency of operation, which when absorbed by a resonant cavity will cause rf oscillations.)

Before the electrons with different accelerations are completely bunched, they enter into the repeller-plate field, which is negative and repels the electrons. An electron which was accelerated by the field at the cavity grids will penetrate the electric field at the repeller plate to a greater depth than one which was accelerated less or not at all, and will require a longer time to return to the cavity. Thus, bunching can be achieved by adjustment of the repeller plate voltage to the optimum value. When the voltage is optimized, bunches are formed at the cavity by those electrons which were accelerated meeting those which were not accelerated, but which passed through the gap at a later time, and also by those decelerated electrons which passed through at a still later time. A typical Appfegate diagram illustrating the bunching effect is shown in the accompanying figure.



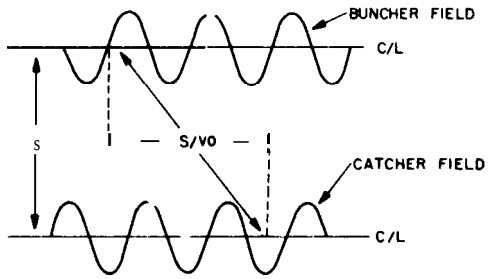
Applegate Diagram

To more clearly understand buncher and catcher operation, we shall review the operation of the two-cavity type of tube. Action is based upon the fact that electrons will give up energy when slowed down, and absorb energy when accelerated. In order for an electron to give up the greatest amount of energy to the catcher, it is necessary that the electron arrive at the center of the catcher at the instant when the electric field at the center of the catcher has its maximum negative (retarding) value. Similarly, in order for a symmetrical group of electrons to deliver as much energy as possible, the center of the group must arrive at the center of the catcher when the catcher field has its maximum negative value. Since the electron at the center of the group is the one that passed the center of the buncher at the instant when the buncher field was changing from negative to positive, the time s/v_o required by this electron to move through the distances from the center of the buncher to the center of the catcher, must be equaI to the time interval between the zero of the buncher fields and a negative maximum of the catcher field, as shown in the following figure. It is evident from

examination of the illustration that for maximum energy transfer, the catcher field must lag the buncher field by the angle

$$\frac{s}{V.} \times \frac{2\pi}{T} + 2\pi(\tfrac{1}{4} - n),$$

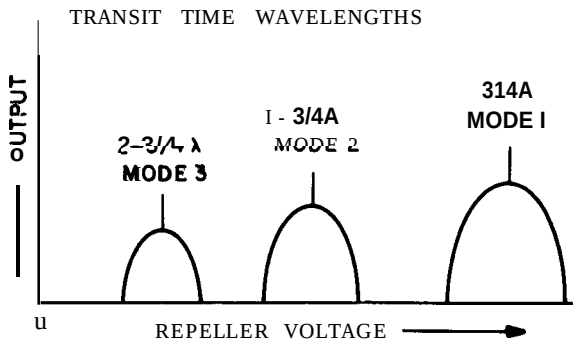
where T is the period of the field and n is any integer.



Buncher-Catcher Phase Relationships

Up to this point nothing has been said regarding the means by which the catcher is kept in oscillation. The motion of an electron through a cavity resonator sets up an electromagnetic field within the resonator. In a klystron the electrons pass through the catcher in bunches; therefore, the fields resulting from individual electrons will, for the most part, reinforce each other and thus produce a resultant field of appreciable magnitude. Because the bunches pass through the catcher at time intervals equal to the natural period of oscillation of the catcher, the catcher is set into oscillation. Since the amplitude of oscillation can build up only if the catcher gains energy, the oscillation automatically tends to assume the proper phase relative to the cycle of arrival of electron bunches to result in maximum transfer of energy from the electrons to the catcher. Since the cavity of the reflex klystron acts both as a buncher and a catcher, if an output is to be obtained, the returning electrons must be phased so as to impart energy to the cavity and be absorbed. It is necessary that they approach the cavity when the buncher voltage originally induced is opposing them, or producing deceleration. Therefore, the time taken for a bunch to return to the cavity must be 3/4 of a cycle of the operating frequency to supply energy by feedback and satisfy the requirements for oscillation. The phasing must be such that the electrons add energy to the cavity. Therefore, during the first quarter cycle they have not yet returned, and during the second quarter cycle they are in phase opposition (180° apart), but at the 3/4 cycle they are in phase and will add energy to the cavity. A bunch of electrons which returns to the cavity at a time equal to 3/4 of a cycle, or any whole number of cycles plus 3/4 cycle, will supply energy of the proper phase for sustaining oscillations. Thus, oscillations may be obtained at a number of repeller plate voltages for a given frequency setting of the resonator cavity.

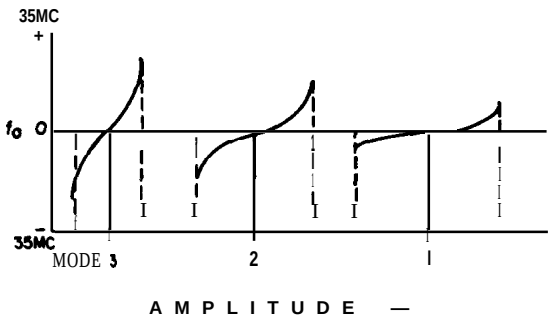
Oscillations of maximum amplitude are obtained when the frequency of operation, as determined by the return time of the reflected electrons forming a bunch, coincides with the frequency to which the resonator is tuned. Since only one resonator is used, the tuning of the reflex klystron is relatively simple. Although the frequency of operation for fixed cavity tuning may be varied by changing the repeller voltage, the power output drops off on either side of the cavity frequency because the field of the gap does not provide optimum retardation. The various values of repeller voltage which produce oscillation result in what is known as different modes of operation. The most negative repeller voltage for which oscillation results is known as mode 1. Lower values of repeller voltage successively produce the higher modes (2, 3, 4, etc) of operation. A typical output response with repeller voltage variation is illustrated in the following figure.



Power Output vs Repeller Voltage

Since the bunching of the electrons for the higher-numbered modes is not so well defined, the net

energy given up by the beam to the resonator field is less, and the output power is smaller, as illustrated. On the other hand, because the bunching is not so well defined, the modes of higher number are tunable over a greater range of frequencies (by adjustment of the repeller voltage). The accompanying illustration of electronic tuning ranges verses modes indicates that for the lower repeller voltages (mode 3) the range of electronic tuning increases but the output decreases.



Tuning Ranges vs Modes of Oparation

The variation of frequency with changes in the repeller voltage permits the reflex klystron to be used with an automatic- frequency-control circuit, which controls the klystron frequency by lowering (or by increasing) the repeller voltage in the proper direction to compensate for any frequency change. Thus, the circuit can be made self-tuning and provide reasonably good frequency stability, particularly in pulsed operation where voltages and pulse amplitudes change drastically. (See the Special Circuits Section of this handbook for a discussion of the various types of AFC circuits.)

Tuning Methods. The method used for tuning the resonator has an important bearing on the performance of a reflex klystron. Tuning is commonly accomplished by varying the length of the r-f gap, to adjust the capacitive portion of the resonator, although in some tubes the inductive portion is altered. Capacitive tuning requires small motions for large frequency shifts, particularly near the low-frequency end of the tuning range. This extra sensitivity can be either an advantage or a disadvantage depending upon the application. Generally speaking, it creates a problem when temperature compensation is attempted because there must be considerable reduction of motion by a mechanical linkage between the control knob and the gap itself.

The use of capacitive tuning reduces the range over which reasonable efficiency is obtained. As the frequency is raised by lengthening the gap, the transit angle through the gap increases rapidly because the electrons have farther to go and less time to make the trip. The beam coupling coefficient also drops rapidly at the high frequencies so that the output drops quickly. On the low-frequency side of resonance, a similar drop-off occurs, but it is not so rapid. Since the resonator must incorporate a flexible diaphragm to permit capacitive tuning, problems arise in providing the proper vacuum seal; also, the tube is susceptible to changes cause by strong sound waves impinging on the diaphragm, and to changes in barometric pressure, which cause problems in aeronautical applications.

On the other hand, inductive tuning is usually less sensitive because larger mechanical motions are required to produce the same effect. In radial cavities, screw plugs are used (as many as four to six) for tuning. This method of tuning usually results in a fixed-tuned arrangement because of the mechanical difficulties in providing remote control of a number of plugs. However, since the transit time varies directly with the phase angle, rather than the 3/2 power as in capacitive tuning, much larger tuning ranges are available with inductive tuning. The largest tuning range (approximately 2 to 1) is provided by a coaxial cavity, but at greatly reduced efficiency (capacitive tuning range is about 0.7 to 1).

Mechanical tuning is usually employed in preference to thermal tuning because of the complexity of the frequency control circuit. Since the thermal motion is usually small, capacitive tuning is practically always used for thermal control. The main drawback of thermal control is thermal inertia, which prevents a rapid response to sudden frequency changes; as a result, overshoot becomes a major problem. In general, thermal tuning is used only for special applications where the simpler types of tuning are inadequate.

Output Coupling. Tubes with integral resonators usually have built-in output circuits that consist basically of a coupling device and an output transmission line. The most common pickup device is an inductive loop formed on the end of a coaxial line

and inserted in a region of the cavity where the magnetic field is high. Aperture coupling, sometimes called iris coupling, is also used, but to a lesser extent than the pickup loop. In waveguide applications, the aperture is usually used for simplicity and convenience. For external cavity tubes employing coaxial-line tuners, a capacitive probe is sometimes used.

Failure Analysis.

No Output. Incorrect or no plate voltage can prevent oscillation. An incorrect repeller voltage can usually be re-adjusted (within range of the control) to the proper value, or output frequency may be adjusted by tuning the cavity until the tube operates on some other frequency. Lack of oscillation for all values of repeller voltage and cavity tuning indicates an open circuit, loss of accelerator anode voltage, or a defective tube. With an external cavity klystron, poor electrode contacts can also cause lack of output. A voltage check will quickly indicate whether the potentials are normal. Note: *Although low* voltages are used, the cavity is positive while the repeller is negative so both supplies in series provide a possibility of dangerous shock. Observe safety precautions when testing. A tube with decreasing emission indicates incipient failure by a gradual reduction of plate current, and failure to oscillate at the usual repeller control settings. Such a condition becomes progressively worse over a period of time, and complete failure can be anticipated. Loss of output when automatic frequency control is used can result from failure of the AFC circuits; this type of trouble can be determined by switching to manual and noting whether normal tuning occurs. Since the reflex klystron is an integral unit with only output and supply connections, complete loss of oscillation is usually due to mistuning, loss of supply" voltage, or a defective unit.

Reduced Output. In the majority of cases, reduced output is caused by mistuning or lack of proper electrode voltages. Mistuning can usually be corrected by a slight readjustment of the repeller voltage and the cavity tuning unless the tube or supply is defective. There is also a possibility that the output load has changed, requiring a readjustment of the controls. Where stub tuners are employed in the output circuit, reduced output may be caused by improper stub tuning. In either case, a slight readjustment of each of the tuning controls should quickly indicate which is at fault. Operation on a lower mode due to incorrect supply voltage can be detected by a voltage check; this condition is usually indicated when the controls must be set to a position other than normal for maximum output, or when reduced output is obtained at the optimum adjustment point. If the supply voltages and load are normal, reduced output usually indicates incipient tube failure.

Incorrect Frequency. Slight changes in frequency can usually be corrected by making slight repeller voltage changes and by tuning the cavity. Normally a rough frequency setting is obtained by adjusting the cavity tuning, and a fine frequency setting with optimum output is obtained by adjusting the repeller control. A simple voltage check should indicate whether the repeller and cavity voltages are correct. If the cavity tuning is operable and the repeller voltage is correct, incorrect frequency operation can be caused only by load changes or by a change in the tube cavity mechanism with age. It should be possible to restore the frequency by proper load adjustment. Changes in the mode of operation can be detected by noting whether the tuning range is greater and the output is less. Where AFC circuits are used to maintain the frequency, a shift to manual control will quickly determine whether they are at fault.

Changes in frequency resulting from changes in temperature are usually compensated for by adjustment of the tuning controls; such changes may be caused by localized heating due to improper operation when power type klystrons are used, or by greater than normal ambient temperature changes. When proper operation and normal temperature are restored, the unit should again stabilize at the proper frequency. Unless thermal compensation circuits or devices are provided, it will be necessary to compensate by the use of manual tuning. It continued drift is observed, the tube ratings are probably being exceeded. Where a stable frequency is important, an AFC circuit is usually incorporated. Improper operation of the AFC can be checked by switching to manual operation and observing whether operation is normal.

BACKWARD WAVE (CARCINOTRON) OSCILLATOR

Application.

The carcinotron oscillator is used to supply ultra-high frequency and microwave frequency outputs for transmitting applications.

Characteristics.

Frequency reange is from approximately 200 MHz to over 100 GHz.

Output is from a few milliwatts to 150 watts or more.

Efficiency is low, from about 10 to 30 percent.

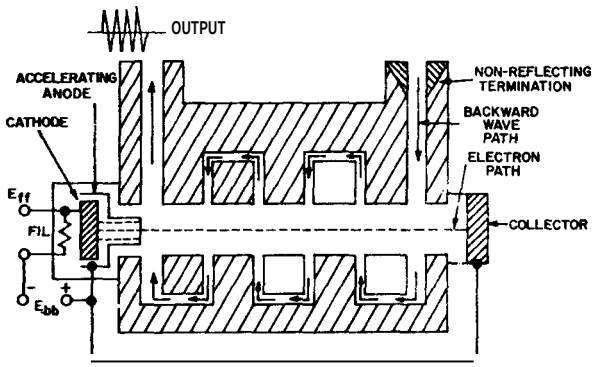
Output frequency is determined by applied voltage.

An electron gun and magnetic field are used to produce electron bunching.

Circuit Analysis.

General. There are two general types of carcinotron in use, the "O" type and the "M" type. The first type uses an electric field to impart kinetic energy to electrons. The kinetic energy of the electron is then extracted by a traveling wave; in the second type, a combination of electric and magnetic fields are used to extract potential energy from the dc field, utilizing electrons as the pivot for this action. Since the O-type is simpler and easier to understand, discussion will be limited to that type. The backward-wave tube is similar to the traveling-wave tube except that basically it is an oscillator rather than an amplifier, and it is the backward component of the traveling wave which produces the action. The typical backward wave oscillator consists of a folded transmission line or waveguide operating in the TE_1, O mode, constructed so that the waveguide winds back and forth across a center line which produces an axial component of the electric field. The total path length from one end of the tube to the other is on the order of 12 wavelengths, and in a typical tube it will cross the axis about 50 times. An electron beam is directed along the axis through holes in the structure. When this beam has suitable velocity, an interaction occurs between the electron stream traveling from left to right and the backward wave traveling from right to left. This infraction causes energy to be delivered to the backward wave by the electron beam, producing an r-f output.

Circuit Operation. The schematic of a typical backward oscillator of the folded type is shown in the accompanying illustration.



Folded-Line Backward Wave oscillator

As can be seen from the illustration, a beam of electrons from an electron gun is directed through a hole in the center of a series of rectangularly folded waveguide sections. The collector electrode is placed at the end opposite the accelerating anode, and a non-reflecting termination is also placed at this end of the waveguide (if it were used as an amplifier this would be the input end). The output is at the electron gun end of the tube. The electron gun is a typical Pierce type, using a filament connected to a cathode and a separate cylindrical accelerating grid or anode. The collector and accelerating anode are connected to a source of positive voltage to attract the electrons from the cathode. Changing this voltage over a ten to one range produces a two to one frequency change which is about the maximum tuning range possible. Backward wave oscillation may also be obtained from a tube using a helix instead of a folded waveguide; in this instance, the circumference of a single turn must be between a quarter and a half wavelength.

Although the Pierce electron gun produces a series of essentially parallel-path electrons, in some tubes there is a tendency for the parallel electrons to be deflected or to stray from the parallel path. This is overcome by adding a solenoid around the envelope of the tube whose axis is in a longitudinal direction.

The focusing field of the solenoid deflects any stray electrons back into the electron steam so that they must travel through the center of the holes in the wave guide. The accelerating anode creates the initial electric field which attracts the electrons from the cathode, while the collector serves to collect the spent electrons after they pass through the waveguide, and return them to the power source. The r-f output is coupled from the waveguide through a probe or an aperture in the end of the waveguide.

Normally, thermal noise produced by current variations in the electron beam produces a noise signal in the waveguide to initiate oscillation. The purpose of the waveguide is to provide a path for the r-f oscillations in proximity to the electron beam, so that interaction can occur between the beam field and the signal field. When a noise signal is generated within the waveguide it is offered a conduction path from the collector back to the cathode end of the tube through which the r-f output current flows. While the electron beam and r-f oscillation (backward wave) signal both travel at the speed of light, and path through the waveguide is longer. Therefore, the backward wave oscillations pass through the waveguide at a much slower speed than the electron, which passes through the center of the waveguide and follows the shorter direct path between cathode and collector. Note that while the electrons flow from left to right, the backward wave travels in the opposite direction from right to left.

When the backward wave oscillation field opposes the field of the electrons passing through the gap at the center of the waveguide, the electrons are decelerated, and are overtaken by other electrons. During the time the beam electrons are decelerated they relinquish kinetic energy to the r-f field which causes them to form in bunches. When the backward oscillation field increases at the gap it enhances the electron field and accelerates the beam electrons, and energy is transferred from the r-f field to the electron beam field. As the oscillating field and electron beam progress in opposite directions through the tube, more bunching occurs. Thus, more beam electrons are available to give up kinetic energy while passing through a decelerating field. Since more time is spent by a beam electron in a decelerating field than in an accelerating field, it gives up more energy to the r-f field than it receives. To ensure the proper phase relationship between the field at the gap and the electron beam, the electron velocity is chosen so that the total phase difference at the collector end of the tube is approximately one half cycle. Therefore, over most of the length of the tube, the beam electron bunches encounter relatively strong decelerating fields as they cross the gaps. These fields slow down the beam electrons and cause energy to be delivered to the backward wave. If the beam current is sufficiently great self-sustaining oscillations are developed. The amplitude of the backward wave builds up and becomes larger as it progresses from the collector to the gun end of the tube, and passes more and more bunches of beam electrons from which it receives energy. Simultaneously, the beam electron bunching becomes greater as the electrons progress toward the collector. Actually, the backward wave oscillator is a special type of traveling wave tube which characteristically contains a built-in feedback mechanism. In this mechanism, the power generated by a traveling-wave type of interaction is used to supply the signal required at the gun end of the tube to produce bunching of the electron stream.

Failure Analysis.

General. The carcinotron is manufactured as an integral unit and cannot be repaired or altered by the electronic technician. Usually the filament may be observed visually to see if it is illuminated, and the high voltage and beam current may be measured. WARNING-be certain to employ all safety precautions since highly dangerous voltages are employed. Always disconnect the power and discharge the circuit with a shorting stick before attaching the voltmeter or ammeter test prods. If normal voltages and currents are obtained but the unit does not oscillate, a higher than normal voltage and beam current may be employed to determine if the tube will oscillate at all. Usually, if normal voltage and current will not produce an output, or produce a much lower than normal output, the tube may be defective. If the tube operates but not on the desired frequency it is possible to increase the frequency by applying higher voltage, or to lower it by reducing the voltage. Such a condition indicates a change in tube characteristics and may be a preliminary indication of incipient failure. Other other possibility of trouble could exist; this would be a poor match to the load or a shorting of the load. This possibility can be checked by using a dummy load of the proper value and observing if the output and voltages return to normal.

PART 6-4 BLOCKING AND SHOCK EXCITED

FREE-RUNNING PRF GENERATOR (ELECTRON TUBE)

Application.

The free-running prf generator is a basic blocking oscillator. It produces short-time-duration, large-amplitude pukes for use as timing, synchronizing, or trigger pulses in radar modulators and display indicators.

Characteristics.

Output pulse is a single cycle of oscillation caused by tube conduction at the beginning of each pulse-repetition period.

Pulse-repetition time is determined primarily by the R-C time constant of the grid circuit. The pulse repetition frequency is generally fixed within the range of 200 to 2000 Hz, although the circuit can be arranged to change the R-C time constant and provide for operation at other fixed pulse-repetition frequencies.

Frequency stability is ±5 percent.

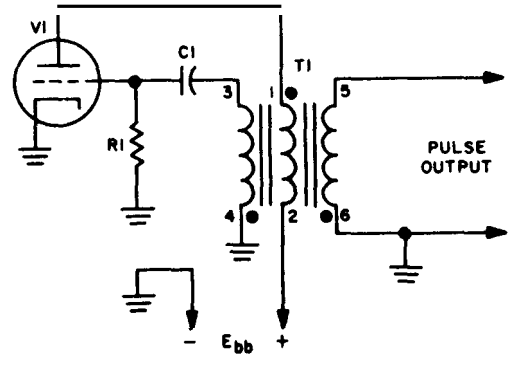
Pulse width and rise time of the output pulse are determined primarily by the transformer characteristics.

Output-pulse polarity is determined by the phasing of the transformer output-tertiary winding. With minor circuit changes, output can also be taken from the cathode circuit.

Circuit Analysis.

General. The free-running blocking oscillator (prf generator) is a special-type oscillator in that the oscillator completes one cycle of operation to produce a pulse and then becomes inactive (blocked) for a considerable period of time, whereupon the cycle of operation to produce a pulse is repeated and the oscillator again becomes inactive. This mode of operation continues, and thus produces a series of output pulses which are of short-time duration, separated by relatively long time intervals.

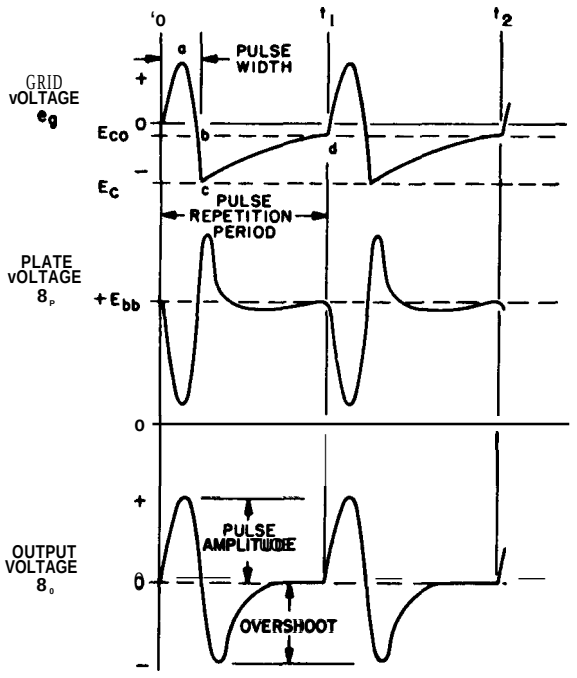
Circuit Operation. The following circuit schematic illustrates a triode electron tube in a basic free-running blocking oscillator circuit. Transformer T1 provides the necessary coupling between the plate and grid of electron tube VI; terminals 1 and 2 of transformer T1 connect to the plate (primary) winding, terminals 3 and 4 connect to the grid (secondary) winding, and terminals 5 and 6 connect to the output (tertiary) winding. Capacitor Cl and resistor RI form an R-C circuit to determine the discharge time constant in the grid circuit circuit. The output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer T1.



Free-Running PRF Generator

On the circuit schematic, note the placement of small dots near winding terminals 1, 4, and 6 of transformer T1. These dots are used to indicate similar winding polarities. For example, if current flows through the plate windings and terminal 1 is negative, the voltage induced in each of the other windings is such that the dot end is also negative in each winding at the same time; therefore, at this same instant of time, terminals 3 and 5 are positive.

For the discussion of circuit operation which follows, refer to the following illustration of the blocking oscillator grid-signal, plate-signal, and output-voltage waveforms.



Theoretical Grid-, Plate-, and Output-Voltage Waveforms

When plate voltage is first applied to the circuit, the grid of VI is at zero bias and plate current starts to flow through the plate winding (terminals 1 and 2) of transformer T1. A magnetic field is set up about the plate winding and a voltage is induced (through transformer action) in the grid winding (terminals 3 and 4) of transformer T1. Because of the phasing of the plate and grid windings, the voltage produced across the grid winding is impressed on the grid of the tube through coupling capacitor Cl with such polarity as to drive the grid to a positive direction. This results in an increase in the tube plate current, and the action continues with the grid being driven further in the positive direction. When the grid is driven sufficiently positive, the tube begins to draw grid current and capacitor Cl begins to charge. Grid capacitor Cl is charged through the relatively low internal cathode-to-grid resistance of the tube, causing the plate of capacitor C 1, which is attached to the grid of V1, to accumulate a surplus of electrons. At this time, however, the plate current has reached its saturation value and the current through the plate winding of transformer T1 can no longer increase (change); as a result, the voltage induced in the grid winding of the transformer can no longer increase (point a on grid-voltage waveform). As a further result, since no induced voltage appears in the grid winding, capacitor C 1 starts to discharge through resistor R1 causing the grid potential of V1 to become slightly less positive. This causes the plate current in the plate winding to decrease slightly, accompanied by a decrease in the magnetic field about the plate winding. As the magnetic field begins to collapse, a voltage is induced in the grid winding of a polarity opposite that originally produced; thus, the grid is driven in a negative direction.

As the grid of V1 is driven negative, the plate current continues to decrease and the magnetic field about the plate winding collapses completely. This causes the grid to be driven still further in a negative direction until cutoff is reached (point *b* on waveform) at which time plate current no longer flows through transformer T1.

The highly negative charge existing on capacitor Cl places the grid of V1 below cutoff (point c on waveform); then the capacitor slowly discharges through resistor R1 and the grid winding of transformer T1. Since the resistance of the grid winding is low compared to that of the resistor, RI, the resistor is the determining factor in the discharge time of capacitor Cl. Furthermore, since the resistance of R1 is large compared to the internal cathode grid resistance of the tube when the grid of V1 is positive, resistor R1 does not affect the charging of capacitor c1.

After an elapsed period of time, as governed by the time constant of RI and Cl, capacitor Cl discharges through resistor R1 to a point near cutoff (point *d* on waveform), where the grid voltage allows the tube to conduct. As plate current once again starts to flow through the plate winding of transformer T1, the entire cycle of operation is repeated.

The changing magnetic field produced about the plate winding of transformer T1 also induces a changing voltage in the tertiary or output winding (terminals 5 and 6). Thus, an output-voltage waveform is produced across the tertiary winding which is similar to the plate-voltage waveform of the blocking oscillator. The pulse output can be of either polarity (with respect to ground) depending upon which terminal of the tertiary winding is grounded. As shown in the

circuit schematic, terminal 6 of T1 is grounded; therefore, the initial output pulse is positive with respect to ground. If desired, limiting or clipping techniques can be applied to the output signal to reduce or eliminate the overshoot (amplitude extreme) in the output waveform. In some instances the desired signal may actually be the overshoot and is used to provide a trigger pulse which is delayed in time by the width of the initial pulse.

The approximate time interval required for the capacitor voltage, E_c, to discharge from maximum to the cutoff value, E_{co} (point c to point *d* on the grid-voltage waveform), may be determined by use of the following formula:

$$t \cong 2.30\ RC\ \log \frac{E_c}{E_{co}}$$

Where: t = time interval to discharge to cutoff (seconds)
E_c = maximum voltage change across capacitor
E_{co} = negative cutoff value for tube
R = resistance of grid resistor (megohms)
c = capacitance of grid-coupling capacitor (μf)

Since the pulse width of the blocking oscillator is usually small compared with the capacitor discharge time, the pulse width may be neglected when approximating the natural operating frequency of the oscillator. The natural operating frequency (Hertz), f_o, can be expressed as the reciprocal of capacitor discharge time; thus, the blocking-oscillator frequency may be approximated using the following formula:

$$f_o \cong \frac{1}{t}$$

Where: t = capacitor discharge time (seconds)

The free-running blocking oscillator, with minor circuit changes, may be synchronized to an external trigger signal by chosing values of R1 and Cl so that the natural oscillating frequency of the blocking oscillator is slightly lower than the desired frequency. The synchronizing trigger signal, then, must be slightly above the natural oscillating frequency of the blocking oscillator. Under these conditions, when the tube is held below cutoff, the application of a positive synchronizing pulse will drive the tube into conduction somewhat earlier than the R-C time constant would normally permit. Thus, the oscillator will synchronize its frequency of operation with that of the trigger source and the repetition period of the blocking oscillator will be that of the trigger source.

In a practical blocking-oscillator circuit, resistance RI is usually made up of two resistors: a fixed resistance and a variable resistance connected in series. The variable resistance is then adjusted to provide operation at the desired pulse-repetition frequency. The operating frequency of the blocking oscillator can be changed by switching values of R, C, or both R and C, to alter the time constant. For example, a blocking oscillator designed to operate at 600 pps can be changed to a lower frequency, such as 300 pps, by switching a larger value of R, C, or both, into the circuit to lower the pulse-repetition frequency. Another method of shifting the operating frequency of the blocking oscillator, over a limited range, is to change the quiesent grid voltage of the tube. This method is unaffected by lead resistance, stray capacitance, etc, and is well adapted to remote-control operation.

Important factors affecting the frequency stability of the blocking oscillator are: the stability of grid resistor R1 and of capacitor C 1, the variation or changes in applied filament and plate voltages, and the changes occurring in the electron tube. The circuit is particularly sensitive to changes in filament voltage; a 10 percent decrease in filament voltage may change the oscillator frequency as much as 2 percent, while a 10 percent increase in filament voltage may change the frequency about 1 percent. A change in plate voltage of 10 percent will change the frequency about 1 percent.

Failure Analysis.

No Output. In a nonoscillating condition, negative grid voltage will not be developed; the measured plate voltage at the plate of V1 will be below normal because of the steady value of plate current flowing through the plate winding of transformer T1 (assuming the plate winding is not open). Capacitor Cl and resistor R1 directly affect the pulse timing; a shorted capacitor will cause oscillations to cease and prevent development of oscillator grid voltage, and an open

resistor will prevent capacitor discharge. Sustained periodic oscillations of the blocking oscillator depend upon feedback obtained from transformer Tl as well as the action of capacitor C 1 and resistor R1. Therefore, any defect in the transformer, such as an open plate or grid winding or a number of shorted turns in either of these windings, will prevent the circuit from operating. A shorted output winding or shorted load impedance may also cause the circuit to stop oscillating, since the tertiary winding is coupled to the plate and grid windings of the transformer. In this case, the impedance reflected to the plate and grid windings may cause excessive losses which will prevent sustained oscillations. Note that if the tertiary winding should open, the circuit will continue to operate; however, no output will be obtained from the tertiary winding.

Incorrect Frequency. The value of oscillator R-C components should be within design tolerance in order to produce the desired operating frequency; where an adjustment is provided, a small change in operating frequency can be compensated for by adjustment of the variable resistance in the grid circuit. It is resonable to assume that any change in the R-C time constant of the blocking-oscillator grid circuit (change in value of resistance or capacitance, leaky capacitor, etc) will be accompanied by a change in operating frequency. Also, changes in applied filament and plate potentials will affect the operating frequency.

Indiscriminate substitution of tubes in the free-running blocking-oscillator circuit can cause a frequency change because of differences in individual tube characteristics.

incorrect Pulse Width Or Unstable Output. Capacitor Cl affects the pulse width as well as the R-C discharge time; however, transformer T1 is of greatest influence in determining pulse width and the rise time of the output pulse. The rate of rise of the leading edge of the output pulse depends upon the transformer turns ratio between plate and grid windings and also upon the rate at which current may rise in the windings as determined by their inductance. (A transformer with high step-up ratio and low inductance will produce relatively short-duration pulses.) The pulse width normally obtained is approximately equal to the time of one-half cycle which would be produced at the natural oscillating frequency if the relative large grid-blocking capacitor Cl were not used in the circuit. Thus, a defect in the transformer, T1, would be likely to cause a change in pulse width accompanied by unstable or erratic output.

The instantaneous blocking-oscillator grid-to-cathode voltage is the difference between the instantaneous charge voltage on the capacitor and the instantaneous negative voltage produced across the grid winding of transformer T1. A rise in capacitor voltage causes the grid voltage to become less positive faster than if the action depended upon transformer voltage alone; thus, the initial pulse is effectively shortened. If either capacitor Cl or resistor R1 should change value, the effect would be more readily noticed as a change of frequency rather than a change of pulse width.

FREE-RUNNING PRF GENERATOR (SEMICONDUCTOR)

Application.

The free-running (prf generator) blocking oscillator is a basic blocking oscillator. It produces short-time-duration, Iarge-amplitide pulses for use as timing, synchronizing, or trigger pulses.

Characteristics.

Output pulse is a single cycle of oscillation caused by transistor (collector element) conduction at the beginning of each pulse-repetition period.

Pulse-repetition time is determined primarily by the R-C time constant in the base-emitter circuit. The pulse-repetition frequency is generally fixed within the range of 200 to 2000 pulses per second.

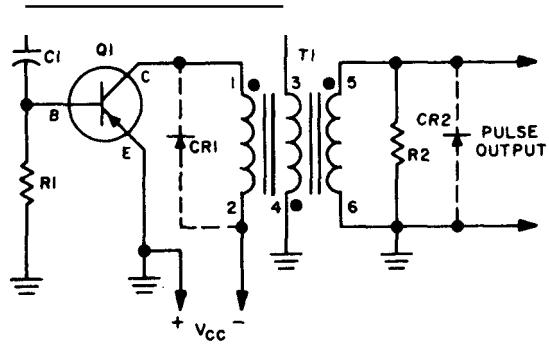
Pulse width and rise time of the output pulse are determined primarily by the transformer characteristics.

Output-pulse polarity is determined by the phasing of the transformer output-tertiary winding.

Circuit Analysis.

General. The free-running blocking oscillator (prf generator) is a special-type oscillator in that the transistor conducts for a short period to produce a pulse and then becomes cut off (blocked) for a much longer period of time; then the cycle of operation to produce an output pulse is repeated and the oscillator again becomes inactive. This mode of operation continues and thus produces a series of output pulses which are of short-time duration, separated by relatively long time intervals.

Circuit Operation. The following circuit schematic illustrates a PNP transistor in a basic free-running blocking oscillator circuit. (Note the similarity between the blocking oscillator circuit given here and the L-C tickler-Coil oscillator circuit given earlier in this section.



Free-Running PRF Generator Using PNP Transistor

Transformer T1 provides the necessary regenerative feedback coupling from the collector to the base of transistor Q1; terminals 1 and 2 of transformer T] connect to the collector (primary) winding, terminals 3 and 4 connect to the base (secondary) winding, and terminals 5 and 6 connect to the output (tertiary) winding. Capacitor Cl and resistor R1 form the R-C circuit which determines the time constant in the base-emitter circuit.

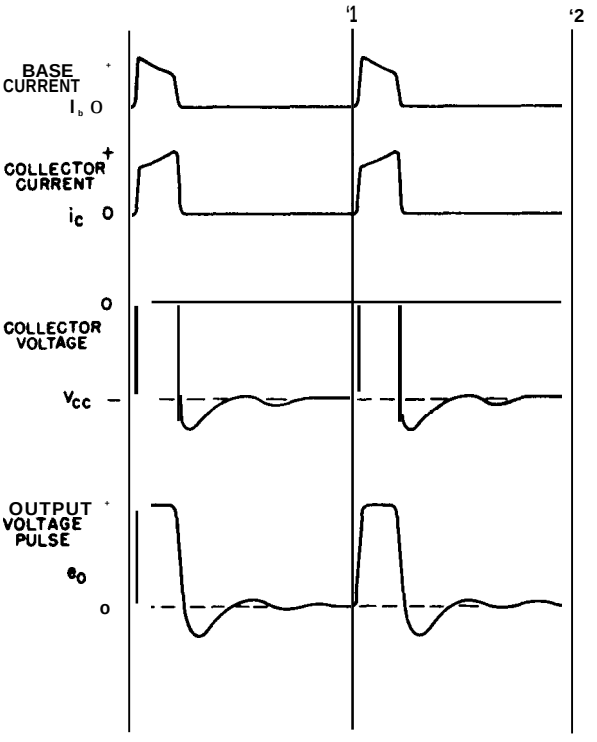
The output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer T1. Damping resistor R2 is connected across the tertiary winding to reduce the amplitude of the back voltage resulting from the collapse of the magnetic field about the transformer after the occurrence of the initial output pulse.

On the circuit schematic, note the placement of small dots near winding terminals 1,4, and 5 of transformer T1. These dots are used to indicate similar winding polarities. For example, if current flows through the collector winding and terminal 1 is positive, the voltage induced in each of the other windings is such that the dot end is also positive in each winding at the same time; therefore at this same instant of time, terminals 3 and 6 are negative.

Bias and stabilization techniques employed for a transistor oscillator are essentially the same as those employed for a transistor amplifier. The common-emitter circuit configuration illustrated utilizes a single-battery power source; this source directly produces the required reverse bias voltage in the collector-base circuit. Forward bias for the PNP transistor requires the base to be negative with respect to the emitter. Since the collector is at a negative potential and the emitter is at a positive potential, the two PN junctions within the transistor act as a voltage divider. The junction between collector and base represents a relatively high resistance and develops a large portion of the voltage drop. The junction between emitter and base represents a low resistance and develops a lower voltage drop. The base of the transistor is structurally between the collector and the emitter and assumes a potential which is between the two voltage extremes; therefore, the base can be considered to be less positive than the emitter, or negative with respect to the emitter. Thus, the correct polarity is established to produce a forward bias between the emitter and the base.

The blocking oscillator can be compared to an amplifier with feedback of the proper phase and amplitude to provide regeneration. In the accompanying circuit schematic a common-emitter configuration circuit schematic a common-emitter configuration is shown using a PNP transistor; the regenerative feedback signal must undergo a polarity reversal in passing from the collector to the base. If an NPN transistor is used, the polarity of the supply voltage must be opposite to that given on the schematic in order to maintain forward bias in the base-emitter circuit and reverse bias in the collector-base circuit; however, for either type of transistor the transformer must provide a polarity reversal when feedback is from collector to base.

For the discussion of circuit operation which follows, refer to the accompanying illustration of the blocking oscillator waveforms.



Theoretical Waveforms for Blocking Oscillator

When dc power is first applied to the circuit, a small amount of collector current, i_c, will start to flow through the collector winding (terminals 1 and 2) of transformer TI. The current flow in the collector winding induces a voltage in the base winding (terminals 3 and 4) which is negative with respect to ground. The induced voltage causes capacitor Cl to charge through the relatively low forward resistance of the base-emitter junction, and the induced voltage appears across the forward resistance to increase the forward bias. The increase in forward bias, in turn, increases the collector current, and regeneration continues rapidly until the transistor becomes saturated. During the essentially flat-top portion of the collector voltage waveform, the collector current, i_c, increases at a slower rate, as determined by the amount of magnetizing current necessary to maintain the voltage drop across the collector winding of transformer T1. Also during this period of time, the base curent, i_b, gradually falls off from its peak value as a result of the inability of the transistor to maintain the same rate of increase in magnetizing current as the transistor approaches saturation; further, at this same time a charge is accumulating on capacitor Cl which subtracts from the voltage supplied by the base winding of transformer T1. At saturation, the collector current, i_c, can no longer continue to increase, and thus becomes a constant value; therefore, there is no longer a voltage induced in the base winding, terminals 3 and 4. As a result, the magnetic field begins to collapse and induces a voltage across the winding which is of opposite polarity to the original voltage. At the same time, capacitor Cl starts to discharge through resistor R1 and the base winding (terminals 3 and 4). The discharge current of capacitor Cl produces a voltage drop across resistor RI which is of positive polarity at the base of the transistor, thereby driving the base in a positive direction to reduce the forward bias of the base-emitter junction. The reduction in forward bias causes the collector current, i_c, to decay rapidly, which further accelerates the process; thus reverse bias is rapidly achieved at the base-emitter junction. At this time the base and collector currents drop to zero.

Because of the reverse bias, the transistor remains held at cutoff until capacitor Cl discharges through resistor RI (and transformer Tl) to a point where the transistor returns to a forward-biased condition. When the forward-biased condition is reached, conduction begins and another cycle of operation is initiated.

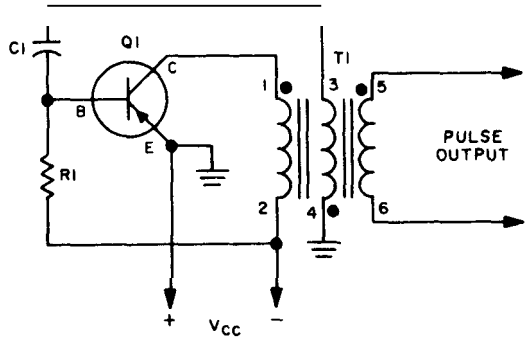
The output pulse width depends principally on the inductance of the transformer, T1. The smaller the inductance, the more rapidly the collector current must increase to maintain magnetizing current, and the faster the collector current will reach saturation. Normally, capacitor Cl has relatively little effect on the pulse width; however, if it is made small enough that it approaches a value where the capacitor charge can change appreciably during the pulse time, there will be a noticeable decrease in pulse duration (width). As the capacitor is made still smaller, the effect will be more pronounced and the pulse duration will be further reduced.

The repetition rate of the free-running blocking oscillator is determined by the time constant of resistor R1 and capacitor Cl. Although the resistance of the base winding (terminals 3 and 4) of the pulse transformer also has an effect upon the discharge time constant, the resistance of the winding is low compared to that of resistor RI.

The output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer T1. Damping resistor R2 is connected across the tertiary winding of the transformer to reduce the amplitude of the back voltage (or overshoot) which results from the collapse of the magnetic field about the transformer at the termination of the desired output pulse. If it were not for the damping resistor, the amplitude of the back-voltage pulse could exceed the breakdown voltage of the transistor and cause damage to the transistor. Several modifications can be made to the basic circuit to further reduce the amplitude or to eliminate the undesirable back voltage. One such modification is to connect a clamping diode across the collector winding (terminals 1 and 2) of the transformer as shown on the circuit schematic by the dotted lines connecting diode CR1. Similarly, a clamping diode can be connected across the output winding (terminals 5 and 6) as shown on the circuit schematic by the dotted lines connecting diode CR2, to accomplish the same purpose. In either case, the diode (CR] or CR2) is connected in the circuit to conduct whenever the back-voltage pulse occurs and to effectively place a short circuit across the associated transformer winding for the duration of the inducted back-voltage pulse; thus it prevents the application of an excessive voltage between the collector and emitter.

The accompanying circuit schematic illustrates a variation of the basic free-running prf generator. In this circuit resistor RI is returned to the negative terminal of the supply voltage, V_{cc}. Resistor R1 not only limits the base current and establishes the initial condition of forward-bias, but also operates in conjunction with capacitor Cl to determine the operating frequency of the blocking oscillator.

The circuit operation is essentially the same as that previously described.



Variation of Basic Free-Running PRF Generator

Failure Analysis.

No Output. Voltage measurements should be made with an electronic voltmeter to determine whether the input voltage is present and whether the correct bias voltages are applied to the collector and base of the transistor. It is possible that the base-emitter junction may change resistance and thereby change the forward bias on the base; such a condition may cause thermal runaway with subsequent damage to the transistor.

Any defect in transformer T1, such as an open collector or base winding or shorted turns in any of the windings, will prevent the circuit from operating properly, since oscillations depend upon regenerative feedback from the transformer. A shorted load impedance, reflected to the collector and base windings, may cause excessive losses which will prevent sustained oscillations. Note that if the output winding

should open, the circuit will continue to operate; however, no output will be obtained from the winding. Furthermore, if damping resistor R2 should open, the induced back-voltage could exceed the voltage breakdown of the collector-emitter junctions and result in damage to the transistor.

A shorted or open capacitor Cl will prevent oscillations, since the regenerative action of the circuit depends upon the charge and discharge of Cl. Also, if resistor R1 should open, the base-emitter current path will be broken and thereby prevent transistor operation.

Where the basic oscillator circuit illustrated has been modified to include a clamping diode (CR1 or CR2) across either the collector winding or the output winding, a defective diode with a low front-to-back ratio may cause circuit losses and prevent oscillation. Furthermore, if damping resistor R2 should decrease in value or if the load impedance should drop to an extremely low value, oscillations may not occur because of induced circuit losses.

Reduced Output. The input supply voltage should be measured with an electronic voltmeter to determine whether the input voltage is the correct value. Voltages at the collector and the base of the transistor should also be measured to determine whether they are within tolerances. Where the basic oscillator circuit illustrated has been modified to include a clamping diode across either the collector winding or the output winding, or across each winding, a defective diode with low front-to-back ratio can cause circuit losses which can reduce the output. Moreover, if either clamping resistor R2 or the load impedance should decrease in value, the output amplitude will decrease. Note that if the circuit losses are excessive, the circuit may not oscillate at all.

Incorrect Frequency. The pulse-repetition frequency of the free-running blocking oscillator is determined by the R-C time constant of resistor RI and capacitor Cl; any change in the values of these components will cause a change in operating frequency. Also, any change in the supply voltage will probably affect the pulse-repetition frequency and may affect the amplitude of the output pulse.

PARALLEL-TRIGGERED BLOCKING OSCILLATOR (ELECTRON TUBE)

Application.

The parallel-triggered blocking oscillator is used to produce short-time duration, large-amplitude pulses for use as synchronizing or trigger pulses in radar modulators and display indicators.

Characteristics.

Output pulse is a single cycle of oscillation caused by trigger-amplifier tube conduction which is, in turn, synchronized by a trigger pulse at the begiming of each pulse-repetition period. Some delay is introduced between the time of trigger application to the trigger amplifier and the development of the leading edge of the output pulse.

Pulse repetition time is determined by an external positive-trigger source in conjunction with the R-C time constant of the grid circuit. The pulse-repetition frequency is generally fixed within the range of 200 to 2000 pulses per second.

Trigger amplifier provides isolation and prevents blocking oscillator from reacting on trigger source; also, amplification of trigger pulse sharpens pulse somewhat.

Pulse width and rise time of the output pulse are determined primarily by the transformer characteristics.

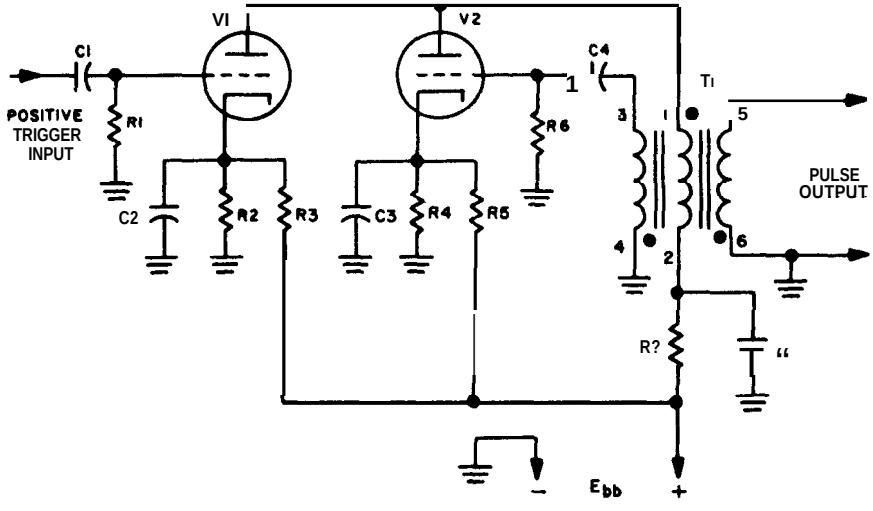
Output-pulse polarity is determined by the phasing of the transformer output-tertiary winding. With minor circuit changes, the output can also be taken from the cathode circuit (positive pulse) or from the plate circuit (negative pulse).

Circuit Analysis.

General. The parallel-triggered blocking oscillator is similar to the free-running prf generator except that its pulse-repetition frequency is determined by a positive synchronizing trigger pulse which is applied to a trigger amplifier. The plates of the trigger-amplifier tube and the blocking-oscillator tube are in parallel

and share a common plate winding of the blocking-oscillator transformer. When the trigger amplifier receives a pulse from an external source, it amplifies the pulse and causes current to flow in the plate winding of the transformer; thus, a cycle of oscillation is initiated. Upon completion of the pulse cycle, the circuit becomes inactive until the amplifier receives another trigger pulse. Normal operation of the parallel-triggered blocking oscillator results in the generation of an output pulse each time a trigger pulse is applied to the trigger amplifier.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a parallel-triggered blocking-oscillator circuit; one electron tube is the blocking oscillator and the other is the trigger amplifier. Although the schematic illustrates two separate triodes, VI and V2, a twin triode is frequently used in this circuit.

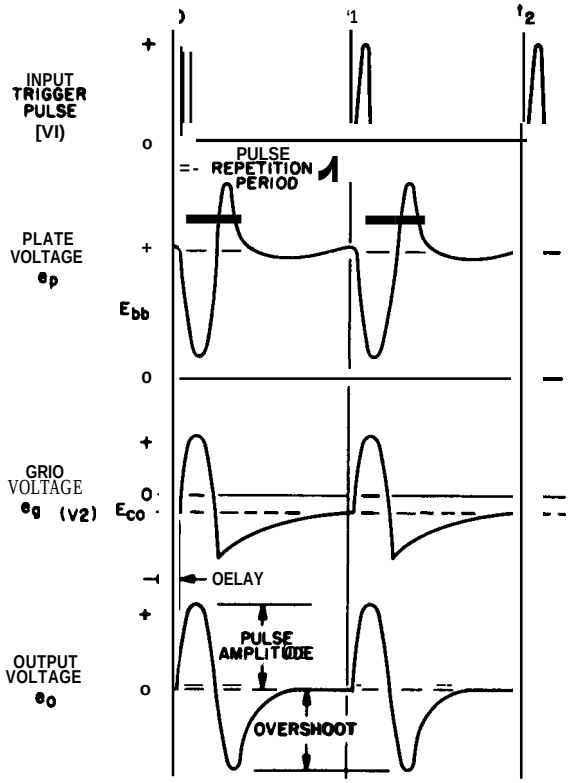


Parallel-Triggered Blocking Oscillator

Transformer TI provides the necessary coupling (inductive feedback) between plate and grid of electron tube V2; terminals 1 and 2 connect to the plate (primary) winding, which is common to bothVl and V2, terminals 3 and 4 connect to the grid (secondary) winding, and terminals 5 and 6 connect to the output (tertiary) winding. Capacitor Cl couples the input trigger pulse to the grid of V1; resistor RI is the grid-return resistor for V1. Resistors R2 and R3 form a voltage divider to provide cathode bias for the trigger-amplifier tube, V1; similarly, resistors R4 and R5 provide cathode bias for the blocking-oscillator tube, V2. Capacitors C2 and C3 are the cathode bypass capacitors for V1 and V2, respectively. Capacitor C4 and resistor R6 form an R-C circuit to determine the discharge time constant in the grid circuit of V2. Resistor R7 and capacitor C5 form a plate decoupling network.

The output pulse from the blocking oscillator is taken from the tertiary winding (terminals 5 and 6) of transformer TI.

For the following discussion of circuit operation, refer to the accompanying illustration which shows the input trigger and blocking-oscillator plate-signal, grid-signal, and output-voltage waveforms. Bias voltage for the trigger amplifier, V1, is developed by cathode resistor R2 as a result of the dc current through the series resistance of R2 and R3, connected as a voltage divider between the supply voltage and ground; also, bias is developed for the blocking oscillator, V2, by cathode resistor R4, which is in series with resistor R5 to form a similar voltage divider. The amount of bias developed by resistor R2 is sufficient to hold the grid of V1 near cutoff, whereas the bias developed by resistor R4 places the grid of V2 below cutoff.



Theoretical Trigger-, Plate-, Grid-, and Output-Voltage Waveforms

To start a single cycle of operation, a positive trigger pulse is applied to the input of trigger amplifier V1 across coupling capacitor Cl and grid-return resistor RI. The trigger pulse developed across resistor R1 is applied to the grid of VI and amplified by the trigger amplifier. As a result of the positive-going pulse on the grid of VI, the tube conducts and plate current flows through the plate winding (terminals 1 and 2) of the pulse transformer, TI. The voltage at the plates of V1 and V2 starts to drop as the current of the trigger amplifier increases in the plate winding; the increasing current through the plate winding sets up a magnetic field about the winding, and a voltage is induced (through transformer action) in the grid winding (terminals 3 and 4) of transformer TI. Since the trigger pulse is of short duration, the trigger amplifier returns to its initial condition at the end of the trigger pulse, and VI ceases to conduct because of the cathode bias developed by resistor R2. The blocking-oscillator action which follows is similar to that which occurs during one cycle of operation for the free-running (prf generator) blocking oscillator.

When trigger-amplifier plate current flows through the plate winding, a grid-signal voltage is produced across the grid winding and is impressed on the grid of V2 through coupling capacitor C4 to drive the grid of V2 in a positive direction. (See grid-voltage waveform.) This causes the blocking-oscillator tube to start to conduct when the positive grid voltage exceeds the value of cathode bias; the regenerative action (feedback) which occurs to complete the cycle of operation is essentially the same as the action previously described for the free-running (prf generator) blocking oscillator. Near the end of the cycle of operation and after the trigger-amplifier tube returns to cutoff, the grid of the blocking oscillator is driven below cutoff as the result of the highly negative charge existing on capacitor C4. (See grid-voltage waveform.) Capacitor C4 slowly discharges through resistor R6 and the grid winding of T1. The time constant of R6 and C4 is chosen so that the grid is held below cutoff for a considerable period of time; thus, the grid gradually approaches the initial value of bias, at which time the circuit is ready to be triggered to initiate another cycle of operation. (The initial value of bias developed across R4 is sufficient to keep the blocking-oscillator tube at or below cutoff.) Under the conditions of operation described above, the blocking oscillator produces an output pulse each time a trigger pulse is applied to the input of the trigger amplifier, VI. The output pulse is delayed slightly, but has the same repetition frequency as the synchronizing trigger pulse.

With minor modification to change the time constant of R6C4, the parallel-triggered blocking oscillator circuit may be used as a pulse-frequency divider to produce output pulses at a submultiple of the trigger-pulse frequency.

The output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer TI in the same manner as that previously described for the free-running (prf generator) blocking-oscillator circuit.

The parallel-triggered blocking oscillator is relatively insensitive to changes in filament and plate supply voltages. A change in plate voltage of 10 percent may reflect a change as great as 7 percent in pulse amplitude; however, there is little change in pulse width or rise time.

Failure Analysis.

No Output. It is important to establish that the cathode bias voltage developed by each voltage divider (R2, R3, and R4, R5) is correct for the trigger-amplifier and blocking-oscillator tubes, V1 and V2. Since the trigger-amplifier and blocking-oscillator tubes are normally biased at or below cutoff, it is also important to establish that a trigger pulse of correct polarity and amplitude is being supplied to the circuit. When the circuit is in a nonoscillating condition, assuming that the bias voltage is correct for both tubes, the voltage measured at the plates of V1 and V2 will approach the value of the supply voltage, provided that the plate winding of T1 and the decoupling filter (R7 and C5) are not defective. Any defect in the plate or grid windings of transformer T1 is likely to prevent the proper regenerative feedback from occurring; as a result, the circuit will not provide the proper output pulse or may not oscillate at all.

If the tertiary winding of transformer T1 should open, the circuit may still operate but no output will be obtained from the tertiary winding.

Unstable output. Whenever the output-puke repetition rate of the blocking oscillator becomes unstable or erratic, the trigger pulse should first be checked to determine whether the fault lies within the trigger-generator circuit. Since the stability of the blocking oscillator is dependent upon the repetition-frequency and pulse-amplitude stability of the trigger source, it is entirely possible that an unstable trigger applied to the trigger amplifier will cause the blocking oscillator to produce output pulses which are synchronized to the faulty trigger. The time constant of R6 and C4 must allow the grid of V2 to return the initial value of bias before the blocking oscillator is triggered ;.otherwise, the blocking oscillator may not respond reliably to the amplified trigger pulse. Random pulsing of the blocking oscillator can also result if the cathode bias (derived from resistors R4 and R5) is reduced and approaches zero bias. In this case, although the trigger pulse will frequently initiate an operating cycle, the oscillator may attempt to become free-running because of the lack of correct bias. Leakage in capacitor C4 will cause a change in the R-C time constant of the blocking oscillator, and will result in an unstable output which is usually accompanied by a decrease in pulse amplitude.

Low Output. Reduced plate-supply voltage will affect the amplitude (and perhaps the pulse width and rise time) of the output pulse. Also, if shorted turns should develop in the tertiary winding of T1 or if a decrease in load impedance should occur, the pulse-output amplitude will be reduced not only because of the change in load impedance but also because of the impedance reflected into the plate and grid windings of transformer T1. If the load impedance should fall considerably below the normal value for the circuit, an increase in time delay will occur between the trigger pulse and the start of the output pulse; also, the rise time of the output pulse will increase and will be accompanied by a decrease in pulse amplitude.

SERIES-TRIGGERED BLOCKING OSCILLATOR (ELECTRON TUBE)

Application.

The series-triggered blocking oscillator is used to produce short-time-duration, large-amplitude pulses for use as synchronizing or trigger pulses in radar modulators and display indicators.

Characteristics.

Output pulse is a single cycle of oscillation caused by tube conduction which is initiated by synchronizing trigger pulse at the beginning of each pulse-repetition period.

Pulse-repetition time is determined by an external positive-trigger source in conjunction with the R-C time constant of the grid circuit. The pulse-repetition frequency is generally fixed within the range of 200 to 2000 pulses per second, although the circuit can be arranged to change the R-C time constant and provide for operation at a submultiple of the trigger-pulse frequency; in this case, the triggered blocking oscillator operates as a pulse frequency divider.

Requires a low-impedance trigger source; there is considerable reaction on the trigger source even if a cathode follower is used for triggering the circuit.

Pulse width and rise time of the output pulse are determined primarily by the transformer characteristics.

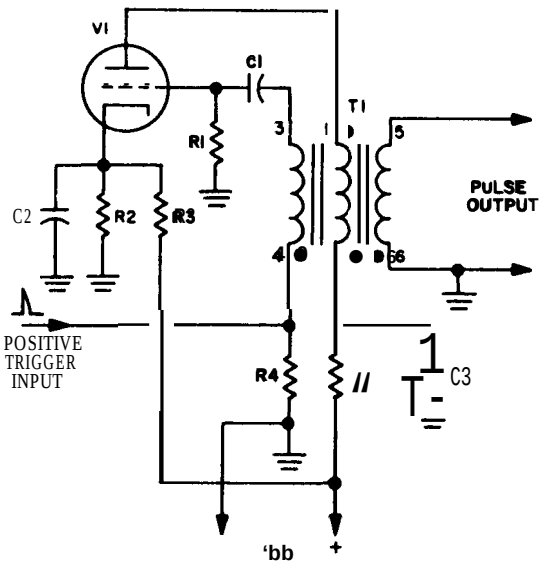
Output-pulse polarity is determined by the phasing of the transformer output-tertiary winding. With minor circuit changes, the output can also be taken from the cathode circuit.

Circuit Analysis.

General. The series-triggered blocking oscillator is similar to the free-running prf generator except that

its pulse-repetition frequency is determined by a positive synchronizing trigger pulse. When the oscillator is triggered by a pulse from an external source, it completes one cycle of operation to produce an output pulse and then becomes inactive; the cycle of operation is repeated upon application of another trigger pulse. Normal operation of the series-triggered blocking oscillator results in the generation of an output puke each time a trigger pulse is applied to the circuit.

Circuit Operation. The following circuit schematic illustrates a triode electron tube in a series-triggered blocking-oscillator circuit. Transformer T1 provides the necessary coupling (inductive feedback) between the plate and grid of electron tube V1; terminals 1 and 2 connect to the plate (primary) winding, terminals 3 and 4 connect to the grid (secondary) winding, and terminals 5 and 6 connect to the output

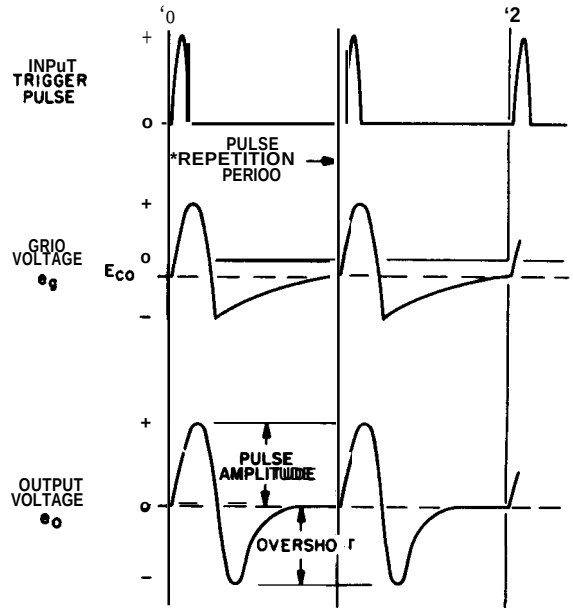


Series-Triggered Blocking Oscillator

(tertiary) winding. Capacitor Cl and resistor Rl, in conjunction with R4, form an R-C circuit to determine the discharge time constant in the grid circuit. Resistors R2 and R3 forma voltage divider to provide cathode bias for the tube; the voltage developed across R2 is sufficient to bias the tube at or below cutoff. Capacitor C2 is a cathode bypass capacitor. The synchronizing trigger pulse is applied across resistor R4, which is effectively in series with the grid signal. The value of resistor R4 is generally low; however as indicated previously, this resistance is a part of the total resistance which determines the R-C time constant of the circuit. Resistor R5 and capacitor C3 form a plate decoupling network.

The output pulse from the blocking oscillator is taken from the tertiary winding (terminals 5 and 6 of transformer T1.

For the brief discussion of circuit operation which follows, refer to the accompanying illustration which shows the blocking-oscillator-trigger, grid-signal, and output voltage waveforms.



Theoretical Trigger, Grid-Vcdtage, and Output-Voltage Waveforms

When voltage is first applied to the circuit, bias voltage for the tube is developed by cathode resistor R2 as a result of the dc current through the series resistance of R2 and R3 connected between the supply voltage and ground. The amount of bias developed is sufficient to hold the grid at or slightly below cutoff; thus, plate current does not flow at this time.

To start a single cycle of operation, a positive trigger pulse is applied across resistor R4. This pulse is applied through the grid winding of transformer T1 and capacitor Cl to the grid of V1, and raises the grid

voltage above cutoff. (The positive-going trigger pulse must be of sufficient amplitude to drive the grid out of the cutoff region to initiate the cycle.) At this time the tube starts to conduct, and the regenerative action which occurs during the cycle of operation is essentially the same as the action previously described for the free-running (prf generator) blocking oscillator. Near the end of the cycle, when the grid is driven below cutoff and plate current no longer flows through the plate winding of T1, the highly negative charge existing on capacitor Cl slowly discharges through resistors RI and R4 and the grid winding of transformer T]. Since the resistance of the grid winding is low in comparison with the combined resistance of R1 and R4, it has little effect on the discharge time of capacitor Cl. Furthermore, the resistance of R4 is low compared to that of Rl; therefore, RI has the predominant effect on the discharge time of capacitor Cl.

After an elapsed period of time, as governed by the time constant of R1, R4, and Cl, capacitor Cl discharges and allows the grid potential to reach a point near cutoff. When a positive trigger pulse is again applied across resistor R4, another cycle of operation is initiated.

If it were not for the periodic application of the positive trigger pulse to resistor R4, the blocking oscillator would remain cut off because of the value of cathode bias developed across cathode resistor R2. Under these conditions, each time a trigger pulse is applied to the circuit, a complete cycle of the blocking oscillator produces an output pulse which is in synchronism with the trigger pulse and has the same repetition frequency. For synchronization to occur the values of R and C must be chosen so that the natural oscillating frequency of the blocking oscillator, in the absence of cathode bias, is slightly lower than the repetition frequency of the synchronizing trigger pulse.

The operating frequency of the triggered blocking oscillator can be conveniently changed to a submultiple of the trigger frequency by switching R-C values to alter the time constant. For example, an additional resistance could be switched into the circuit in series with resistor RI to increase the R-C time constant. In this case, if the time constant were at least doubled, the oscillator would respond to every other trigger pulse and, therefore, the blocking-oscillator repetition frequency would be one-half that of the trigger source.

The output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer T1 in the same manner as previously described for the free-running (prf generator) blocking-oscillator circuit.

In a practical series-triggered blocking-oscillator circuit, resistor R4 may actually be the cathode resistor for a cathode-follower circuit. In this case, the trigger is applied to the grid of the cathode-follower electron tube, and resistor R4, across which the trigger pulse is developed, represents a low-impedance trigger source to the blocking-oscillator circuit.

The series-triggered blocking oscillator is relatively insensitive to changes in filament and plate-supply voltages, although a change in plate voltage of 10 percent may produce a change as great as 10 percent in pulse amplitude and maybe accompanied by some change in pulse width. However, this effect is reduced to some extent by the change in the bias voltage developed across resistor R2 whenever the plate-supply voltage changes.

Failure Analysis.

No Output. Since the oscillator is normally biased to cutoff, it is important that a trigger pulse of the correct polarity and amplitude be supplied to the oscillator circuit. When the circuit is in a nonoscillating condition, assuming that the developed cathode bias is normal, the voltage measured at the plate of V1 will approach the value of the supply voltage, provided that the plate winding of T1 and the decoupling filter (R5 and C3) are not defective. Any defect in the plate or grid windings of transformer T1 is likely to prevent the proper regenerative feedback from occurring; as a result, the circuit will not provide the proper output pulse or may not oscillate at all. If the tertiary winding of transformer Tl should open, the circuit may still operate but no output will be obtained from the tertiary winding.

Unstabla Output. Whenever the output-pulse repetition rate of the blocking oscillator becomes unstable or erratic, the trigger pulse whould first be checked to determine whether the fault lies within the trigger-generator circuit. Since the stability of the blocking oscillator is dependent upon the repetition-frequency and pulse-amplitude stability of the trigger source, it is entirely possible that an unstable trigger applied to the oscillator will cause the blocking oscillator to produce output pulses which are synchronized to the random triggering. Random pulsing of

the blocking oscillator can also result if the fixed bias (derived from resistors R2 and R3) should be reduced and approach zero bias. In this case, although the trigger pulse will frequently initiate an operating cycle, the oscillator may attempt to become free-running because of the lack of corect bias. Leakage in capacitor C 1 will cause a change in the R-C time constant of the blocking oscillator, and will result in an unstable output which is usually accompanied by a decrease in pulse amplitude.

Low Output. Reduced plate-supply voltage will affect the amplitude (and perhaps pulse width) of the output pulse. Also, if shorted turns should develop in the tertiary winding or if a decrease in load impedance should occur, the output will be reduced not only because of the change in load impedance but also because of the impedance reflected into the plate and grid windings of transformer T1.

TRIGGERED BLOCKING OSCILLATOR (SEMICONDUCTOR)

Application.

The basic triggered blocking oscillator is used to produce synchronized, large-amplitude pulses for use as timing, trigger, or control pulses in radar equipment, television sets, and similar electronic switching devices.

Characteristics.

Requires a negative input trigger pulse.

Output pulse is a single cycle of oscillation (positive and negative alternations).

Output-pulse-repetition frequency is determined by the input trigger frequency.

Output-pulse width and rise time are determined primarily by the transformer inductance, capacitance, and resistance characteristics.

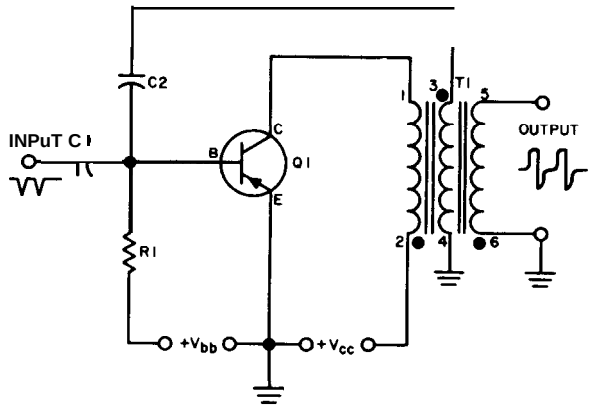
Output-pulse polarity is determined by the transformer output (tertiary) winding phasing.

Fixed, Class B (cutoff) bias is employed.

Circuit Analysis.

General. The basic blocking oscillator produces an output pulse each time an input pulse is applied to activate the circuit. Between trigger pulses, the transistor remains cut off (non-conducting), and no output is produced until an input trigger pulse of sufficient amplitude to produce conduction is again applied. The circuit produces one output pulse and then returns to the inactive (quiescent) state, awaiting the next trigger.

Circuit Operation. The accompanying circuit schematic illustrates a basic triggered blocking oscillator using a PNP transistor connected in the common-emitter configuration. Transformer T1 provides the regenerative feedback necessary between the collector and the base of transistor Q1 to obtain oscillation. The primary winding (terminals 1 and 2) is connected in series with collector supply V_{cc} and the collector of transistor Q1. The secondary winding (terminals 3 and 4) supplies the feedback voltage, which is applied to the base of transistor Q1 through capacitor C2. Capacitor C2 is also a dc blocking capacitor used to isolate the base from the dc shunting effect of the secondary winding of transformer T1, preventing it from shorting to ground the fixed cutoff bias applied to transistor Q1 through base resistor R1. The negative input trigger is applied through coupling capacitor Cl to the base of transistor Q1, and the output pulse is taken from the tertiary winding (terminals 5 and 6) of transformer T1.

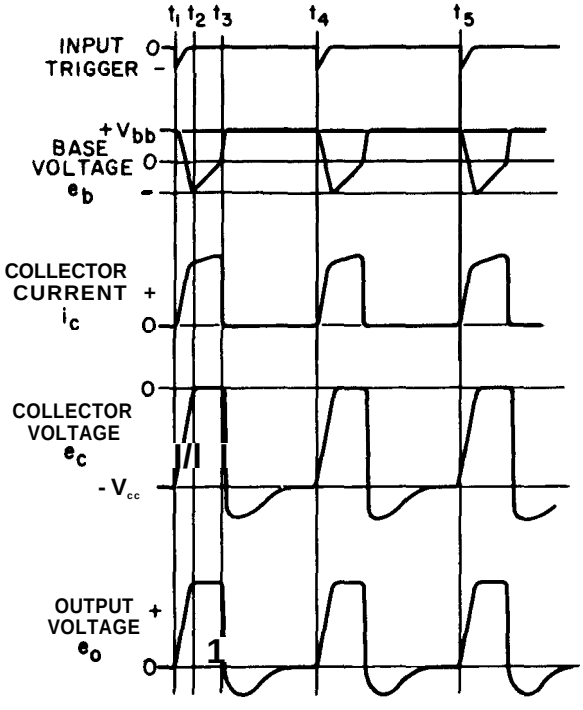


Basic Blocking Oscillator

The collector of transistor Q1 is reverse-biased by the negative collector supply, V_{cc}; the positive base bias supply, V_{BB}, furnishes fixed reverse bias to the base of transistor Q1 through base resistor R1. Thus, in the quiescent state with no input trigger applied, transistor Q1 is completely reverse-biased and cannot conduct. Hence, no output is produced.

When a negative trigger pulse, such as that shown at time t_1 on the accompanying waveform

illustration, is applied through coupling capacitor Cl to the base of transistor QI, it forward-biases



Theoretical Waveforms for Basic Blocking Oscillator

the transistor, causing collector current to flow. The collector current, flowing from the collector supply through the collector (primary) winding of transformer T1 to the transistor, causes a magnetic field to be built up around the collector (primary) winding of the transformer. This increasing magnetic field induces into the base winding of the transformer a voltage of such polarity that the potential on terminals 3 of the winding is negative with respect to ground (terminal 4). This negative potential is applied to the base of transistor Q1 (through capacitor C2), and increases the forward bias on the transistor, causing the collector current to increase further. As the collector current flowing through the collector winding of transformer T1 increases. The magnetic field around the winding increases accordingly, inducing a larger voltage into the base winding of the transformer. The increasing induced voltage is fed back to the base of transistor Q1, causing the forward bias on the transistor and hence the collector current, to increase still further. Thus, this regenerative feedback from the collector to the base of transistor Q1 causes the collector current to continue to increase until the transistor reaches saturation. When transistor Q1 reaches collector-current saturation (time t_2 on the waveform illustration), the collector current flowing through the collector winding of transformer T1 can no longer increase. Therefore, the magnetic field around the collector winding no longer increases; consequently, no feedback voltage is induced into the secondary (base) winding of the transformer. As a result, the voltage across the base winding of transformer T1 decays at a rate determined by the inductance, capacitance, and resistance values of the transformer, causing the negative voltage on the base of transistor Q1 to decrease accordingly. At the same time, the decreasing voltage across the base winding of transformer T1 also induces into the collector winding a voltage of such polarity that it aids (adds to) the collector-supply voltage, effectively increasing the value of the collector-supply voltage. The effectively increased collector-supply voltage raises the saturation point of the transistor; consequently, the collector current increases slightly above the previous saturation value. When the voltage across the base winding of transformer TI decays to zero (time t_2 on the waveform illustration), no further forward bias is applied through capacitor C2 to the base of transistor Ql, and the transistor ceases to conduct. Since no further forward bias is supplied, the base bias supply resumes control and applied a positive bias voltage through resistor RI to the base of transistor Ql, reverse-biasing the transistor and holding it below cutoff until the next trigger pulse is applied. Meanwhile, as the transistor decreases in conduction from saturation to cutoff (at time t_3) the collector curent flowing through the collector winding of transformer T1 decreases to zero, and the magnetic field around the winding collapses. This collapsing field induces into the collector winding a voltage of such polarity that it tends to keep current flowing in the same direction as the original current flow (that is, the induced voltage aids the collector-supply voltage). The result of adding these voltages is that the voltage on the collector of transistor Q1 momentarily becomes much more negative than the negative collector-supply value. This large negative voltage pulse is called overshoot (point

A on the collector-voltage waveform). As the magnetic field around the collector winding of transformer T1 collapses completely, the induced voltage (overshoot) also decreases to zero, and the collector voltage returns to the quiescent value.

Any change of current in the collector winding of transformer T1 also induces a changing voltage into the tertiary, or output, winding of the transformer. The polarity of the output pulse is determined by which terminal of the output winding is grounded. As shown in the circuit schematic, terminal 6 is grounded, and a positive output pulse results (a negative output pulse would be obtained if terminal 5 were grounded instead).

Failura Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of the standard 20,000 ohms-per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias applied through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A no-output condition maybe caused by an improper input trigger, a lack of supply voltage, or a defective circuit component. First, use an oscilloscope to observe the input trigger voltage waveform. Compare the observed waveform with one shown in the equipment instruction book to be certain that the proper input trigger is applied. Next, use a vacuum-tube voltmeter to measure the supply voltage and eliminate the possibility of a defective power supply. If the correct input trigger is applied and the normal supply voltage is present, further checks must be made to locate the defective component. Use an in-circuit capacitor checker to check capacitors Cl and C2 for opens and leakage, and an ohmmeter to check resistor R1 and transformer T1 for continuity and proper resistance vrdue. If these checks fail to locate a defective component, transistor Q1 is probably at fault.

Low or Distorted **Output. Low** supply voltage, a defective transistor (Ql), or a defective transformer (Tl j may cause either low-amplitude or distorted output pulses. Measure the supply voltage with a vacuum-tube voltmeter. If the normal value of voltage is measured, the trouble is in the blocking oscillator and not in the power supply.

FAST-RECOVERY BLOCKING OSCILLATOR (ELECTRON TUBE)

Application.

The fast-recovery blocking oscillator produces short-time-duration, large-amplitude pulses for use as timing, synchronizing, or trigger pulses in radar modulators and display indicators.

Characteristics.

Output is a single pulse caused by tube conduction and initiated by a trigger pulse at the beginning of each pulse repetition period.

Pulse repetition frequency is determined by an external trigger source.

Pulse repetition period is much shorter in the fast-recovery blocking oscillator than in other types of blocking oscillators.

Pulse width and rise time are determined primarily by the transformer characteristics.

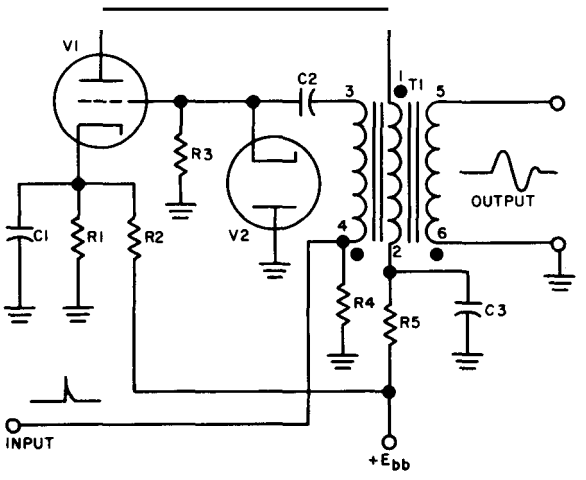
Output pulse polarity is determined by the phasing of the transformer output (tertiary) winding.

Circuit Analysis.

General. The fast-recovery blocking oscillator is similar to other types of triggered blocking oscillators in that, when triggered, it supplies one output pulse and then becomes inactive. In the normal triggered blocking oscillator, the grid voltage must be allowed to return to a point near cutoff before the circuit is triggered again. This period of time, called *recovery* time, is normally much longer than the pulse width and limits the pulse repetition frequency. The fast-recovery blocking oscillator uses a number of methods to overcome the difficulty of long recovery time.

Circuit Operation. The accompanying circuit schematic illustrates one type of fast-recovery blocking

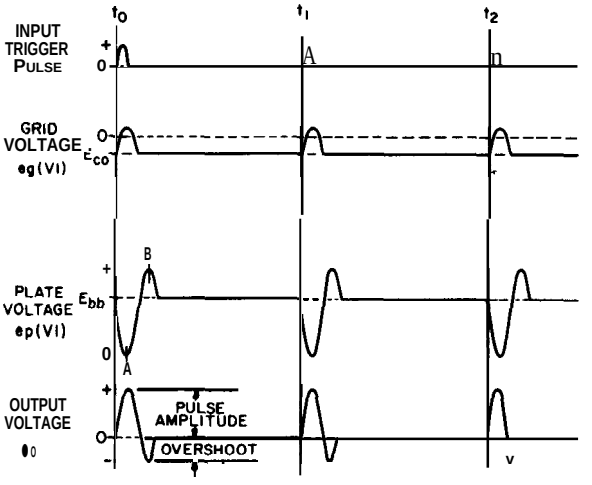
491-044 0- 73- 47



Fast-Recovery Blocking Oscillator

oscillator. With the exception of diode V2, it is identical to the series-triggered blocking oscillator discussed previously in this section of the Handbook. Transformer T] provides the necessary coupling (inductive feedback) between plate and grid of electron tube V1. Terminals 1 and 2 connect to the plate (primary) winding, terminals 3 and 4 connect to the grid (secondary) winding, and terminals 5 and 6 connect to the output (tertiary) winding. Resistors R1 and R2 form a voltage divider which provides cathode bias for triode V1. The voltage developed across cathode resistor R1 biases triode V1 to plate current cutoff. Capacitor Cl is the cathode bypass capacitor for triode V1, and resistor R3 is the grid return resistor. The positive trigger pulse is applied across resistor R4, which has a relatively low value of resistance. Grid capacitor C2 and resistors R3 and R4 normally determine the time constant of the grid circuit. However, when capacitor C2 discharges, diode V2 conducts, shunting grid resistor R3, and the discharge time for the circuit is greatly reduced. Resistor R5 and capacitor C3 forma conventional plate decoupling network. The output from the blocking oscillator is taken from the tertiary winding (terminals 5 and 6) of transformer T1.

The following illustration shows the trigger-, grid-, plate-, and output-voltage waveforms in their proper time relationship. When voltage is first applied to the circuit, dc current flows through voltage divider consisting ot resistor RI and R2. This current flow develops a bias voltage on the cathode of triode V1 which is sufficient to keep the tube biased to plate-current cutoff. Hence, no current flows in the-plate circuit.



Trigger-, Grid-, Plate-, and Output Voltage Waveforms

When a positive trigger pulse is applied to resistor R4, it passes through the grid winding of transformer T1 and is applied to grid capacitor C2. The positive potential on the transformer side of capacitor C2 causes an electron flow from ground through grid resistor R3 to the grid side of the capacitor. This current flow, which eventually charges the capacitor, develops a positive voltage across grid resistor R3 sufficient to raise the bias of triode V1 above cutoff and cause VI to conduct. As plate current increases and flows through the plate winding terminals 1 and 2) of transformer Tl, it produces a magnetic field around the winding. This increasing magnetic field induces a voltage into the grid winding of the transformer. The transformer phasing is such that the induced positive voltage increases the voltage across C2, causes more current to flow through grid resistor R3, increases the charge on grid capacitor C2, and drives the grid of V1 further positive. The increase in positive grid voltage, due to feedback, causes the plate current to increase still further. This regenerative action continues. That is a continual increase in grid voltage causes a continual increase in plate current which, in turn, causes a further increase in the grid

(feedback) voltage. Meanwhile, as the plate current rapidly increases toward plate-current saturation, the grid voltage becomes more positive until it reaches zero bias, and grid current flows, charging grid capacitor C2 to its maximum value.

When the plate-current saturation point is reached (point A on the plate-voltage waveform), current flow in the plate winding of transformer T1 no longer increases. Since there is no longer a changing magnetic field around the plate winding of the transformer, no further voltage is induced into the grid winding. Grid capacitor C2 is now fully charged, and since there is no longer a voltage across the grid winding of transformer T1 to sustain this charge, the capacitor begins to discharge. Normally, the capacitor would discharge through grid resistor R3, resistor R4, and the grid winding of the transformer. However, the negatively charged side of grid capacitor C2 is connected to the cathode of diode V2. This negative potential on the cathode of the diode makes it conduct, shunting grid resistor R3. Capacitor C2 now discharges through diode V2, resistor R4, and the grid winding of transformer T1. Since the high resistance of grid resistor R3 is shunted by diode V2 and effectively removed from the circuit, resistor R4 alone determines the discharge time constant of the circuit. Since the value of R4 is low, the time constant is short, and capacitor C2 discharges very quickly. When capacitor C2 discharges, the grid voltage level drops until it reaches the fixed cathode bias (determined by resistors RI and R2) which keeps the triode biased to cutoff, and plate current ceases.

As plate current stops flowing in the plate winding of transformer T1, the magnetic field around the winding collapses. The collapsing field induces into the plate winding a voltage of a polarity which tends to keep current flowing in the same direction. (That is, the polarity of the induced voltage is series-aiding with that of the plate-supply voltage.) The result of adding these voltages is a momentary increase in plate voltage over and above the plate-supply voltage, called overshoot (point B on the plate-voltage waveform). As the magnetic field around transformer T1 decreases in intensity, the induced voltage (overshoot) decreases accordingly, and the plate voltage quickly returns to the normal quiescent value.

Any changes of current in the primary winding of transformer T1 also induce a changing voltage into the tertiary, or output, winding (terminals 5 and 6). The polarity of the output pulse from this winding is determined by which terminal is comected to ground. As shown in the circuit schematic, terminal 6 is grounded. Therefore, in this case, a positive output pulse results (for a negative output it would be necessary to ground terminal 5 instead).

The fast-recovery blocking oscillator provides one output pulse each time a positive trigger pulse is applied. It is ready again almost immediately to receive another trigger pulse and produce another output pulse. Therefore, it is preferred for circuits operating at fast repetition rates.

Failure Analysis.

No Output. Since the oscillator depends on a positive trigger pulse to initiate operation, it is important to determine whether the input pulse is of the proper polarity and of sufficient amplitude to drive the grid of VI above cutoff. Use an oscilloscope to observe the input waveform. If the proper trigger pulses are present at the input, use the oscilloscope to observe the signal at the plate of VI. If pulses similar to those shown in the illustration of the plate-voltage waveform are observed, but still no output is obtained, the output (tertiary) winding of transformer T1 is either open or shorted. Use an ohmmeter to check the continuity of this winding; also check for a short to ground (indication of less than O.lohm). If no pulses are observed at the plate of V1, either no plate voltage is present or there is a defective feedback circuit or a defective cathode-bias circuit. Measure the voltage on the plate of V1 with a high-resistance voltmeter. If no voltage is measured at this point, a number of other possibilities exist: either an open in the plate winding of transformer TI, an open plate resistor R5, or a shorted bypass capacitor C3. Use an ohmmeter to check these components and isolate the trouble. If the proper voltage is measured at the plate of V1 but no plate pulses are seen on the oscilloscope, the trouble is in either the feedback of bias circuits. Use an ohmmeter to check for an open grid capacitor, C2, or for an open grid winding of transformer T1 to clear the feedback circuits. Then check for proper resistance values of resistors Rl, R2, R3, and R4 to clear the bias circuits. If these checks fail to locate the trouble, the tube is probably at fault.

Unstable Output. Since the output stability of the oscillator is dependent upon the input trigger pulse, it is important to be certain that the input trigger is of the proper amplitude and frequency. Use an oscilloscope to observe the input waveform. If the proper

input waveform is observed, the bias circuit or feedback circuit may be faulty. Use an ohmmeter to check capacitor C 1 for an open or a short, and to check bias resistors RI and R2 for proper resistance values. If these checks shown that the bias circuit is not defective, check the feedback circuit with an ohmmeter. First check grid capacitor C2 for a short, and then check resistors R3 and R4 for the proper resistance values. Also use the ohmmeter to check transformer T1 for continuity of the grid and plate windings, for shorts between the windings, and for shorts to ground (less than 1 ohm).

Low Output. Low output may be caused by weak emission in the triode, low plate-supply voltage, or excessive circuit loading. If substituting a good tube for triode V1 does not remedy the trouble, use a high-resistance voltmeter to measure the plate-supply voltage. If this voltage is low, the trouble is in the power supply. If the plate-supply voltage is normal, the transformer is probably defective.

NONSATURATING DIODE-CLAMPED BLOCKING OSCILLATOR (SEMICONDUCTOR)

Application.

The nonsaturating, diode-clamped blocking oscillator is used to produce synchronized, large-amplitude pulses for use as timing or synchronizing pulses in radar, communications, and data-processing equipment.

Characteristics.

Requires a negative input trigger pulse. Output is a single square pulse caused by transistor conduction.

Output-pulse repetition frequency is determined by the input trigger frequency.

Output-pulse width and rise time are determined primarily by the transformer inductance, capacitance, and resistance characteristics.

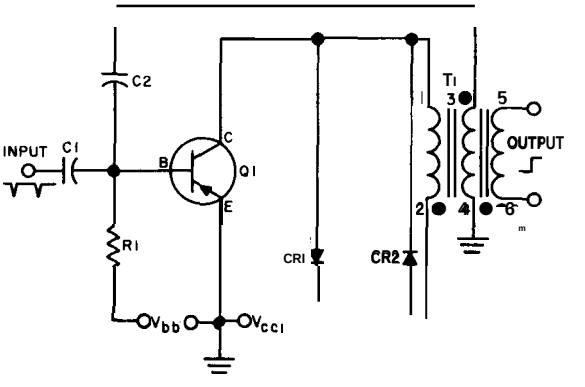
Output-pulse polarity is determined by the transformer output (tertiary) winding phasing.

Fixed, class B (cutoff) bias is employed.

Circuit Analysis.

General. The nonsaturating, diode-clamped blocking oscillator produces one output puke each time a trigger pulse is applied to activate the circuit. Between trigger pulses the circuit remains in the inactive (quiescent) state, and no output is produced. The operation of the onosaturating, diode-clamped blocking oscillator is similar to that of other types of blocking oscillators except that in this circuit, diode clamping is employed to prevent transistor saturation and to eliminate the normal overshoot which is present in the output of other types of blocking oscillators.

Circuit Operation. The accompanying circuit schematic illustrates a nonsaturating, diode-clamped blocking oscillator using a PNP transistor connected in the common-emitter configuration. Transformer T1 provides the regenerative feedback necessary between the collector and the base of transistor Q1 to obtain oscillation. The primary winding (terminals 1 and 2) is connected in series with the collector supply (made Up of V_{CC1} and V_{CC2}) and the collector of transistor Q1. The secondary winding (terminals 3 and 4) is connected from ground to the base of transistor QI through dc blocking capacitor C2. This capacitor prevents the base (secondary) winding of the transformer from acting as a dc shunt to ground for the fixed cutoff bias applied to transistor Q1 through base resistor R1. Clamping diodes CR1 and CR2 limit the collector voltage swing, and prevent transistor saturation and overshoot in the output pulse. The negative input trigger is applied through coupling capacitor C 1 to the base of transistor Ql, and the output pulse is taken from the tertiary or output winding (terminals 5 and 6) of transformer T1.

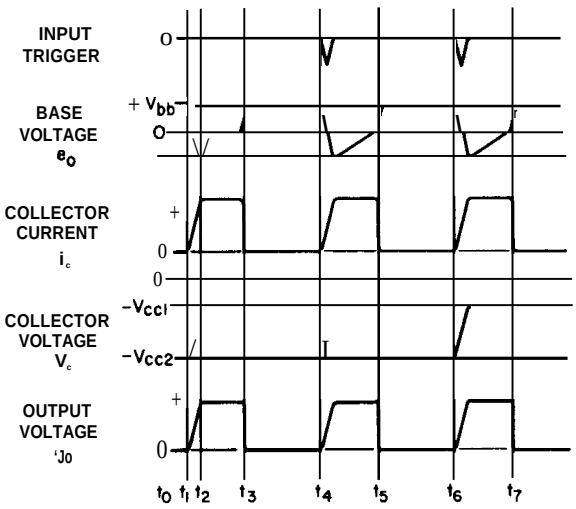


Nonsaturating, Diode-Clamped Blocking Oscillator

The collector of transistor Q1 is reverse-biased by the combined negative voltage of V_{CC1} and V_{CC2}.

The base of transistor Q1 is reverse-biased by the positive voltage applied from the bias supply (V_{BB}) through base resistor R1. Thus, in the quiescent state with no input applied transistor Q1 is completely reverse-biased and cannot conduct. Diode CR1 is reverse-biased by V_{CC2}, which is connected across the diode through the collector (primary) winding of transformer Tl, diode CR2 has no bias applied because there is no current flow through the collector winding of transformer T1, and hence no voltage drop occurs it to bias diode CR2. Consequently, neither diode conducts while the circuit is in the quiescent state.

When a negative trigger pulse (such as that shown at time t_1 on the accompanying waveform illustration) is applied through coupling capacitor Cl to the base of transistor Ql, it forward-biases the transistor, causing collector current to begin to flow.



Theoretical Waveforms for Nonsaturating, Diode-Clamped Blocking Oscillator

The collector **current flowing from** V_{CC2} **through** the collector winding of transformer T1 to the transistor causes a magnetic field to be built up around the collector winding. The increasing magnetic field induces into the base winding of the transformer a voltage of such polarity that the potential on terminal 3 of the winding is negative with respect to ground (terminal 4). This negative potential is applied **through** capacitor C2 to the base of transistor Ql; it increases the forward bias on the transistor and causes the collector current to further increase. As the collector current flowing through the primary (collector) winding of transformer T1 increases, the magnetic field around the winding increases accordingly and induces a larger voltage into the base winding of the transformer. This increasing induced voltage is fed back to the base of transistor Q1, increasing the forward bias and causing the collector current to increase still further. Thus, the regenerative feedback from the collector to the base of transistor Q1 causes the collector current to continue to increase once the input trigger puke starts current flowing. As the collector current increases the voltage on the collector of transistor Q1 decreases from the negative (cutoff) value of V_{CC2} to the less negative value of V_{ccl} (time t_2 on the waveform illustration). When the collector voltage becomes less negative than the value of V_{ccl} diode CR1 becomes forward-biased and conducts. Since the forward-biased (conducting) diode has a very low resistance, the voltage drop across it is negligible and the voltage on the collector of transistor Q1 is held equal to the negative value of V_{ccl}. Thus, diode CR1 *clamps* the collector voltage to the negative **value** of V_{ccl}; in other words, it prevents the collector voltage from becoming less negative (more positive) than V_{ccl}. Consequently, the collector current flowing through the collector winding of transformer T1, increases, as a result of the regenerative feedback, until the collector voltage drops to the value of V_{ccl}. At this time, diode CR1 begins to conduct and shunts any additional collector current flow around the collector winding of the transformer. Since there is no longer an increasing current flow in the collector winding of transformer T1, the magnetic field around the winding ceases to increase and no further voltage is induced into the base winding. Since no further induced voltage is present, the voltage across the base winding of transformer T1 decays at a rate determined by the inductance, capacitance, and resistance values of the transformer. When the voltage across the base winding of the transformer decays to zero (time t_3 on the waveform illustration), no further forward bias is applied to the base of transistor Q1 and the transistor ceases to conduct. The base bias supply (V_{BB}) again furnishes reverse bias to the base of transistor Q1 to hold the transistor or below cutoff until the next input trigger is applied. Meanwhile, as the collector current flow through the collector winding of transformer T1 decreases to

zero, the magnetic field around the winding collapses; this induces into the collector winding a voltage of such polarity that it tends to keep current flowing in the direction of the original collector current flow. The induced voltage forward-biases diode CR2, and the diode conducts, allowing the induced current to flow through it. Thus, diode CR2 effectively shorts out the voltage induced into the collector winding of transformer T1, and prevents it from having any effect on the remainder of the circuit. Consequently, as the collector current decreases from maximum to zero, the collector voltage increases in the negative direction from the negative value of V_{cc1} to the more negative value of V_{CC2}, and the circuit returns to the quiescent state.

Any change in current in the collector winding of transformer T1 also induces a changing voltage into the tertiary, or output, winding of the transformer. The polarity of this output voltage is determined by grounding the proper terminal of the output winding. As shown in the circuit schematic, terminal 6 is grounded. Therefore, in this case, a positive output pulse results (for a negative output pulse, terminal 5 is grounded instead).

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of the standard 20,000-ohms-per-volt meter. Be careful to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** A no-output condition maybe caused by an improper input trigger, a lack of supply voltage, or a defective circuit component. First, use an oscilloscope to observe the input trigger voltage waveform, and compare it with the one shown in the equipment instruction book to determine whether the proper input trigger is applied. Next, use a vacuum-tube voltmeter to measure the supply voltage and eliminate the possibility of a defective power supply. If the proper input trigger is applied and the normal supply voltage is present, further checks must be made to locate the defective circuit component. Use an in-circuit capacitor checker to check capacitors Cl and C2 for open circuits and leakage. Use an ohmmeter to check resistor R1 and transformer T1 for continuity and proper resistance value. Also use the ohmmeter as a diode tester, to check the forward and reverse resistance of diodes CR1 and CR2.

Low or Distorted Output. Low supply voltage, a defective diode (CR1 or CR2), a defective transistor (Q1) or a faulty transformer (Tl) may cause either low-amplitude or distroted output pulses. Measure the supply voltage with a vacuum-tube voltmeter to be certain that the power supply is not at fault. If the normal supply voltage is present, use an ohmmeter or diode tester to check diodes CR1 and CR2 for an adequate front-to-back ratio. If neither diode is defective, the fault is probably in either transistor Q1 or transformer T1.

PULSE-FREQUENCY DIVIDER (ELECTRON TUBE)

Application.

The pulse-frequency divider is used to produce high-amplitude pulses at a submultiple of the input trigger pulse frequency for use as timing or synchronizing pulses in radar and communications equipment.

Characteristics.

Output pulse frequency is a submultiple of the input pulse frequency.

Frequency-division ratio can be adjusted within a small range.

Requires a high-impedance trigger source which produces positive trigger pulses.

Output pulse width and rise time are determined primarily by the transformer characteristics.

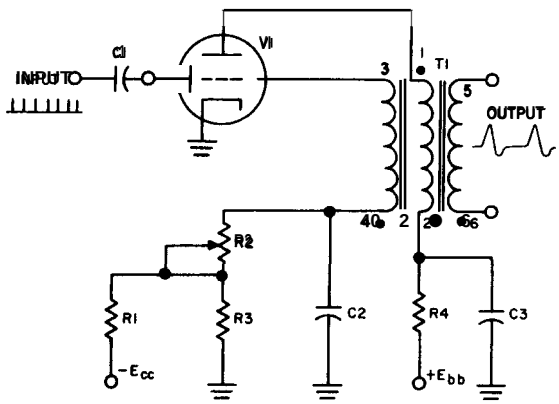
Output pulse polarity is determined by the phasing of the transformer output (tertiary) winding.

Circuit Analysis.

General. The operation of the pulse-frequency divider is similar to that of other types of triggered blocking oscillators. However, the pulse-frequency divider is designed so that, instead of producing output pulses at the same frequency as the input pulse frequency, it produces output pulses at a frequency which is only a fraction of the input pulse frequency. In other words, the circuit divides the input pulse frequency down to a lower frequency. The ratio of the input pulse frequency to the output pulse frequency is called the division ratio. Although pulse-frequency divider circuits have been designed with

division ratios as high as 100:1, a low division ratio (less than 6:1) gives the best stability. Consequently, most pulse-frequency dividers are designed to operate at low division ratios.

Circuit Operation. The accompanying circuit schematic illustrates a pulse-frequency divider with a division ratio that can be adjusted between 2:1 and

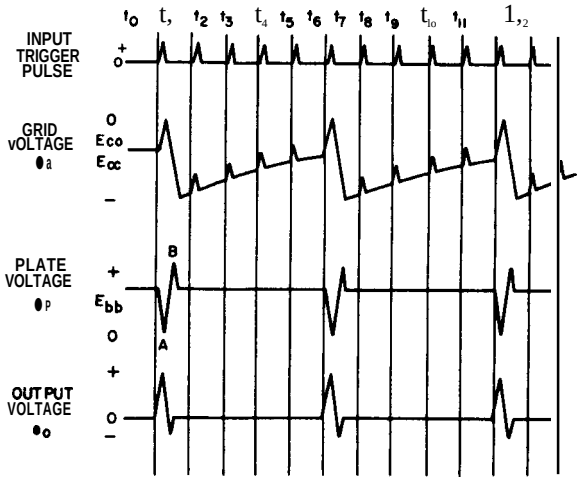


Pulse-Frequency Divider

5:1. Transformer T1 provides the coupling (inductive feed-back) between the plate and the grid of triode V1. Terminals 1 and 2 connect to the plate (primary) winding, terminals 3 and 4 comect to the grid (secondary) winding, and terminals 5 and 6 comect to the output (tertiary) winding. The positive trigger pulses are applied through coupling capacitor Cl to the grid of triode VI. Capacitor C2 and resistors R2 and R3 make up the grid R-C circuit. Resistor R2 is variable and allows the time constant of this R-C circuit to be adjusted for the desired division ratio. Resistors RI and R3 form a voltage-divider network which supplies fixed grid bias voltage for triode V1. Resistor R4 and capacitor C3 form a conventional plate decoupling network.

The following illustration shows the trigger-, grid-, plate-, and output-voltage waveforms in their proper time relationship.

In the quiescent condition (with no trigger pulse applied), VI is held at plate-current cutoff by the fixed negative bias taken from the voltage divider made up of resistors R1 and R3, and applied through grid resistor R2 and the grid winding of transformer T1 to the grid of V1 (time t. on the waveform illustration).



Trigger-, Grid-, Plate-, and Output-Voltege Waveforms

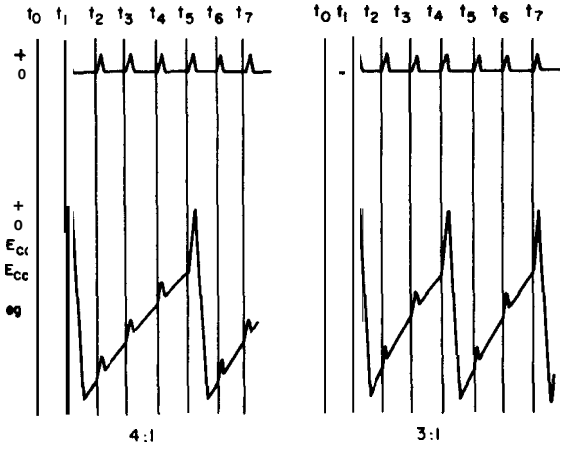
When the first positive trigger pulse is applied to the grid of triode V1 through coupling capacitor Cl, it drives the grid above cutoff and causes the tube to conduct (time t_1 on the waveform illustration). The increasing plate current flowing through the plate winding (terminals 1 and 2) of transformer T1 produces a magnetic field in the transformer. The changing magnetic field induces a feedback voltage into the grid winding of transformer T1. The transformer phasing the polarity are such that the induced feedback voltage drives the grid of triode VI more positive, and the plate of capacitor C2 which is connected to the negative end of the grid winding more negative. Thus, the induced feedback voltage causes two things to occur simultaneously: the capacitor charges to a higher potential, and the tube is biased more positive. The increased positive bias causes the plate current of triode V1 to increase further. The increasing plate-current flow through the plate winding of transformer T1 causes the magnetic field in the transformer to increase accordingly, and induces a still larger voltage into the grid winding of

transformer T1. This continuous increase in feedback voltage, grid voltage, and plate current produces a regenerative-feedback action which quickly drives the tube toward plate-current saturation. As the grid of triode V1 is driven more and more positive, grid current eventually begins to flow. The flow of grid current through the grid winding of transformer T1 to capacitor C2 causes the capacitor to quickly charge to its maximum negative value.

When plate-current saturation is reached (point A on the plate-voltage waveform), the plate current can no longer increase. Consequently, the magnetic field in transformer T1 no longer increases, and no feedback voltage is now induced into the grid winding. The grid of triode VI is therefore driven negative by the large negative charge on capacitor C2. This negative grid voltage causes the triode plate current to decrease. As the plate current through the plate winding of transformer T1 decreases, the magnetic field in the transformer decreases accordingly, inducing a feedback voltage of opposite polarity into the grid winding of the transformer. This induced feedback voltage drives the grid of triode V1 further negative, increasing the negative grid bias, and causing plate< urrent flow through the plate winding of transformer T1 to decrease still further. As previously explained, the regenerative feedback from the plate to the grid of triode V1 produces a continuous cycle which causes the grid to be driven far below cutoff. As plate-current occurs, the plate current ceases to flow, and the magnetic field in the transformer collapses. The collapsing magnetic field induces into the plate winding of transformer T1 a voltage os such polarity that it tends to keep current flowing in the same direction as the original plate-current flow (that is, the induced voltage is series-aiding with the plate-supply voltage). The result of adding these voltages is a momentary increase in plate voltage over and above the plate-supply voltage, called overshoot (point B on the plate-voltage waveform). As the magnetic field decreases to zero, the induced voltage (overshoot) decreases accordingly, and the plate voltage returns to the normal, quiescent value.

When plate current ceases, the charge on capacitor C2 is no longer sustained, and the capacitor discharges through resistors R2 and R3 towards the negative fixed-bias value. Since the time constant of this R-C circuit is very large, capacitor C2 discharges very slowly, and its potential decreases only a small amount by the time the plate pulse and overshoot are completed. The discharge time of the circuit is, in fact, many times longer than the input pulse repetition period. Consequently, the next input trigger pulse (time t_2 on the waveform illustration) occurs while capacitor C2 is still discharging and reducing the bias towards the fixed cutoff bias value. This positive trigger pulse (number 2), when combined with the negative grid voltage remaining on capacitor C2, is not of sufficient amplitude to raise the grid of triode V1 above cutoff. Therefore, trigger pulse number 2 has no effect on the operation of the circuit, and triode VI remains cut off with capacitor C2 still discharging. The same result occurs during the next three input trigger pulses (times t_3, t_4, and t_5 on the waveform illustration). However, when the next input trigger pulse (time t_6 on the waveform illustration) occurs, capacitor C2 is now discharged to nearly the fixed negative bias voltage across resistor R3 (cutoff bias). Therefore, when trigger pulse number 6 is combined with the negative grid voltage remaining on capacitor C2, the resulting pulse is of sufficient amplitude to again drive the grid of triode V1 above cutoff and cause the tube to conduct. Thus, the sixth trigger pulse causes the circuit to begin another cycle of operation. The pulse-frequency divider produces an output pulse as previously explained, and then remains inactive for the next four input trigger pulses. It produces an output pulse for every fifth input pulse. Therefore, the circuit is said to have a division ratio of 5: 1.

The division ratio of the pulse-frequency divider is entirely dependent upon the discharge time of capacitor C2, which is determined by the time constant of the grid R-C circuit. Resistor R2 is made variable so that the time constant of the R-C circuit can be adjusted for the desired output frequency. If the value of resistor R2 is decreased, the time constant of the R-C circuit decreases and capacitor C2 discharges more quickly. Thus by proper adjustment of resistor R2, the circuit will operate on every fourth input trigger pulse, giving a division ratio of 4:1. As the value of resistor R2 is decreased still further, the division ratio decreases accordingly. The following illustration shows the trigger- and grid- voltage waveforms for two different frequency-division ratios.



Trigger- and Grid- Voltage Waveforms for Two Settings of Resistor R2

Failure Analysis.

General. Since the output signal of the pulse-frequency divider is dependent upon the input signal, it is important to be certain that the proper trigger pulses are applied. If the proper input trigger pulses are not applied, the output from the circuit, if present at all, will be unstable or of the wrong frequency. Therefore, the first step in trouble-shooting this circuit is to use an oscilloscope to observe the input waveform, and compare it with the waveform shown in the equipment instruction book to be certain that it si of the proper polarity, amplitude, and frequency.

No **Output.** In addition to an improper input signrd, a no-output condition may be caused by a lack of plate-supply voltage, a fault in the grid circuit, a fault in the plate circuit, a defective tube, or an open output winding of transformer T1. After checking the input signal with an oscilloscope (as explained in the previous paragraph), use the oscilloscope to observe the waveform at the grid of triode V1. If no signal appears at this point, capacitor Cl is open and must be replaced. If the proper grid-voltage waveform is observed, use the oscilloscope to observe the waveform on the plate of triode VI. A proper plate-voltage waveform indicates that the output winding of transformer T1 is defective. If no signal is observed on the plate of triode V1, voltage and resistance checks must be made to isolate the defective component. Use a high-resistance voltmeter to measure the plate-supply voltage and determine whether the power supply is at fault. Next, use the voltmeter to measure the voltage on the plate of triode V1. If no plate voltage is present, plate circuit components T1 (primary winding), C3, or R4 are either open or shorted. Use an ohmmeter to check continuity and resistance, and isolate the defective component. If the proper plate voltage is present, either the tube is defective, transformer T1 (secondary winding) is open, resistors RI, R2, or R3 are open, or capacitors Cl or C2 are shorted. Use an ohmmeter to isolate the defective component.

Improper Division Ratio or Unstable Output. An improper input signal, an improper bias-supply voltage, a defective tube, an open or shorted grid circuit, or a defective transformer, T1, may cause either an improper division ratio or an unstable output. After checking the input signal with an oscilloscope (as explained previously), use a high-resistance voltmeter to measure the bias-supply voltage. If the bias-supply voltage is correct, the trouble is in the divider circuit and not in the power supply. Use an ohmmeter to check the grid circuit of the divider for open or shorted components (C 1, C2, R1, R2, R3). Triode VI may also be at fault. Replace the tube with one known to be good, and if this still does not correct the trouble, transformer TI is probable shorted.

Low Output. A low output may be caused by three conditions: low plate voltage, low tube emission, or excessive circuit loading. Use a high-resistance voltmeter to measure the plate-supply voltage and eliminate the possibility of a faulty power supply. Since defects in capacitor C3 or resistor R4 may also cause low plate voltage, use an ohmmeter to check these components. The low output may also be caused by low emission in triode VI. If replacing the tube with a good one does not correct the trouble, the low output may be caused by excessive circuit loading. Such a dondition may be caused by shorted turns in transformer T1.

DISTANCE-MARK DIVIDER (ELECTRON TUBE)

Application.

The distance-mark divider is used to produce short time duration pulses at a submultiple of the input trigger frequency for use as distance marks in radar display indicators.

Characteristics.

Produces output pulses at a submultiple of the input trigger pulse frequency.

Requires a low-impedance trigger source which produces positive trigger pulses.

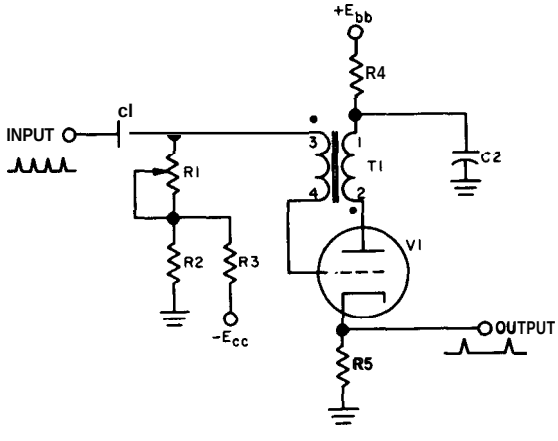
Output consists of positive pulses taken from the cathode of the tube.

Output pulse width and rise time are determined primarily by the transformer characteristics.

Circuit Analysis.

General. The distance-mark divider is a specific application of the pulse-frequency divider discussed earlier in this section of the Handbook. Like the pulse-frequency divider, the distance-mark divider produces output pulses at a submultiple of the input pulse frequency. That is, it divides the input pulse frequency down to a lower frequency. The ratio of input pulse frequency to output pulse frequency is called the diviswn ratw of the circuit. While the division ratio of many pulse-frequency divider circuits is adjustable within a small range, the division ratio of the distance-mark divider is normally freed (usually 2:1 or 3:1). In this way, the circuit can be designed to give the desired characteristics in the output pulse. Moreover, taking the output from the cathode of the tube also helps to produce the desired output pulse shape and eliminates the overshoot present in other types of blocking oscillators.

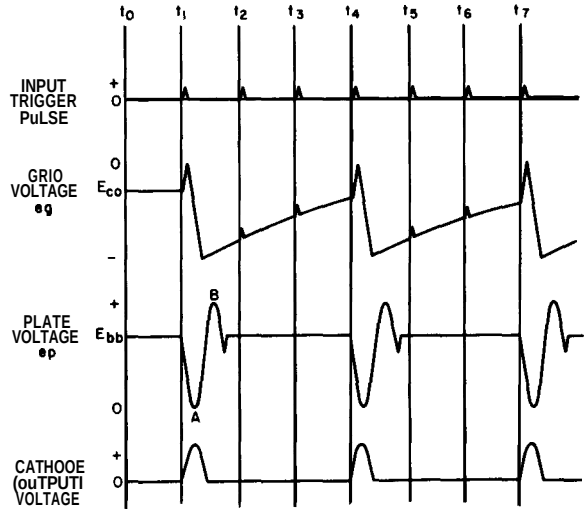
Circuit Operation. The accompanying circuit schematic illustrates a distance-mark divider with a division ratio of 3: 1.



Distana?-Mark Divider

Transformer T1 provides the coupling (inductive feedback) between the plate and the grid of triode V1. Terminals 1 and 2 connect to the plate (primary) winding, and terminals 3 and 4 connect to the grid (secondary) winding. The input trigger pulses are applied through grid capacitor Cl and the grid winding of transformer T1 to the grid of triode VI. The division ratio of the distance-mark divider is determined by the R-C circuit made up of capacitor Cl and resistors R1 and R2. Resistor RI is variable and allows the circuit to be adjusted to compensate for variations in component values, supply voltages, and input trigger pulse amplitude. Resistors R2 and R3 form a voltage divider which provides fixed negative grid bias for triode V1. Resistor R4 and capacitor C2 form a conventional plate decoupling network. The output is taken across resistor R5, which is the cathode resistor for triode V1.

The following illustration shows trigger-, grid-, plate and cathode-voltage waveforms in their proper time relationship.



Trigger-, Grid-, Plate-, and Cathode-Voltage Waveforms

In the quiescent condition (with no trigger pulse applied), triode V1 is held at plate-current cutoff by the fixed negative bias taken from the voltage divider made up of resistors R2 and R3, and applied through grid resistor RI and the grid winding of transformer T1 to the grid of VI (time t. on the waveform illustration).

When the first positive trigger pulse is applied through grid capacitor Cl and the grid winding of transformer T1 to the grid of triode Vl, it drives the grid above cutoff and causes the tube to conduct (time t_1 on the waveform illustration). The increasing current flowing through the plate winding of transformer T1 produces a magnetic field in the transformer. The changing magnetic filed induces a feedback voltage into the grid winding of transformer T1. The transformer phasing and polarity are such that the induced feedback voltage drives the grid of triode V1 more positive and the plate of capacitor Cl which is connected to the negative end of the grid winding more negative. Thus, the induced feedback voltage causes two things to occur simultaneously: the capacitor charges to a higher potential, and the tube is biased more positive. The increased positive bias causes the plate current of triode V1 to increase further. The increasing plate current flow through the plate winding of transformer T1 causes the magnetic field in the transformer to increase accordingly, and induce a still larger voltage into the grid winding. This continuous increase in feedback voltage, grid voltage, and plate current produces a regenerative feedback action which quickly drives the tube toward plate current saturation. As the grid of triode V1 is driven more and positive, grid current eventually begins to flow. The flow of grid current through the grid winding of transformer T1 to capacitor C 1 causes the capacitor to quickly charge to its maximum negative value.

When plate-current saturation is reached (point A on the plate-voltage waveform), the plate current can no longer increase. Consequently, the magnetic field in transformer T1 no longer increases, and no feedback voltage is now induced into the grid winding. The grid of triode V1 is therefore driven negative by the large negative charge on capacitor Cl. This negative grid voltage, and the positive cathode voltage caused by current flow through cathode resistor R5, cause the triode plate current to decrease. As the plate current through the plate winding of transformer T1 decreases, the magnetic field in the transformer decreases accordingly, inducing a feedback voltage of opposite polarity into the grid winding of the transformer. This induced feedback voltage drives the grid of triode V1 further negative, increasing the negative grid bias, and causing plate-current flow through the plate winding of transformer T1 to decrease still further. As previously explained, the regenerative feedback from the plate to the grid of triode V1 produces a continuous cycle of operation which causes the grid to be driven far below cutoff. As plate-current cutoff occurs, the plate current ceases to flow and the magnetic field in the transformer collapses. The collapsing field induces a momentary surge of voltage called overshoot, into the plate winding of transformer T1 (point B on the plate-voltage waveform). However, since tiode V1 is cut off, no current can flow through cathode resistor R5, and the overshoot is not present in the output.

When plate current ceases to flow, the charge on capacitor Cl is no longer sustained, and the capacitor discharges through resistors R1 and R2 twoard the fixed negative bias value. The time constant of this R-C circuit is very large, and the discharge time of capacitor C 1 is many times longer than the input trigger pulse repetition period. Consequently, the next input trigger pulse (time t_2 on the waveform illustration) occurs while capacitor Cl is still discharging and reducing the bias toward the fixed cutoff bias balue. This positive trigger pulse (number 2), when combined with the negative grid voltage remaining on capacitor C 1, is not of sufficient amplitude to raise the grid voltage of triode V1 above cutoff. Therefore, trigger pulse number 2 has no effect on the operation of the circuit, and triode V1 remains cut off with capacitor Cl still discharging. The same result occurs during the next input trigger pulse (time t_2 on the waveform illustration). However, when the next input trigger pulse (time t_4 on the waveform illustration) occurs, capacitor Cl is discharged to nearly the fixed negative bias voltage across register R2 (cutoff bias). Therefore, when trigger pulse number 4 is combined with the negative grid voltzge remaining on capacitor Cl, the resulting pulse is of sufficient amplitude to again drive the grid of triode V1 above cutoff and cause the tube to conduct. Thus, the fourth trigger pulse causes the circuit to begin another cycle of operation. The distance-mark divider produces an output pulse as previously explained, and then remains inactive for the next two input trigger pulses. It produces an output pulse for every third input pulse. Therefore, the circuit is said to have a division ratio of 3: 1.

The division ratio of the distance-mark divider is entirely dependent upon the discharge time of capacitor C 1, which is determined by the time constant of the grid R-C circuit. Thus, the distance-mark divider can be made to produce different division

ratios by using various component values in the grid R-C circuit. Although resistor RI is variable, and will change the time constant of the circuit somewhat, this range is not normally broad enough to change the division ratio. Normally, resistor R1 is used only to adjust the circuit to compensate for variations in trigger pulse amplitude and supply voltages.

Failure Analysis.

No Output. A no-output condition maybe caused by an improper input signal, a lack of plate-supply voltage, a fault in the grid circuit, a fault in the plate circuit, a fault in the cathode circuit, or a defective tube. After checking the input signal with an oscilloscope to be certain that the proper input is applied, use the oscilloscope to observe the waveform at the grid of triode V1. If no signal appears at this point, either capacitor Cl or the grid winding of transformer T1 is open. Use an ohmmeter to make resistance checks and isolate the defective component. If the proper grid-voltage waveform is observed, further voltage and resistance checks must be made to isolate the defective component. Use a high-resistance voltmeter to measure the plate-supply voltage and determine whether the power supply is at fault. Next, measure the voltage on the plate of triode V1. If no plate voltage is present, plate components T1 (primary winding), R4, or C2 are either open or shorted. Use an ohmmeter to check continuity and resistance, and isolate the defective component. If the proper plate voltage is present, either the tube is defective, transformer T1 (secondary winding) is open, or resistors R1, R2, R3, or R5 are open or shorted. Use an ohmmeter to isolate the defective component.

Improper Division Ratio or Unstable Output. An improper input signal, an improper bias-supply voltage, a defective tube, an open or shorted grid circuit, or a defective transformer may cause either an improper division ratio or an unstable output. After checking the input signal with an oscilloscope to be certain that it is of the proper amplitude and frequency, use a high-resistance voltmeter to measure the bias-supply voltage. If the bias-supply voltage is correct, the trouble is in the divider circuit and not in the power supply. Use an ohmmeter to check the grid circuit of the divider for open or shorted components (Cl, Rl, R2, R3). Triode V1 may also be at fault. Replace the tube with one known to be good. If this still does not correct the trouble, transformer T1 is probably shorted.

Low Output. A low output is usually caused either by low plate voltage or by low tube emission. Use a high-resistance voltmeter to measure the plate-supply voltage and eliminate the possibility of a faulty power supply. Since defects in capacitor C2 or resistor R4 may also cause low plate voltage, use an ohmmeter to check these components. If these checks fail to locate the trouble, the low output is probably caused by low emission in triode V1.

SHOCK-EXCITED RINGING OSCILLATOR (ELECTRON TUBE)

Application.

The shock-excited ringing oscillator produces a short series of r-f oscillations each time an input gate is applied. The r-f oscillations are normally used as distance marks in radar indicators.

Characteristics.

Requires a high-impedance, negative input gate.

Produces an output only when gated.

R-F output pulse duration is equal to that of the input gate.

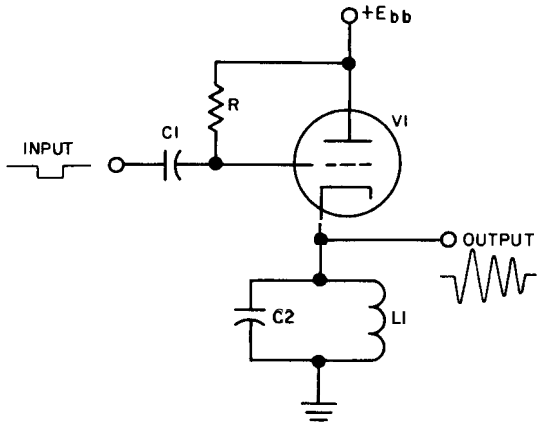
Uses a high-Q resonant tank circuit to produce an r-f output.

Output frequency is determined by the tank-circuit inductance and capacitance values.

Circuit Analysis.

General. The shock-excited ringing oscillator uses a parallel-resonant L-C (tank) circuit to produce an r-f output. An electron tube is used as a switch to control (gate) the r-f oscillations. While the basic circuit discussed below serves to illustrate the principles of operation of the shock-excited ringing oscillator, it is not suitable for use in practicrd circuits. A typical practical circuit is discussed after the basic circuit operation is established.

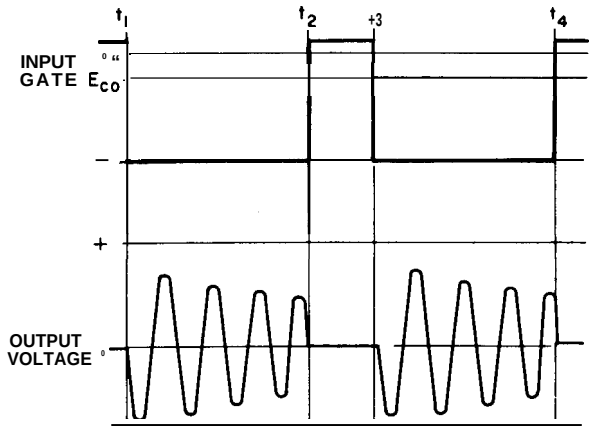
Circuit Operation. The accompanying circuit schematic illustrates a basic shock-excited ringing oscillator.



Basic Shock-Excited Ringing Oscillator

In the quiescent state (with no negative gate applied), positive grid bias is applied from the plate supply through grid resistor RI to the grid of triode VI, and causes the tube to conduct heavily near plate-current saturation. Electron flow is from ground, through inductor L1 and the tube to the plate supply, building up a magnetic field around the inductor. So long as a negative gate is not applied, the circuit remains in this quiescent state (triode VI conducting heavily and no r-f output).

When a negative input-gate is applied through coupling capacitor Cl to the grid of triode V1, it instantaneously drives the grid below plate-current cutoff, and holds it at cutoff for the duration of the input gate. Plate-current flow through inductor L1 abruptly ceases, and the magnetic field around the inductor collapses. The collapsing magnetic field induces into the inductance a voltage of such polarity that it tends to keep current flowing in the same direction. This is, the induced voltage causes a current to flow from ground toward the cathode of triode V1. The triode, however, is biased below cutoff by the negative gate; therefore, no current will flow through the tube. Consequently, the induced current flows around the tank circuit and charges capacitor C2 negative with respect to ground. When the magnetic field has completely collapsed, no further voltage is induced into inductor L1, and the induced current ceases to flow in the tank circuit. Since there is no longer any induced voltage sustain the charge on capacitor C2, the capacitor discharges back through inductor L1. The capacitor discharge current flowing through inductor L1 builds up a magnetic field around the inductor which is of opposite polarity from the original magnetic field. When capacitor C2 is full discharged, current flow around the tank circuit again ceases, and the magnetic field around inductor L1 again collapses and induces into the inductance a voltage which tends to keep current flowing in the same direction. This induced voltage causes current to flow around the tank circuit and charges capacitor C2 positive with respect to ground. After the magnetic field completely collapses, the charge on the tank capacitor is no longer sustained, and the capacitor again discharges through inductor L1, once again building up a magnetic field around the inductor in the original direction. This cycle of charge and discharge continues to repeat, producing a ***ringing*** effect in the tank circuit. That is, the capacitor and inductor charge and discharge alternately, causing the tank circuit to oscillate at a radio-frequency rate. Since the tank circuit has a very high Q (low loss), the r-f oscillations continue for many cycles. Because of the loss in the tank circuit produced by the d-c resistance of the inductor, successive oscillations gradually decrease in amplitude as the energy in the tank circuit is dissipated by this resistance. The resulting output waveform across the tank circuit is a series of damped oscillations, as shown in the following illustration.



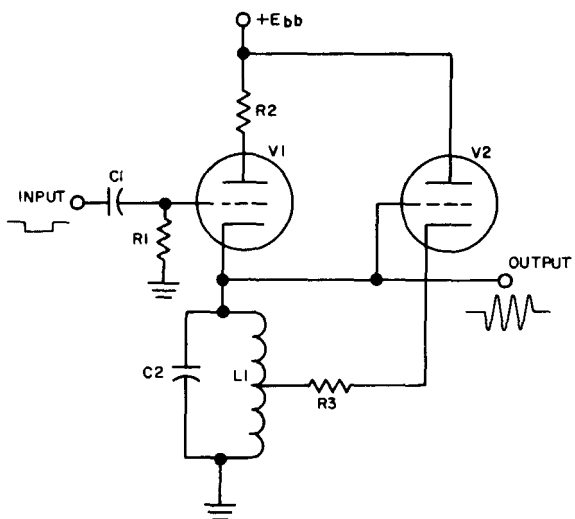
Input Gate and Output-Voltage Waveforms

The damped oscillations continue until the end of the input gate. When the negative input-gate ends, the positive bias supplied by grid resistor R1 resumes control and causes triode V1 to again conduct heavily

near plate-current saturation. When the tube conducts, the heavy plate-current flow through inductor L] produces a magnetic field around the inductor in one unchanging direction, which effectively shunts the tank circuit and decreases the circuit Q. Consequently, the r-f oscillations are effectively damped out very quickly. The heavy plate current flowing through inductor L1 once again builds up a steady magnetic field around the inductor which effectively prevents any possibility of r-f oscillation, and the circuit remains in the quiescent (no-output) state until the next input gate is applied.

Since triode V1 is cut off while output oscillations are being produced, the frequency of the output oscillations is not affected by the tube. Thus, the output frequency is determined solely by the values of inductance and capacitance in the tank circuit. The duration of the train of r-f output oscillations is determined solely by the length of time triode V1 remains cut off, and is therefore controlled by the duration of the input gate.

The basic shock-excited ringing oscillator just discussed always produced damped oscillations when an input gate is applied. Since these oscillations decrease in amplitude, they are not suitable for many applications, particularly for producing distance marks. The following circuit schematic illustrates a practical type of shock-excited ringing oscillator which produces r-f oscillations of a constant amplitude when the input gate is applied.



Typical Shock-Excited Ringing Oscillator

The two-tube shock-excited ringing oscillator shown in the illustration is actually a switched Hartley oscillator (see Section 7 of this Handbook for a detailed discussion of Hartley circuit operation). The circuit consisting of triode V2, capacitor C2, inductor L1, and Resistor R3 is a conventional series-fed Hartley oscillator, consisting of triode V1, capacitor Cl, and resistors R1 and R2 is a switching circuit which controls the operation of the Hartley oscillator.

In the quiescent state (with no negative gate applied), no bias is applied to the grid of triode V1 and the tube conducts heaviIy near plate-current saturation. The electron flow is from ground, through inductor L1, triode V1, and resistor R2 to the plate supply, building up a magnetic field around inductor L1. When triode V1 is conducting, the heavy plate-current flow through inductor L1 produces a steady magnetic field around the tank inductor which effectively shunts the tank circuit and prevents the oscillator from functioning. Consequently, no r-f output oscillations are produced and the circuit remains in this state.

When a negative input-gate is applied to the grid of triode V1 through coupling capacitor Cl, it drives the grid far below cutoff. As plate current ceases to flow through tank inductor L1, the magnetic field around it collapses, inducing a voltage into the inductor which tends to keep current flowing in the same direction as the original plate-current flow (that is, from ground thru the inductor to the cathode of triode V]). As in the basic circuit discussed previously, the induced current cannot flow through triode VI (which is cut off); consequently, it flows around the tank circuit, charging capacitor C2 and initiating a ringing effect. In this practical circuit, however, any potential across the tank is also applied to the grid of oscillator tube V2, and the oscillator section of the circuit functions as a normal Hartley oscillator, producing oscillations of a constant amplitude in the tank circuit. The oscillator portion of this circuit replaces the energy dissipated in the tank coil resistance so that the resulting oscillations are always of constant amplitude. Thus, as long as the negative gate is applied, triode V1 remains cut off, and the oscillator portion of the circuit operates, producing constant-amplitude r-f oscillations.

The oscillator operates until the end of the negative input gate. When the negative gate ends, the grid bias on triode VI returns to zero, and the triode again begins to conduct heavily near plate-current saturation. When the tube conducts, the heavy current flow through inductor L1 produces a steady magnetic field around the tank inductor, effectively damping out the r-f oscillations very quickly. Thus the circuit is once again operating in the quiescent state, with triode V1 conducting heavily near saturation, and no r-f output.

The practical shock-excited ringing oscillator produces r-f oscillations of constant amplitude when a negative input gate is applied. As in the basic shock-excited ringing oscillator, the output frequency is determined by the values of inductance and capacitance in the tank circuit, and the duration of the r-f output is determined by the length of the input gate. The output waveform is the same as that shown for the basic circuit, except that all the oscillations are of constant amplitude.

Failure Analysis.

No Output. Failure of the shock-excited ringing oscillator to produce an output when the gate is applied may be caused by a defective switching circuit, by a defective oscillator circuit, or by a lack of plate-supply voltage. To isolate the trouble to one portion of the circuit, temporarily remove triode V1. If continuous output oscillations are now produced, the trouble is in the switching section of the circuit. Use an ohmmeter to check capacitor Cl for a shorted condition, and resistors R1 and R2 for continuity and proper value. If none of these parts are defective, triode V1 is probably shorted. If continuous output oscillations are not produced when triode V1 is temporarily removed, the fault is either in the oscillator section of the circuit or due to a lack of plate-supply voltage. Use a high-resistance voltmeter to check the supply voltage and the plate voltage of triode V2. Proper values of these voltages indicate that the trouble is in the oscillator section of the circuit and not in the power supply. Use an ohmmeter to check capacitor C2 and inductor L1 for a shorted condition, and to check resistor R3 for continuity and proper value. If the trouble still persists, triode V2 is probably at fault.

Continuous R-F Output. Defects in the switching portion of the shock-excited ringing oscillator may cause the circuit to produce output oscillations whether or not the input gate is present. Use an ohmmeter to check capacitor Cl and resistors R1 and R2 for a shorted or open condition. If none of these parts are defective, triode VI is probably at fault.

Low Output. Defects in the oscillator portion of the circuit or a low plate-supply voltage may cause either low-amplitude output oscillations or damped (decreasing) output oscillations. First measure the plate-supply voltage with a high-resistance voltmeter to eliminate the possibility of low-supply voltage. If the plate-supply voltage is normal, the trouble is in the oscillator section of the circuit and not in the power supply. (If the output oscillations are damped, triode V2 is probably inoperative and should be replaced with a tube known to be good.) Use an ohmmeter to check inductor L1, capacitor Cl, and resistor R3 for continuity of shorts. If no defective parts are found, triode V2 is probably defective.

SHOCK-EXCITED PEAKING OSCILLATOR (ELECTRON TUBE)

Application.

The shock-excited peaking oscillator is used to produce very narrow positive pulses at the beginning of each input gate for use as trigger or synchronizing pulses in radar modulators, display indicators, and other electronic devices.

Characteristics.

Requires a high-impedance, negative input gate.

Produces one very sharp positive pulse at the beginning of each negative input gate.

Produces one relatively broad negative pulse at the end of each negative input gate.

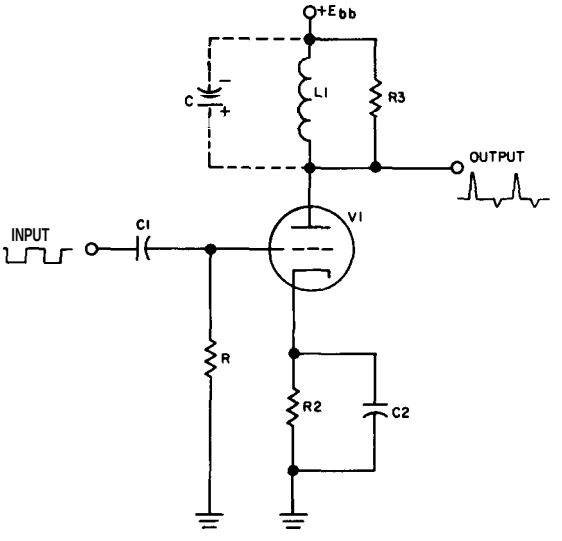
Uses a critically damped tank circuit to produce an output.

Shape of positive output pulse is determined by tank inductance and capacitance valves.

Circuit Analysis.

General. The shock-excited peaking oscillator uses a critically damped resonant L-C (tank) circuit to produce a peaked output. An electron tube is used as a switch to control (gate) the tank circuit.

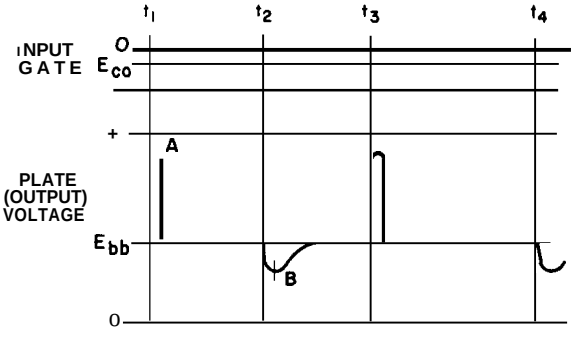
Circuit Operation. The accompanying circuit schematic illustrates a typical shock-excited peaking oscillator.



Shock-Excited Peaking Oscillator

Capacitor Cl and resistor R1 form a conventional R-C input circuit for triode Vl, and capacitor C2 and resistor R2 form a conventional cathode bias circuit for the tube. Inductor L1 and its distributed capacitance, C, form a parallel-resonant tank circuit. Since the distributor capacitance is small, the resonant frequency of the tank circuit is very high (approximately 2 me). This r-f tank is critically damped by resistor R3. That is, the value of resistor R3 is such that it allows the tank circuit to oscillate for only a half cycle after oscillation is started.

The following illustration shows the input-gate and plate-voltage (output) waveform in their proper time relationship.



input-Gete and Plate-Voltage Waveforms

In the quiescent state (with no negative input-gate applied), no bias is applied to the grid of triode VI, and the tube conducts heavily near plate-current saturation. The plate current is held constant by the cathode bias developed across cathode resistor R2. This constant plate current flowing through inductor LI builds up a steady magnetic field around the inductance. So long as a negative gate is not applied, the circuit remains in this quiescent state.

When a negative gate is applied through coupling capacitor Cl to the grid of triode VI (time t_1 on the waveform illustration), it instantaneously drives the grid far below cutoff, and holds it below cutoff for the duration of the input gate. Plate-current flow through inductor L] abruptly ceases, and the magnetic field around the inductor collapses. The collapsing magnetic field induces into the inductance a voltage of such polarity that it tends to keep current flowing in the same direction as the original plate-current flow. This induced current flowing in

the inductor charges the distributed (tank) capacitance, C, negative on the plate-supply side of the capacitance and positive on the triode side of the capacitance (polarity as shown in schematic). Since the charge time of the capacitance is determined by the resonant frequency of the tank circuit, and the resonant frequency is very high, the capacitance charges very quickly to its maximum value. The potential across the charged capacitance is series-aiding with the plate-supply voltage, and the resultant voltage on the plate of triode V1 momentarily rises above the plate-supply voltage (point A on the plate-voltage waveform). When the magnetic field around the inductor completely collapses, there is no longer any induced voltage to sustain the charge on the distributed (tank) capacitance, the capacitance begins to discharge. Since the dc resistance or resistor R3 is much lower than the impedance of inductor L1 at the resonant frequency, the distributed capacitance discharges very quickly through the resistor, and the triode plate voltage quickly returns to the plate-supply value. Thus, the shock-excited peaking oscillator produces one very sharp positive pulse at the beginning of the negative input gate.

Triode V1 remains cut off, and no further output is produced until the end of the negative input gate. When the input gate ends (time t_2 on the waveform illustration), the grid bias on triode VI returns to zero, and the triode again begins to conduct heavily near plate-current saturation. As plate current flows through inductor Ll, a magnetic field builds up around the inductor. The increasing magnetic field induces into the inductance a voltage of such polarity that it tends to oppose the plate current flowing through the inductor. This induced voltage is series-opposing with the plate-supply voltage, and the resulting voltage on the plate of triode VI momentarily drops below the plate-supply voltage (joint Bon the plate-voltage waveform). As the magnetic field around the inductance builds up to its maximum value and ceases to increase, the opposing induced voltage decreases to zero, and the triode plate voltage returns to the plate-supply value. Thus at the end of the negative input gate the shock-excited peaking oscillator produces a negative-going pulse and then returns to the quiescent state, with triode V1 conducting heavily near saturation and a steady unchanging magnetic field built up around inductor L1.

The output from the shock-excited peaking oscillator is a series of alternate positive- and negative-going pukes occurring respectively at the beginning and the end of the negative input gate. Since the positive output pulses are much sharper, and of greater amplitude, than the negative-going output pulses, the positive pulses are normally the desired portion of the output. The negative-going output pulses are usually eliminated with a clipping or limiting circuit which passes only the desired positive out-put pulses.

Failure Analysis,

No Output. FaiIure of the shock-excited peaking oscillator to produce an output when the proper negative input gate is applied may be caused by a defective circuit component, a defective tube, or a lack of plate-supply voltage. After measuring the plate-supply voltage with a high-resistance voltmeter to be certain that the power supply is operating properly, use the voltmeter to measure the voltage on the cathode of triode V1. A lack of cathode voltage indicates that either resistor R2 or capacitor C2 is shorted, or the triode is faulty. If checking resistor R2 and capacitor C2 with an ohmmeter does not reveal a shorted component, triode VI is probably at fault and should be replaced with a tube known to be good. If the proper voltage is measured on the cathode of triode V1, inductor L1 may be open or shorted, capacitor Cl may be open, or resistor R1 or R3 may be open or shorted. Use an ohmmeter to check these components for continuity, shorts, and proper resistance values. If these checks fail to locate a defective component, triode V1 is probably defective.

Low Output. Output pulses of low amplitude may be caused by low plate-supply voltage, low tube emission, or a defective cathode bias circuit. First, measure the plate-supply voltage with a high-resistance voltmeter to eliminate the possibility of a faulty power supply. If the proper plate-supply voltage is present, use an in-circuit capacitor checker to check cathode capacitor C2 for an open. If this capacitor is open, degenerative action in the cathode bias circuit will cause a low output. If both the plate-supply voltage and capacitor C2 are normal, low emission in triode V1 is probably the cause of the low-output condition. Replace triode VI with a tube known to be good.

Distorted Output. Defeats in the plate circuit of triode V1 may cause a distorted output. Use an ohmmeter to check shunt resistor R3 for continuity and the proper resistance value. If resistor R3 is not defective, inductor L1 is probably at fault.

SECTION 7
MULTI VIBRATORS

PART 7-1. ASTABLE

ASTABLE (FREE-RUNNING) MULTI VIBRATORS

General.

The term astable multivibrator refers to a class of multivibrator or relaxation-oscillator circuits that can function in either of two temporarily stable conditions and is capable of rapidly switching from one temporarily stable condition to the other. The astable multivibrator is frequently referred to as a *free-running* multivibrator. It is basically an oscillator consisting of two stages coupled so that the input signal to each stage is taken from the output of the other. One stage conducts while the other is cut off until a point is reached at which the stages reverse their condition; that is, the stage which had been conducting cuts off, and the stage that had been cut off conducts. Thus, the circuit becomes free-running because of the regenerative feedback, and the frequency of operation is determined primarily by its coupling-circuit constants rather than by an external synchronizing pulse.

In electron tube circuits, the frequency of operation can be as low as one-sixtieth of a Hz or as high as 100 kHz; in semiconductor circuits, the frequency of operation ranges from 400 Hz to 200 kHz.

The output of the astable multivibrator is usually nearly rectangular in form. A symmetrical output results when the R-C time constants of the coupling circuits are made equal. Rectangular pulses of almost any desired width (time duration) can be obtained by proportioning the R-C time constants of the coupling circuits with respect to one another; the resulting pulse output is unsymmetrical since the R-C time constants of the coupling circuits are no longer equal.

The operating frequency of the astable multivibrator can be changed by switching values of R or C, or both R and C, in the coupling circuits to alter the time constants. For example, a multivibrator designed to operate at 800 pps can be changed to a lower frequency, such as 400 pps, by simply switching additional capacitors into the circuit in parallel with the existing coupling capacitors to lower the repetition frequency.

The frequency stability of the multivibrator is somewhat better than that of the typical blocking oscillator. However, a disadvantage of the multivibrator is that its output impedance is essentially equal to the plate-load resistance and this resistance must be relatively high in order to obtain good frequency stability. Also, the negative-going waveform is generated at a much lower impedance than the positive-going waveform. Because a changing load will also affect the frequency stability, the output is sometimes fed to a cathode follower, in order to isolate the load from the multivibrator plate circuit. In some instances the desired output from the multivibrator is a differentiated waveform, and this waveform, in turn, is applied to the cathode follower; in this circuit configuration the load will have the least effect upon the multivibrator frequency stability.

BASIC ASTABLE (FREE-RUNNING) MU LTIVIBRATOR (ELECTRON TUBE)

Application.

The basic (plate-to-grid coupled) astable multivibrator produces a square-wave output for use as trigger or timing pulses.

Characteristics.

Free-running oscillator; does not require trigger pulse to produce oscillations.

Operating frequency is determined primarily by the R-C time constants in the feedback (plate-to-grid) coupling circuits and by applied voltage.

Frequency stability of 3 percent can be obtained. Input tirgger pulses may be applied to the circuit for synchronization to produce a stable output; it may be synchronized at the trigger-ulse frequency or integral submultiple thereof.

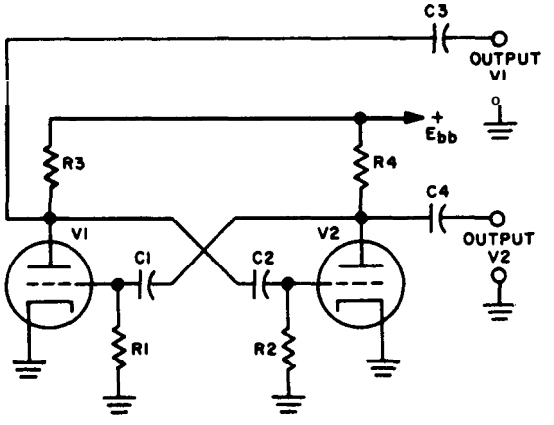
Symmetrical square- or rectangular-wave output is produced when the R-C time constants of the grid circuits are equal. Unsymmetrical output is produced when the R-C time constant of one grid circuit is purposely made several times greater than that of the other; for this condition the two tubes are cut off for unequal periods of time.

Output impedance is essentially equal to plate-load impedance.

Circuit Analysis.

General. The free-running plate-to-grid coupled multivibrator is a basic astable multivibrator. The circuit is fundamentally a two-stage R-C coupled amplifier with the output of the second stage coupled to the input of the first stage! Thus the ouput signal is fed back in the proper phase to reinforce the input signal; as a result, sustained oscillations occur.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a basic free-running rnultivibrator circuit. Electron tubes Vl and V2 are identical-type triode tubes; although the accompanying schematic illustrates two separate triodes, a twin-triode is frequently used in this circuit. Capacitor Cl provides the coupling from the plate of V2 to the grid of V1; capacitor C2 provides the coupling from the plate of V1 to the grid of V2. Resistors RI and R2 are the grid resistors for V1 and V2, respectively; resistors R3 and R4 are the plate-load resistors for V1 and V2, respectively.



Triode Plate-to-Grid **Coupled Astable Multivibrator**

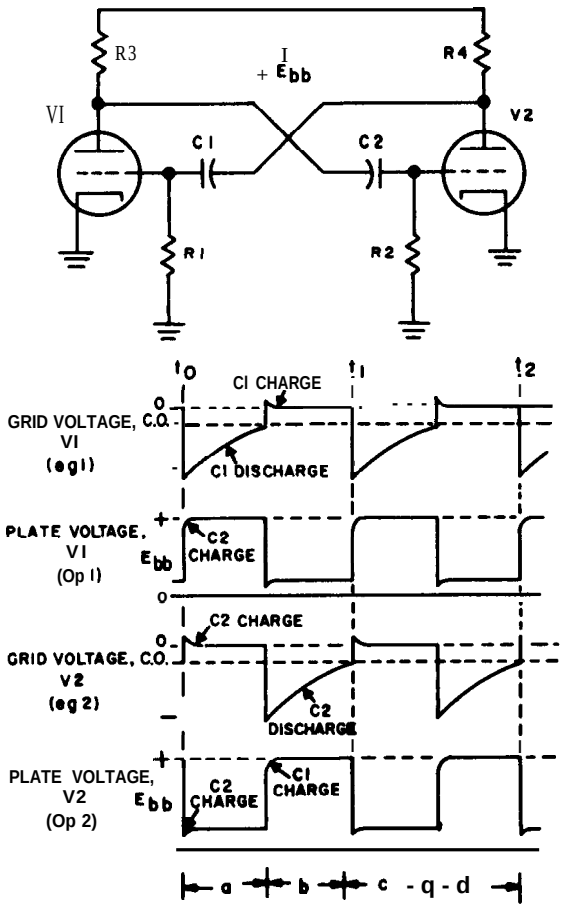
Capacitor Cl and resistor RI form an R-C circuit to determine the discharge time constant in the grid circuit of V1; capacitor C2 and resistor R2 determine the discharge time constant in the grid circuit of V2. Output pulses can be taken from the plate of either or both electron tubes. Capacitors C3 and C4 are the output coupling capacitors for VI and V2, respectively.

When voltage is first applied to the circuit, the grids of both tubes are at zero bias and plate current starts to flow through plate-load resistors R3 and R4. Also, capacitors Cl and C2 begin to charge when the applied voltage appears at the plate of each tube. If the constants of both stages of the circuit are alike, the currents through both tubes may at first be nearly equal. In practice, the symmetrical free-running multivibrator component values are held to close tolerances in order to obtain good frequency stability; the value of coupling capacitors Cl and C2 are at least 2 percent tolerance, grid resistors R1 and R2 are 1 percent tolerance, and plate-load resistors R3 and R4 are usually 5 percent tolerance. Hewer, in spite of the close tolerance of the components, there will always be some slight difference in the two currents. This small difference in tube currents will cause a further unbalance, resulting in a regenerative action which rapidly switches the circuit to a condition wherein one tube is conducting maximum current and the other is cut off.

For example, if initirdly the current through tube V1 should be slightly greater than that through V2, the voltage drop across plate-load resistor R3 will be greater than the drop across resistor R4. This results in a lower plate voltage for VI. This decrease in plate voltage is coupled through coupling capacitor C2 to the grid of V2 as a negative-going instantaneous grid voltage which reduces the plate current of V2. When the current through V2 is decreased, the current through plate-load resistor R4 is also decreased; therefore, the voltage drop across resistor R4 decreases, resulting in a rise in the plate voltage of V2. This increase in plate voltage is coupled through coupling capacitor Cl to the grid of V1 as a positive-going instantaneous grid voltage which increases the plate current of VI. The drop across plate-load resistor R3 increases, the plate voltage of V1 decreases, and as before, the decrease in the plate voltage of V1 is coupled to the grid of V2 as a negative-going voltage. The regenerative switching action just described continues rapidly until V2 is cut off and V1 is at maximum conduction.

In order to cut off plate current in V2, the grid of v2 must be driven negative beyond the cutoff voltage. The negative grid voltage results from a charge on coupling capacitor C2. Since this charge leaks off through grid resistor R2, the grid voltage at V2 does not remain in a negative condition but starts to return to zero as **C2** discharges through R2 and the cathode-to-plate conduction resistance of V1. When C2 discharges sufficiently and the grid voltage cutoff point

is reached, plate current once again starts to flow through V2, initiating another switching action similar to the first action described. However, this time as V2 conduts, coupling capacitor Cl discharges through grid resistor R1 to cut off the plate current in Vl, and the switching action ends with V1 cut off and V2 at maximum conduction. Here again, the negative charge existing on coupling capacitor Cl must discharge through grid resistor R1 and tube V2 before the grid voltage cut off point is reached and V1 can conduct to initiate another switching action. The switching action repeats continuously with first one tube and then the other tube conducting.



Theoretical Waveforms for a Symmetrical Free-Running Multivibrator

For the following discussion of circuit operation, refer to the accompanying illustration which shows a simplified schematic and waveforms for a symmetrical free-running multivibrator.

At time t. (start of time interval a) on the waveform illustration, the grid of VI (e_{g1}) has been driven negative to cut off the tube, and, as a result, the plate voltage of V1 (e_{p1}) has risen rapidly to approach the supply-voltage value (E_{bb}). Coupling capacitor C2 is quickly charged through the low cathode-to-grid internal resistance of V2 and the plate-load resistor, R3. The voltage waveform at the plate of VI (e_{p1}) is rounded off, and the waveform at the grid of V2 (e_{g2}) has a small positive spike of the same time duration as a result of the charging of coupling capacitor C2. Since at this time the grid of V2 is slightly positive, V2 conducts heavily and the plate voltage of V2 (e_{p2}) drops to a minimum. Note that the plate voltage waveform (e_{p2}) exhibits a small negative spike of the same time duration as the positive spike on the grid waveform (e_{g2}).

While coupling capacitor C2 is being charged, coupling capacitor Cl (previously charged) discharges through grid resistor RI and through the conduction resistance of V2. Capacitor Cl cannot change its charge immediately; therefore, it produces a negative voltage (e_{g1}) across grid resistor R1, which decays at an exponential rate (toward zero) as capacitor Cl discharges. The rate of discharge is determined primarily by the R-C time constant of RI and Cl. Although the conduction resistance of V2 is included in the discharge path of Cl, the resistance is small as compared with the resistance of R1, and can therefore be neglected.

When the negative voltage (e_{g1}) produced across grid resistor R1 decreases near the end of time interval a and reaches cutoff, V1 immediately conducts and the plate voltage of V1 (e_{p1}) drops to a minimum; the circuit now switches to the other condition with V2 cut off by the discharge of capacitor C2 through grid resistor R2. This condition is shown on the waveform illustration as the start of time interval b. Coupling capacitor C2 discharges through grid resistor R2 and through the conduction resistance of V1. The rate of discharge is determined primarily by the R-C time constant of R2 and C2. (The conduction resistance of V1 is small and can be neglected.)

When the negative voltage (e_{g2}) produced across grid resistor R2 decreases near the end of time interval b and reaches cutoff, V2 immediately conducts

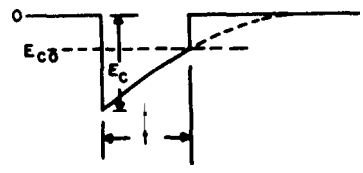
and the plate voltage of V2 (e_{p2}) drops to a minimum; the circuit now switches to the other condition with VI cut off by the discharge of capacitor Cl through grid resistor R1. This condition is shown on the waveform illustration as the termination of interval *b* at time t_1.

In the discussion of circuit operation given above, the multivibrator was assumed to be a symmetrical (or balanced) multivibrator; that is, coupling capacitors Cl and C2 are equal, reistors RI and R2 are equal, and plate-load resistors R3 and R4 are also equal. Therefore, the discharge time constants of RI and C 1 and of R2 and C2 are equal. Also, the time intervals (a, b, c, and d) between the switching actions are equal to one another. To obtain a pulse output which is unsymmetrical (asymmetrical or unbalanced), it is necessary to proportion the time constants in the coupling circuits so that one tube remains cut off for only a short period of time while the other is cut off for a much longer period. For example, if the time constant of R1 and Cl is made short compared to the time constant of R2 and C2, then V1 will be cut off for a short period of time while V2 will be cut off for a longer period. Thus, the time intervals a and c, shown on the waveform illustration will be short while time intervals *b* and *d* will be long.

The time interval for either output pulse may be approximated if the voltage change across the coupling capacitor, the R-C time constant of the discharge path, and the cutoff voltage of the tube are known. The approximate time interval, t, for the capacitor to discharge to cutoff may be determined by use of the following formula:

$$t \cong 2.30\ RC \log \frac{E_c}{E_{co}}$$

where: t = time interval to discharge to cutoff (seconds)
E_c = maximum voltage change across capacitor
E_{co} = negative cutoff value for tube
R = resistance of grid resistor (megohms)
C = capacitance of coupling capacitor (μf)



If the grid resistor, R, is returned to a positive voltage source, such as the plate-supply voltage (E_{bb}), the formula becomes:

$$t \cong 2.30\ RC \log \frac{E_{bb} + E_c}{E_{bb} + e_o}$$

where: E_{bb} = plate-supply voltage

The natural operating frequency (Hertz) of the oscillator, f_o, may be calculated from the following formula:

$$f_o = \frac{1}{t_1 + t_2}$$

where: t_1 = time interval to discharge to cutoff for V1 grid circuit.
t_2 = time interval to discharge to cutoff for V2 grid circuit.

The free-running multivibrator may be synchronized with a stable external source to force the period of multivibrator action to be exactly the same as the synchronizing source. In this case the multivibrator is called a driven multivibrator. Synchronizing signals, when used, are applied to the grid of one multivibrator tube if the impedance of the synchronizing source is high, or to the cathode if the impedance of the source is low. In either case, the frequency of the synchronizing signal must be slightly higher than the natural operating frequency of the multivibrator so

that the synchronizing pulse occurs just prior to the time that normal switching action would occur.

The output of the multivibrator is taken from either or both plate circuits through an output-coupling capacitor (C3 or C4). In cases where it is desired to minimize the effect of a varying load impedance on the multivibrator frequency stability, a cathode follower is used for isolation.

Failure Analysis

No Output. Assuming that the multivibrator is a free-running type and no synchronizing signal is applied, the applied plate and filament voltages should be measured to determine whether they are within specified values. If either coupling capacitor Cl and C2 should become leaky or shorted, a positive potential will be present on the grid of the associated tube and, as a result, the tube will conduct heavily; the other tube will also conduct heavily, since it will be at zero bias. A similar condition could exist if either coupling capacitor Cl or C2 should open; in this case the feedback necessary to sustain oscillations cannot. occur and both tubes will conduct heavily because the grids are at zero bias. If the circuit is in a nonoscillating condition, the voltage at each plate should be measured to determine whether plate-load resistor R3 or R4 is open. If either is open, there will be no plate voltage present on the associated plate; also, the other tube will donduct heavily because of zero bias, and its plate voltage will be low. If either output coupling capacitor (C3 or C4) should become leaky or shorted, the input resistor of the following stage can form a voltage divider which also includes the associated plate-load resistor (R3 or R4). If the input resistor of the foilowing stage is returned to ground or to a negative potential, voltagedivider action may reduce the voltage available at the plate of the multivibrator to the point where oscillations will cease; also, the additional current through the plate-load resistor (R3 or R4) may cause the resistor to burn out.

Incorrect Frequency or Pulse Width. 'f'he critical components governing the frequency and pulse width of the multivibrator are those in the coupling circuits. Any change in components governing the R-C discharge time constant will directly affect frequency and pulse width; a change in capacitor Cl or C2 or resistor R1 or R2 will have the greatest effect. A change in the value of plate-load resistor R3 or R4 will affect the amplitude of the output, and it will also have an effect upon the frequency, but not nearly as much as the components mentioned above.

A drift in frequency of the free-running multivibrator will generally occur if the applied plate voltage should change approximately 10 percent from the specified value; also, some frequency drift may occur if the lament voltage should drop below the specified value.

In a practical circuit, where the muhivibrator is free-running and is not synchronized from an external source, means should be provided to adjust the applied plate voltage or to adjust the value of resistance in each grid circuit. This provision enables the circuit to be adjusted to the correct frequency and pulse width, and compensates for differences in individual tube characteristics when a tube substitution has been made.

If either output coupling capacitor (C3 or C4) should become leaky or shorted, the voltagedivider action which can occur may reduce the amplitude of the output waveform and cause the multivibrator to operate at a higher frequency, since the grid capacitor (Cl or C2) discharge time is dependent upon the amount of change in capacitor voltage. The operation of the following stage may also be affected by the change in grid-bias voltage resulting from the voltage-divider action.

BASIC ASTABLE (FREE-RUNNING) MU LTIVIBRATORS (SEMICONDUCTOR)

Application.

The free-running astable multivibrator circuit is a basic circuit. It is normally used to produce a square-wave output for use as a trigger or timing pulse in electronic equipments; this basic curcuit, when modified for application to switching circuitry, is representative of a class of circuits which perform computer logical operations (counting, shift register, and memory circuits), control functions (relay driver circuits), and a variety of similar applications in radar and communications systems.

Characteristics.

Free-running oscillator; does not require a trigger pulse to produce oscillations.

Operating frequency is determined primarily by the time constants in the feedback (collector-to-base) coupling circuits and by the applied voltage.

Symmetrical square-wave or rectangular-wave output is produced when the time constants of the coupling circuits are equal. Unsymmetrical output is produced when the time constant of one coupling circuit is purposely made several times greater than that of the other; for this condition the transistors are cut off or conducting for unequal periods of time.

Output taken from collector of either transistor in common-emitter circuit configuration.

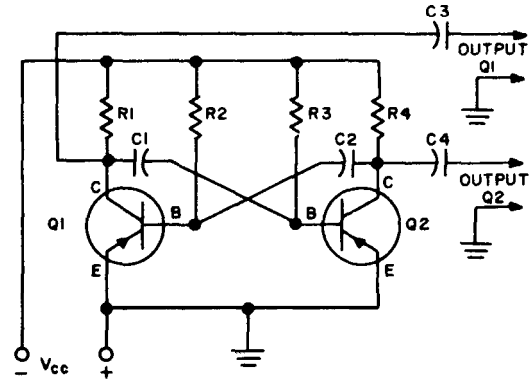
Output impedance is very low when transistor is in conducting (on) state; output impedance is approximately equal to collector load resistance when transistor is in cutoff (off) state.

Circuit Analysis.

General. The free-running collector-coupled multivibrator is a basic astable mtdtivibrator. The circuit is fundamentally a two-stage, R-C-coupled, common-emitter amplifier, with the output of the second stage coupled to the input of the first stage. Since the signal in the collector circuit of a common-emitter amplifier is reversed in phase with respect to the input to the base, a portion of the collector output of each stage is fed to the base electrode of the other stage. Thus, the output signal from each stage is fed back in the proper phase to reinforce the input signal on the base electrode of the other stage; as a result of this regenerative feedback, sustained oscillations occur.

The collector-coupled, common-emitter multivibrator circuit described in the following paragraphs is analogous to the basic plate-to-grid-coupled electron-tube mtdtivibrator circuit described earlier in this section of the handbook.

Circuit Oparation. The following circuit schematic illustrates two transistors in a basic free-running multivibrator circuit.



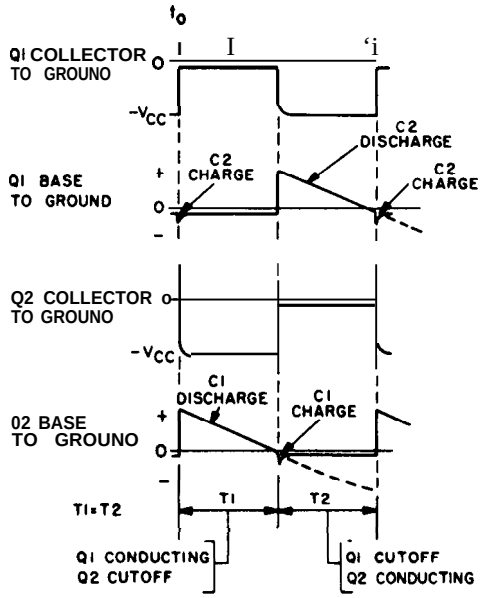
Basic Free-Running Astable Multivibrator Using PNP Transistors

Transistors Q1 and Q2 are identical PNP transistors used in a common-emitter circuit configuration; either junction or point contack transistors may be used in this circuit. Resistors R1 and R4 are the collector load resistors for Q1 and Q2, respectively; R2 and R3 are the base-biasing resistors for Q1 and Q2, respectively. Capacitor C 1 provides the coupling from the collector of Q1 to the base of Q2; capacitor C2 provides the coupling from the collector of Q2 to the base of Q1. Capacitor Cl and resistor R3 form an R-C circuit to determine the discharge time constant for the base of Q2; capacitor C2 and resistor R2 determine the discharge time constant for the base of Q1. Capacitors C3 and C4 are the output coupling capacitors for Q1 and Q2, respectively. An output waveform can be taken from the collector element of either transistor, or output waveforms can be taken from the collector elements of both transistors.

The common-emitter configuration illustrated uses a single-battery power source, V_{cc}. Forward bias for the base of transistor Q1 is obtained through the low-resistance emitter-base junction, which is in series with resistor R2 across the voltage source, V_{CC}; since the base of Q1 is placed at a negative potential with respect to its emitter, the required forward bias for the PNP transistor is thereby established. In a like manner, forward bias for the base of transistor Q2 is obtained through the emitter-base junction and resistor R3. When voltage is first applied to the multivibrator, the current which flows in each collector load resistor, RI and R4, is determined by the effective resistance offered by transistors Q1 and Q2 for a given value of base-bias voltage.

The multvibrator circuit shown in the schematic appears to be a balanced (or symmetrical) circuit, since each R-C-coupled stage is identical to the other; however, in spite of the use of close-tolerance components, there will always be minor differences in circuit resistances ana in junction resistances within the transistors themselves. (A balanced circuit is assumed here and not necessarily a multivibrator designed for unsymmetrical output.) As a result of this inherent unbalance, the initial collector current (resulting from the forward-bias conditions set up by the emitter-base junction resistances and bias resistors R2 and R3) for each transistor is different, and the immediate effect produced by regenerative action between the coupled stages is that one transistor conducts while the other is cut off. For the purpose of this explanation, assume that initially more collector current flows through transistor Q1 than through transistor Q2; thus, as the collector current of Q1 increases, the voltage at the collector of Q1 decreases with respect to its emitter, or ground. In other words, the collector of Q1 becomes less negative and this, in effect, acts as a positive-going pulse, which is coupled through capacitor Cl to the base of transistor Q2. The positive-going pulse at the base of Q2 makes the base positive with respect to its emitter (ground) and, as a result, Q2 approaches cutoff. The collector current of Q2 decreases because of the revers-bias action, and the voltage at the collector of Q2 increases, and approaches the supply voltage, $-V_{cc}$. In other words, the collector of Q2 becomes more negative and this, in effect, acts as a negative-going pulse, which is coupled through capacitor C2 to the base of transistor Q1. The negative-going pulse at the base of QI places the base negative with respect to its emitter (ground), and the collector current of QI is further increased because of the forward-bias action. This regenerative process continues until Q1 is driven into saturation (as a result of increased forward-bias), and Q2 is cut off (as a result of the reverse-bias conditions).

For the following discussion of circuit operation, refer to the circuit schematic shown previously, and also to the waveforms shown in the following illustration.



Theoretical Waveforms for a Symmetrical Free-Running Multivibrator (Using PNP Transistors]

Assume that transistor Q1 is conducting and has just reached saturation. When Q1 is at saturation, its collector current no longer increases but rather becomes a constant value (see Q1 collector waveform for period Tl); therfore, there is no further change in collector voltage to be coupled through capacitor Cl to the base of transistor Q2. The voltage at the base of QI is only a few tenths of a volt negative, and, as a result, capacitor C2 quickly charges (see Q1 base waveform for period Tl) through the low resistance of R4 to a potential which is approximately equal to

$-V_{cc}$. Since the collector voltage at QI (Q1 is conducting heavily) is at nearly ground potential, capacitor Cl (previously charged) starts discharging (see Q2 base waveform for period Tl) at a rate which is equal to the time constant R3C1, through transistor Ql, the voltage source, and resistor R3.

As capacitor Cl discharges, the voltage at the base of Q2 becomes less and less positive (negative-going) until a point is reached where reverse bias is no longer applied and Q2 is able to conduct (as shown in the Q2 base waveform at the end of period Tl).

When the base of Q2 returns to a forward-bias condition, Q2 begins to conduct and its collector current begins to flow through load resistor R4. As the collector voltage at Q2 drops (see Q2 collector waveform for period T2), a changing (positive-going pulse) voltage is coupled through capacitor C2 to the base of transistor Q1. The voltage at the base of Q1 is only a few tenths of a volt negative, and, as a result of the charge on capacitor C2, reverse bias is applied to the base of Q1. Transistor Q1 is driven to cutoff, and the collector voltage of Q1 rises (see Q1 collector waveform for period T2). This rise, coupled through Cl, will drive the base of Q2 further into the forward-bias condition. The voltage at the base of Q2 is only a few tenths of a volt negative, and the collector voltage at Q1 is approximately $-V_{cc}$; as a result, capacitor Cl quickly recharges (see Q2 base waveform for period T2) through the low resistance of RI to a potential which is approximately equal to $-V_{cc}$. Since the collector voltage at Q2 (Q2 is conducting heavily) is at nearly ground potential (see Q2 collector waveform for period T2), capacitor C2 (previously charged) starts discharging at a rate which is equal to the time constant R2C2, through transistor Q2, the voltage source, and resistor R2.

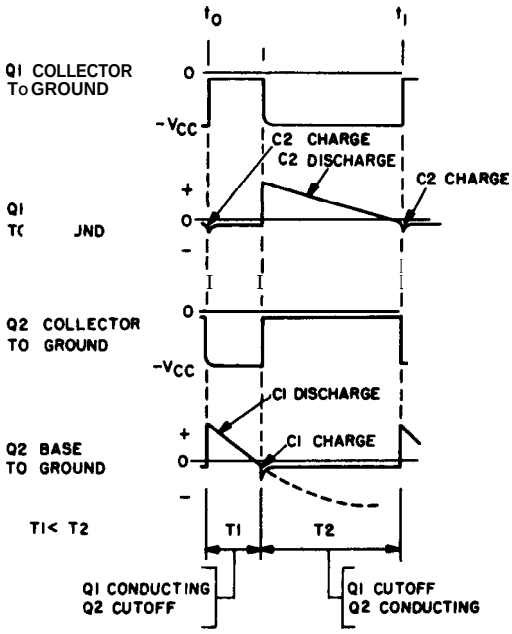
As capacitor C2 discharges (see Q1 base waveform for period T2), the voltage at the base of Q1 becomes less and less positive (negative-going) until a point is reached where reverse bias is no longer applied, and Q1 is able to conduct.

When the base of Q1 begins to conduct, collector current begins to increase through load resistor R1. As the voltage drops at the collector of Q1 a changing (positive-going pulse) voltage is coupled through capacitor C 1 to the base of transistor Q2 to initiate another cycle of operation.

For each half-cycle of operation, whenever a changeover of the multivibrator takes place one of two actions occurs: in one case capacitor Cl recharges through load resistor R1 and the base-emitter junction of Q2 to the vrdue of the supply voltage, V_{cc}, while capacitor C2 discharges through the series circuit consisting of transistor Q2, the voltage source, and resistor R2; in the other case, capacitor C2 recharges through load resistor R4 and the base-emitter junction of Q1 to the value of the supply voltage, V_{cc}, while capacitor Cl discharges through the series circuit consisting of transistor Q1, the voltage source, and resistor R3.

The discharge times of capacitors Cl and C2 are relatively long as compared with their charge times; thus, the capacitor which is charging reaches its final potential long before the other capacitor has completely discharged. This action can be clearly seen if the Q1 and Q2 base waveforms in the illustration are compared for periods T1 and T2.

The waveforms shown in the preceding illustration are for a symmetrical multivibrator, and the output taken from the collector of either transistor is a square wave. The waveforms shown in the following illustration are for an unsymmetrical multivibrator, and the output waveforms have unequal time durations. The general circuit operation is identical with that of the symmetrical multivibrator; however, the on and off times, or charge and discharge times, are different since different R-C values are used.



Theoretical Waveforms for an Unsymmetrical Fraa-Running Multivibrator (Using PNP Transistors)

Failure Analysis.

No Output. An open-circuited, short-circuited, or over-biased condition, as well as a defective transistor, can cause lack of output. The transistor element voltages can be checked against their proper values to determine the defective component. With the circuit in the non-oscillating condition, a check of the voltages at the collector of each transistor will reveal whether load resistor R1 or R4 is open. If either resistor is open, there will be no collector voltage on the associated transistor; also, the other transistor will conduct heavily because of the reduced bais (the circuit is inoperative), and its collector voltage will be low, (In this case the collector resistor can burn out.) If coupling capacitor Cl or C2 is leaky or shorted, the collector resistor of one transistor will be shunted across the base resistor of the other transistor, and the fixed bias on the base of the transistor to which the defective capacitor is connected, will be increased. If the increase in bias is sufficient, the transistor will be rendered inoperative. (Under certain conditions, an unsymmetrical output can occur.) Also, if coupling capacitor Cl or C2 is open, or if resistor R3 or R4 is open, the circuit will be rendered inoperative, since the R-C circuit resistance will be infinite. If output capacitor C3 or C4 is open, the circuit will operate at a slightly different frequency because of load changes, but no output will be observed.

Incorrect Frequency and Pulse Width. The critical components governing the frequency and pulse width of the multivibrator are those in the coupling circuits. Any change in the components governing the R-C discharge time constant will directly affect the frequency and pulse width. A change in value of coupling capacitor C 1 or C2 or in the base resistance R2 or R3 will have the greatest effect. Although a change in the value of collector resistor RI or R4 will affect the frequency and pulse width, it will have a greater effect on the output amplitude of the waveform.

A 10 percent variation in the collector voltage may cause some frequency drift. However, in practical circuits where the multivibrator is unsynchronized and free-running, adjustments are usually provided to adjust the collector voltage or the base resistance (usually the latter). In this manner the circuit can be set to the correct frequency and pulse width, and can be compensated for the difference in transistor characteristics when a replacement is made.

If output coupling capacitor C3 or C4 is leaky or shorted, the voltage divider action which can occur through the base resistance of the next stage may reduce the amplitude of the output waveform and cause the multivibrator to operate at a higher frequency. This is true because the discharge time in the base circuit is dependent on the amount of change in the voltage applied to the capacitor. Another effect can be a change in the operation of the following stage caused by the bias voltage resulting from this voltage divider action.

If this following stage employs a PNP transistor, the forward bias on the transistor will be increased, with a resultant "increase in collector current. The excessive collector current may cause burnout of the collector resistor or the transistor, depending on the ratings of those parts. If the stage employs an NPN transistor the bias will be reversed and cutoff may occur.

PENTODE ELECTRON-CO UPLEO ASTABLE MULTIVIBRATOR

Application.

The pentode electron-coupled astable multivibrator produces a square-wave output for use as trigger or timing pulses.

Characteristics.

Essentially the same characteristics as the basic astable multivibrator discussed earlier in this section with following exceptions:

Operating frequency is determined primarily by the R-C time constants in the feedback (screen-to-grid) coupling circuits and by the applied screen voltage.

Changes in load have minimum effect upon multivibrator frequency because load is isolated from pentode screen (multivibrator plate) circuit by electron-stream coupling and supressor-grid action of tube.

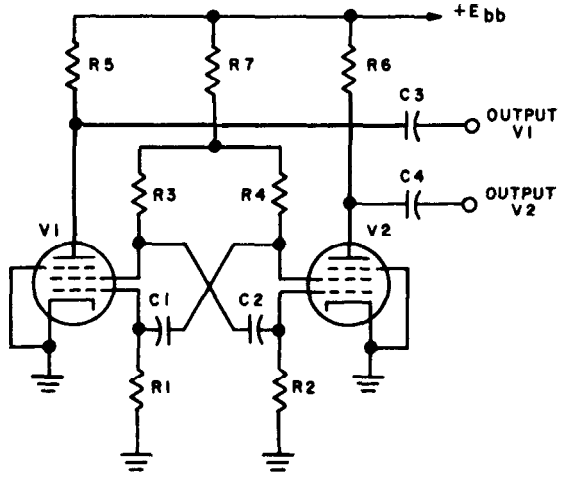
Circuit Analysis.

General. The pentode electron-coupled multivibrator is basically a free-running (triode) plate-to-grid-coupled multivibrator using the screen grids of sharp cutoff, pentode-type tubes as plates for the multivibrator switching function. The circuit is fundamentally a two-stage R-C amplifier with the output (screen grid) of the second stage coupled to the input of the first stage. The screen grid of each tube functions in the oscillator circuit as though it were the plate of a triode. Thus, the ouput signal from the screen grid is fed back in the proper phase to reinforce the input signal; as a result, sustained oscillations occur. The output, taken from the plate-load resistor, is coupled to the mr.dtivibrator oscillatory circuit through the electron stream of the pentode tube.

Circuit Operation. The following circuit schematic illustrates two pentode electron tubes in a basic free-running multivibrator circuit. Electron tubes VI or V2 are identical sharp cutoff, pentode-type tubes. Capacitor Cl provides the coupling from the screen grid of V2 to the grid of Vl; capacitor C2 provides the coupling from the screen grid of VI to the grid of V2. Resistors R1 and R2 are the grid resistors for V1 and V2, respectively; resistors R3 and R4 are the screen resistors for VI and V2. Resistors R5 and R6 are the plate-load resistors for V1 and V2, respectively. Resistor R7 is a series voltage-dropping resistor which is common to both screen-grid circuits.

Capacitor Cl and resistor R1 form an R-C circuit to determine the discharge time constant in the grid circuit of VI; capacitor C2 and resistor R2 determine the discharge time constant in the grid circuit of V2.

Output pulses can be taken from the plate of either or both electron tubes. Capacitors C3 and C4 are the output coupling capacitors for V1 and V2, respectively.



Pentode Electron-Coupled Astable Multivibrator

The switching action of the electron-coupled multivibrator is similar to that of the triode plate-to-grid-coupled multivibrator circuit, previously described in this section.

When voltage is first applied to the circuit, the grids of both tubes are at zero bias and both plate and screen curents start to flow; the plate currents pass through plate-load resistors R5 and R6, and the screen currents pass through resistors R3 and R4 and through the common voltage-dropping resistor, R7. Also, capacitors Cl and C2 begin to charge when the applied voltage appears at the screen of each tube. The currents through both tubes may be equal at first; however, in spite of the close tolerances of the components in the control-grid and screen-grid circuits, there will always be some slight difference in the total currents of the tubes. The difference in screen-grid currents will cause a further unbalance, resulting in a regenerative action which rapidly

switches the circuit to a condition wherein one tube is conducting maximum screen and plate currents and the other is cut off.

For example, if initially the total plate and screen current through tube VI should be slightly greater than that through V2, the voltage drop across screen resistor R3 will be greater than the drop across screen resistor R4. This results in a lower screen voltage for V1. This decrease in screen voltage is applied through coupling capacitor C2 to the grid of V2 as a negative going instantaneous grid voltage which reduces the plate and screen currents of V2. When the screen current of V2 is decreased, the current through screen resistor R4 (and resistor R7) is also decreased; therfore, the voltage drop across resistor R4 decreases, resulting in a rise in the screen voltage of V2. This increase in screen voltage is fed through coupling capacitor Cl to the grid of V1 as a positive-going instantaneous grid voltage which increases the screen current of V1. The voltage drop across screen resistor R3 increases as the screen current increases, the screen voltage of V1 decreases, and, as before, the decrease in the screen voltage of V1 is applied to the grid of V2 as a negative-going voltage. Note that as the screen current of V1 increases the screen current of V2 decreases. Since the screen currents of V1 and V2 flow through dropping resistor R7, the voltage (with respect to ground) at the junction of resistors R3, R4, and R7 remains essentially constant throughout the entire period of oscillation.

The regenerative switching action just described for the screen-grid to control-grid coupling of the pentode multivibrator circuit continues rapidly until V1 is cut off and VI is at maximum conduction. In order to cut off plate and screen current in V2, the grid of V2 must be driven negative beyond the cutoff voltage. The negative grid voltage results from a charge on coupling capacitor C2. Since this charge leaks off through grid resistor R2, the grid voltage of V2 does not remain in a negative condition but starts to return to zero as C2 discharges through resistor R2 and the conduction resistance (cathode to screen grid) of VI. When capacitor C2 discharges sufficiently and the grid voltage cutoff point is reached, the plate and screen currents once again start to flow through V2, initiating another switching action similar to the first action described. However, this time as V2 conducts, coupling capacitor Cl discharges through grid resistor R1 to cut off the plate and screen currents in Vl, and the switching ac tion ends with V1 cut off and V2 at maximum conduction. Here again, the charge existing on coupling capacitor C 1 must discharge through grid resistor R1 and tube V2 before the grid voltage cutoff point is reached and VI can conduct to initiate another switching action.

In a sharp cutoff pentode tube, as long as the plate voltage is greater than the applied screen voltage, the plate current in the tube depends largely upon the screen voltage rather than upon the value of the applied plate voltage. The screen grid is made positive with respect to the cathode and therefore attracts electrons from the cathode; however, most of the electrons attracted by the screen pass on through the screen grid and reach the plate. It is this flow of electrons to the plate that couples the multivibrator action to the plate circuit, from which the output waveform is obtained. The term electron coupled refers to this method of coupling within the tube.

The fact that plate current is largely independent of applied plate voltage makes it possible to produce the desired output waveform in the plate circuit since the positive potential existing on the screen will control the number of electrons arriving at the plate. Furthermore, the plate and screen currents are controlled by the action of the control grid; therefore, when the tube is at maximum conduction and plate current flows through the plate-load resistor, the voltage drop across the plate-load resistor is also maximum and the plate voltage of the tube is minimum. When the tube is cut off, the plate voltage is at maximum. Thus, the voltage at the plate of the tube is determined by the coupling of the electron stream to the plate circuit, and this, in turn, is governed by the switching action of the multivibrator oscillatory circuit (control and screen grids). The suppressor grid acts to shield the screen from the plate and prevents changes in loading from affecting the oscillatory circuit; therefore, the frequency of the multivibrator is reasonably independent of changes in output loading.

Like the triode plate-to-grid-coupled multivibrator, described previously in this section, the proportioning of the R-C time constants of the coupling circuits (R1C1 and R2C2) determine whether the output waveform will be symmetrical or unsymmetrical.

The output waveform is taken from either or both plate circuits and coupled to the load through an output-coupling capacitor (C3 or C4).

Failure Analysis.

No Output. Assuming that the multivibrator is a free-running type and no synchronizing signal is ap plied, the plate, screen, and filament voltages should be measured to determine whether they are within specified values. If either coupling capacitor Cl or C2 should become leaky or shorted, a positive potential will be present on the grid of the associated tube, and, as a result, the tube will conduct continuously; the other tube will also conduct, since it will be at zero bias. A similar condition could exist if either coupling capacitor Cl or C2 should open; in this case, the feedback necessary to sustain oscillations cannot occur, and both tubes will conduct continuously because the grids are at zero bias. If this circuit is in a nonoscillating conditon, the voltage at each screen grid should be measured to determine whether screen resistor R3 or R4 is open. If either is open, there will be no screen voltage present on the associated screen grid, and the tube will be cut off; also, the other tube will conduct continuously because of zero bias, and its plate and screen voltages will be low. Furthermore, if resistor R7 should open, there will be no voltage at either screen grid, and both tubes will be cut off.

Note that, if a plate load resistor (R5 or R6) should open, the multivibrator oscillatory circuit (control and screen grids) may function normally, but no output waveform will be obtained from the tube associated with the open plate-load resistor.

Incorrect Frequency or Pulse Width. The critical components governing the frequency and pulse width of the multivibrator are those in the coupling circuits. Any change in components governing the R-C discharge time constant will directly affect frequency and pulse width; a change in capacitor C1 or C2 or resistor R1 or R2 will have the greatest effect. A change in the value of screen resistor R3 or R4 or dropping resistor R7 will also have an effect upon the frequency and pulse width, but not nearly as much as the coupling components mentioned above.

In a practical circuit, where the multivibrator is free-running and is not synchronized from an external source, means may be provided to adjust the applied screen voltage or to adjust the value of resistance in each control-grid circuit. This provision enables the circuit to be adjusted to the correct frequency and pulse width and compensates for differences in individual tube characteristics when a tube substitution has been made.

Reclucad Output. A reduction in ouput amplitude is generally caused by a defective tube; however, it can also be caused by a decrease in the applied plate voltage or an increase in the resistance of the associated plate-load resistor (R5 or R6). A similar condition can also result from a change in the value of the applied screen voltage; however, in this case the multivibrator frequency will probably be affected before a noticeable change in output occurs.

If either output coupling capacitor (C3 or C4) should become leaky or shorted, the input resistor of the following stage can form a voltage divider which - also includes the associated plate-load resistor (R5 or R6). If the input resistor of the following stage is returned to ground or to a negative potential, voltage-divider action may reduce the voltage available at the plate of the multivibrator and reduce the amplitude of the output waveform; also, the additional current through the plate-load resistor (R5 or R6) may cause the resistor to burn out. Furthermore, the operation of the following stage may also be affected by the change in grid-bias voltage resulting from the voltage-divider action.

TRIODE CATHODE-COUPLED ASTABLE MULTIVIBRATOR

Application.

The triode cathode-coupled astable multivibrator produces a square- or rectangular-wave output for use as trigger or timing pulses.

Characteristics.

Free-running oscillator; does not require trigger pulse to produce oscillations.

Operating frequency is determined primarily by the R-C time constant in the grid circuit and by the applied voltage.

Frequency stability is rather poor when unsynchronized; however, stability is good when synchronized by an external timing pulse.

Circuit may be synchronized at the timing-pulse frequency or integral submultiple thereof.

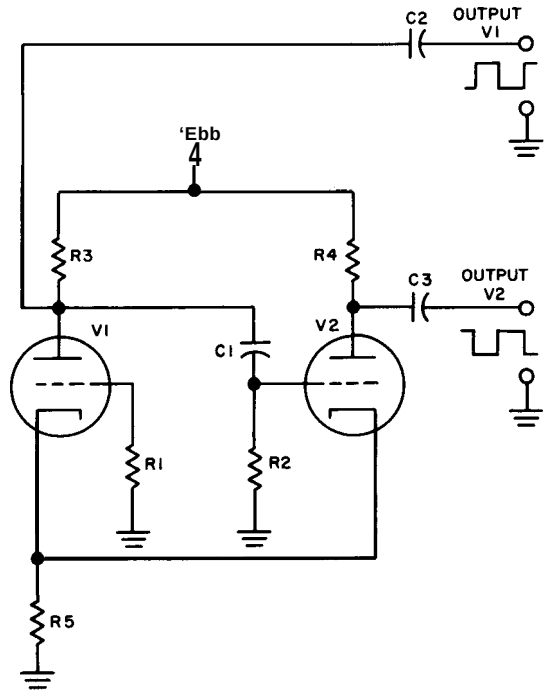
Either a symmetrical square- or rectangular-wave output or an unsymmetrical output maybe produced by changing circuit constants for voltages.

Output impedance is essentially equal to plate-load - impedance.

Circuit Analysis.

General. The triode cathode-coupled astable multivibrator is functiomlly similar to the basic Triode Plate-to-Grid-Coupled Astable Multivibrator discussed at the beginning of this section of the handbook. R-C coupling is provided from the plate of V1 to the grid of V2, as in the basic plate-to-grid-coupled circuit, but in this instance the coupling from V2 to V2 is direct, being affected in the cathode circuit through a common cathode resistor; the R-C coupling (in the basic circuit) from the plate of V2 to the grid of VI, is therefore, omitted. A variation of this cathode coupled circuit uses separate cathode bias resistors, with V2 coupled to V1 through a capacitor rather than directly. Output signals can be taken from the plate of either or both electron tubes, as in the basic plate-to-grid-coupled circuit configuration.

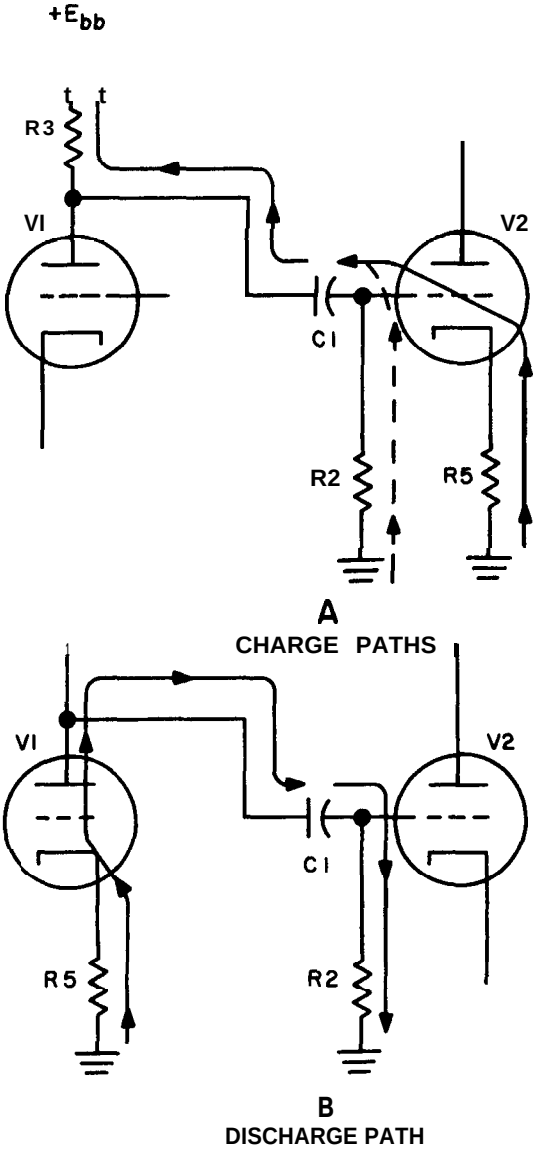
Circuit Operation. **The** following circuit schematic illustrates two triode electron tubes in a basic cathode-coupled astable (free-running) multivibrator circuit employing direct coupling in the cathode circuit. Electron tubes V1 and V2 are identical-type triode tubes; although the schematic illustrates separate triodes, a twin-triode is frequently used in this circuit. Capacitor Cl provides the coupling from the plate of V1 to the grid of V2. Resistors R1 and R2 are the grid resistors of V1 and V2, respectively; resistors R3 and R4 are the plate-load resistors of V1 and V2, respectively. Resistor R5 is the common cathode-coupling and bias resistor coupling V2 to VI.



Triode Cathode-Coupled Astabla Multivibrator (Direct Coupling)

Capacitors C2 and C3 are the output coupling capacitors for V1 and V2, respectively.

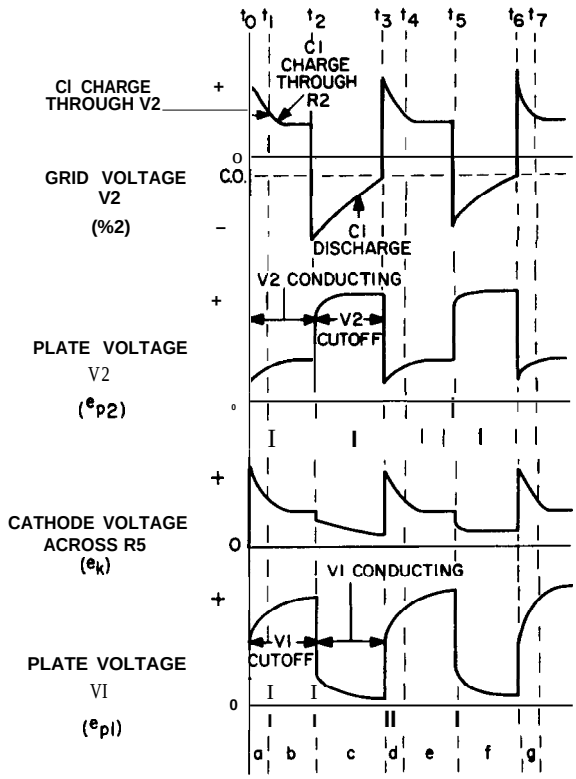
Capacitor Cl and resistor R2 form and R-C circuit establishing the time constant in the grid circuit of V2. The intial charge path for capacitor Cl is from its left side through V1 plate-load resistor R3 and the plate supply voltage to ground, then through cathode resistor R5 and the low (approximately IK) cathode-to-grid conduction resistance of V2 to the right side of Cl, as illustrated by the solid-line path in part A of the following simplified schematic diagram. When the conduction through V2 decreases, and the grid of V2 no longer draws current, the charge path for Cl is completed through grid resistor R2, as illustrated by the dotted-line path in the same diagram. For all practical purposes, Cl charge completely during the time that V2 conducts; the amount of charge via R2 is negligible. Part B of the diagram shows the discharge path for capacitor Cl to be through grid resistor R2, common cathode resistor R5, and the low cathode-to-plate conduction resistance of V1. The time constant of the charge path and the cutoff voltage level of V1 determine the length of time that V1 is cutoff; the time constant of the discharge path and the cutoff voltage level of V2 determine the length of time that V2 is cutoff.



Charge and Discharge paths for Capacitor C1

If the time constants for the charge and discharge of Cl are equal, a symmetrical square-wave output is produced by the circuit; by making the charge and discharge R-C time constants different, the circuit produces an asymmetrical, or unsymmetrical, rectangular-wave output. Although the conduction resistance of VI and the resistance of cathode resistor R5 are in the discharge path, their resistance value is small as compared with that of R2, and are, therefore, neglected in the discharge path time-constant calculations.

For the following discussion or circuit operation, refer to the preceding illustrations in addition to the following illustration which shows the theoretical waveforms for a symmetrical triode cathode-coupled a stable multivibrator employing direct coupling between the cathodes. When voltage is first applied, the grids of both tubes are at zero bias and plate current begins to flow through plate-load resistors R3 and R4. When voltage is applied to the plate of VI, capacitor Cl begins to charge along the path previously outlined. As Cl charges, the grid of V2 becomes positive. Since there is no coupling capacitor from the plate of V2 to the grid of VI, the voltage at the plate of V2 has no effect on the conduction of V1. The plate current of V2 flowing through cathode resistor R5 makes the voltage at the top of the resistor positive with respect to ground. This voltage is a bias voltage of sufficient amplitude to cut off conduction of V1 and still permit V2 to conduct, since at this time the grid of V1 is at ground (zero volts) and the grid of V2 is at a positive potential. Thus, the initial conditions fo circuit operation are established; that is, V2 is conducting and V1 is cut off.



Theoretical Waveforms for Symmetrical Cathode-Coupled Astable Multivibrator (Direct Coupling)

The foregoing multivibrator action is summarized at time t. (start of time interval a) on the waveform

491-044 0-73-49

illustration. Note that the grid of V2 (e_{g2}) is driven positive, causing heavy conduction through this tube. At the same instant, the plate voltage of V2 (e_{P2}) decreases (is negative-going) as a result of plate current through plate-load resistor R4. Also, the same plate current, flowing through common cathode resistor R5, produces a positive voltage (e_k) which provides a bias sufficient to cut off VI and cause the plate voltage (e_{P1}) of this tube to approach B+. The positive-going voltage at the plate of V1 is instantaneously coupled through capacitor Cl to the grid of V2, driving this grid still further positive. All of the action described is instantaneous and cumulative, so that the high positive potential on the grid of V2 causes this tube to conduct heavily, while VI is cut off.

With VI cut off, its plate voltage is at B+, and capacitor Cl charges toward this value. The waveform at the plate of V1 (e_{P1}) is rounded off, and the waveform at the grid of V2 (e_{g2}) has a small positive spike of the same time duration as a result of the charging of capacitor Cl. Since at this time V2 is conducting, its plate voltage (e_{P2}) drops. Note that the plate-voltage waveform has a small negative spike of the same time duration as the positive spike on the grid waveform.

As capacitor Cl charges, electrons are accumulated on its right side; this accumulation of electrons is a negative charge which acts in opposition to the positive potential on the grid of V2, in effect causing this potential to decrease from its most positive excursion. This is illustrated during time interval *a* (between t. and t_1), where the rapid charging of Cl is represented by the steep portion of the V2 grid voltage (e_{g2}) waveform. Note that during the rapid charge time of Cl the positive voltage on the grid of V2 decreases until, at t_1, it is equal to the voltage (e_k) across common cathode resistor R5. At this instant the grid of V2 ceases to draw current. However, Cl continues to charge, but at slower rate through grid resistor R2, which is much larger in value than the total resistance in the "fast" charge path. This change in the R-C time constants of the charging paths of Cl accounts for the abrupt change in the voltage waveforms at t_1.

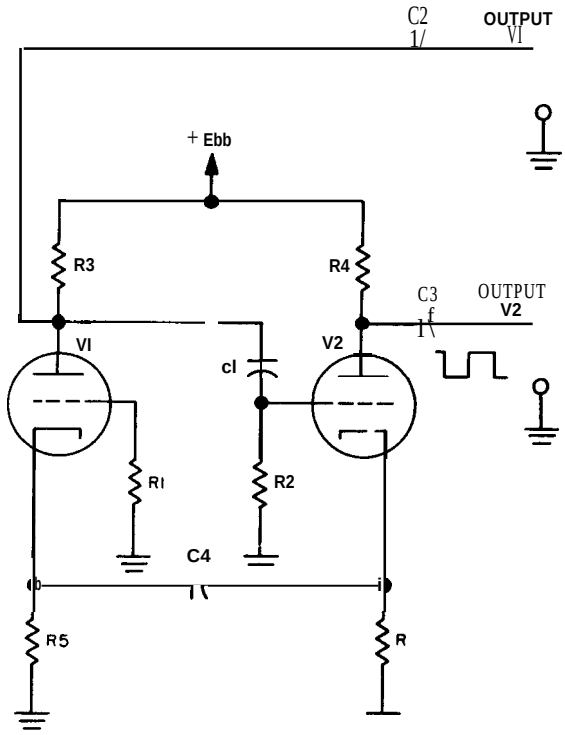
During time interval *b* (from t_1 to t_2), capacitor Cl continues to charge slowly and the grid voltage of V2 decreases slowly; this causes a reduction in the plate current of V2, which results in a decreasing voltage drop across common cathode resistor R5. This action continues until the voltage drop across resistor R5 decreases to the level where tube V1 is no longer held below cutoff. In other words, since the bias on tube V1 is determined by the cathode voltage (e_k), VI remains cut off so long as the cathode voltage is positive with respect to ground by more than the cutoff voltage (bias) of V1. When the cathode voltage drops to the level of the V1 cutoff voltage, as at t_2 on the cathode voltage (e_k) waveform, VI conducts and rapidly cuts off V2 because the large negative-going signal at its plate is coupled through capacitor C1 to the grid of V2. Thus, the first switching action occurs; that is, V2 is cutoff and VI is conducting.

When tube VI is conducting, capacitor Cl discharges through grid resistor R2, common cathode resistor R5, and the plate resistance of VI. The grid voltage of V2 approaches cutoff as capacitor Cl discharges; this is illustrated by the V2 grid voltage (e_{g2}) waveform during time interval c (between t_2 and t_3). At t_3 the grid voltage of V2 just reaches the cutoff level, permitting this tube to conduct. When the plate current of V2 increases, the voltage across common cathode resistor R5 (waveform e_k) also increases (goes positive); this increases the bias on V1 and thereby reduces the conduction of V1. The decreasing plate current of V1 produces a positive-going signal across its plate-load resistor, R3, which, in turn, is coupled through capacitor Cl to the grid of V2, causing this grid to become highly positive. In addition to increasing the plate current of V2, the positive grid voltage again causes grid current flow and charges capacitor Cl. Thus, the second switching action occurs and the cycle is now complete as the intitial conditions once again are reached; that is, V2 is conducting and VI is cutoff.

In the preceding discussion the multivibrator was considered to be a symmetrical type; that is, the periods for conduction and cutoff of the tubes are equal. An asymmetrical, or unbalanced, output can be obtained by having V2 cutoff for a longer period than V1. Adjusting the value of the cathode resistance will permit this to happen, since it is the bias voltage developed across the common cathode resistor that determines when VI begins conduction. In this case, the combined time intervals of a and *b* will be less than time interval c.

Another configuration of a triode cathode-coupled astable multivibrator is the circuit shown in the

following schematic diagram. This circuit is identi-cd to the basic common-cathode-resistor-coupled circuit just discussed, except that the feedback from V2 to VI now is by capacitive coupling through C4 between the two cathodes. Although the same switching action occurs between the two tubes and the cutoff time of V2 is still determined by the discharging of capacitor Cl through grid resistor R2, the cutoff time of VI in this instance is determined by the charging of capacitor C4 through its cathode resistor, R5. (Note that this circuit differs from the basic common-cathode-resistor-coupled multivibrator in that, in addition to capacitive coupling between cathodes, separate cathode resistors are used.)



Triode Cathode-Coupled Astable Muitivibrator (Capacitive Coupling)

The charge and discharge paths for capacitors Cl and C4 are depicted in the following illustration. Note that capacitor Cl (parts A and B of the illustration) the paths are the same as in the direct-coupled circuit just discussed, except that the cathode resistor through which capacitor Cl now charges initially is R6. The charge path for capacitor C4 (part C of the illustration) is from its right side through the low cathode-to-plate conduction resistance of V2, plate-load resistor R4, and the plate-supply voltage to ground, then through V1 cathode resistor R5 to its left side. Part D of the illustration shows the discharge path for capacitor C4 to be from its left side through the low cathode-to-plate conduction resistance of V], plate-load resistor R3, and the plate-supply voltage to ground, then through V2 cathode resistor R6 to its right side.

D. CAPACITOR C4 DISCHARGE PATH

Charge and Discharge Paths for Capacitors Cl and C4 of Capacitive-Coupled Muftivibrator

The free-running frequency of the output signal is determined primarily by the values of R-C time constants R2-C 1 in the grid of V2 and R5-C4 in the cathode circuit, and by the value of the applied voltage. The symmetry of the square-wave output signals depends upon the degree of balance between the two tubes and their associated circuit components.

Consider now the operation of the astable multivibrator being discussed. When voltage is first applied to the circuit, the grids of both tubes are at zero bias, and plate current begins to flow through plate-load resistors R3 and R4. Also, capacitor Cl begins to charge by drawing grid current through resistor R2 and tube V2, making the grid of this tube positive. The plate current of V2 flowing through cathode resistor R6 makes the voltage at the top of the resistor more positive with respect to ground. This positive voltage swing is coupled through capacitor C4 to the cathode of V1, where it acts as a bias voltage to hold V1 cutoff. At this instant, capacitor C4 begins charging through resistor R5 toward the positive voltage at the top of resistor R6. The positive voltage at the top of R5 holds V1 cut off until C4 reaches the approximate potential across R6. At this time, the decrease in current through R5 decreases the bias on VI and allows it to conduct, thereby causing the multivibrator switching action. That is, conduction of VI caauses the voltage at the VI plate to decrease, and this negative-going voltage is coupled through capacitor Cl to the grid of V2, where it drives the grid negative and cuts off V2.

When V2 is cutoff, capacitor Cl discharges through R2, R5, and V1. Also, the voltage on the cathode of V2 decreases (becomes less positive); this negative going voltage is coupled through capacitor C4 to the cathode of V1. Since V1 is already conducting the negative-going signal merely aids its conduction. However, the plate current of V1 flowing through cathode resistor R5 produces a positive voltage at the top of this resistor. Capacitor C4 now discharges through Vl, plate-load resistor R3, and cathode resistor R6. As capacitor C4 discharges, the voltage at the top of resistor R6 decreases (becomes less positive) because of the accumulation of electrons on the right side of capacitor C4. When the combination of the voltage on the grid of V2 (becoming less negative as capacitor Cl discharges through resistor R2) and the voltage on its cathode (becoming less positive as capacitor C4 discharges through resistor R6) decreases sufficiently, V2 again conducts. The switching action repeats continuously with first one tube and then the other tube conducting.

The output of the multivibrator is taken from either or both plate circuits through output coupling capacitor C2 or C3. In cases where it is desired to minimize the effect of varying load impedance on the frequency stability of the multivibrator, a cathode follower is used for stability.

The triode cathode-coupled astable multivibrator, like the plate-to-grid-coupled type, may be synchronized with a stable external souce to force the period of the multivibrator action to be exactly the same as that of the synchronizing source. The frequency of the synchronizing signal must be slightly higher than the natural operating frequency of the multivibrator so that the synchronizing pulse occurs just prior to the time that normal switching action would occur.

Failure Analysis.

No Output. Assuming that the multivibrator is a free-running type and no synchronizing signals are applied, the plate and filament voltages should be measured to determine whether they are within the specified values. If coupling capacitor Cl should become leaky or shorted, a positive potential will be present on the grid of V2 and, as a result, tube V2 will conduct heavily; V1 will remain cutoff because of the high positive potential (bias) on its cathode as a result of the heavy conduction of V2. If the circuit does not oscillate, measure the voltage at each plate to determine whether plate-load resistor R3 or R4 is open. If either resistor is open, there will be no voltage on the associated plate; also, the other tube will conduct heavily and, as a result of the heavy conduction, its plate voltage will be low.

In the common-cathode-resistor-coupled circuit configuration, if cathode resistor R5 were to open there would be no output because neither tube would conduct, and the plate voltage of both tubes would be at B+. In the capacitive-coupled-cathode circuit configuration, if cathode resistor R5 or R6 were to open only the associated tube (V1 or V2, respectively) would not conduct. If coupling capacitor C4 were to open there would be no feedback from V2 to V1, and thus no output from the multivibrator.

Reduced Output. A reduction in the output amplitude is generally caused by a defective tube; however, it can also be caused by a decrease in the applied

plate voltage or an increase in the resistance of the associated plate-load resistor, R3 or R4. If either output coupling capacitor, C2 or C3, should become leaky or shorted, the input resistor of the following stage can form a voltage divider which also includes the associated plate-load resistor, R3 or R4. If the input resistor of the following stage is returned to ground or to a negative potential, voltage-divider action may reduce the voltage available at the plate of the multivibrator and reduce the amplitude of the output waveform; also, the additional current through the plate-load resistor, R3 or R4, may cause the resistor to burn out. Furthermore, the operation of the following stage may also be affected by the change in grid-bias voltage resulting from the voltage-divider action.

Incorract Frequency or Pulse Width. The critical components governing the frequency and pulse width of the muhivibrator are those in the coupling circuits. Any change in the components governing the grid or cathode R-C time constants will directly affect the frequency and pulse width; a change in the R-C combinations of R2-C1 or R5-C4 will have the greatest effect. A change in the value of plate-load resistor R3 or R4 will affect the amplitude of the output; it will also have an effect on the frequency, but not nearly so much as the components mentioned above.

If the plate-supply voltage, $+E_{bb}$, should change approximately 10 percent from the specified value, a drift in frequency will generally occur; some frequency drift may also occur if the filament voltage should drop below the specified value.

In a practical circuit, where the multivibrator is free-running and not synchronized from an external source, a variable resistor may be provided to adjust the applied plate voltage or to adjust the value of resistance in each grid circuit. This provision enables the multivibrator to be adjusted to the correct frequency and pulse width, and permits adjustment to compensate for differences in individual tube characteristics when a tube substitution is made.

If either output coupling capacitor (C2 or C3) should become leaky or shorted, the voltage-divider action which can occur may reduce the amplitude of the output waveform and cause the multivibrator to operate at a higher frequency, since the grid capacitor (Cl) discharge time is dependent upon the amount of change in capacitor voltage.

PART 7-2. BISTABLE

BISTABLE (START-STOP) MULTIVIBRATORS

General.

The term bistable *multivibrator* refers to one class of multivibrator or relaxation oscillator circuits that can function in either of two stable states and is capable of switching rapidly from one stable state to the other upon the application of a trigger pulse. In the strict sense of the word, the bistable multivibrator is not an oscillator; rather, it is a circuit having two conditions of stable (bistable) equilibrium - and requiring two input triggers to complete a single cycle. The operation of the bistable multivibrator is dependent upon the timing-control action involved in the transfer of conduction from one tube to the other, initiated by an input trigger pulse of proper polarity and sufficient amplitude. Because there is a sudden reversal (or "flopping") from one stable state to the other, the bistable multivibrator is frequently referred to as a *flip-flop* circuit.

The bistable multivibrator produces an output pulse, more commonly called a "gate", having fast rise and fall times and extreme flatness on top. To generate this type of waveform the circuit requires one trigger pulse for turn-on (start) and another trigger pulse for turn-off (stop), thus generating a "step" function for each input trigger. When the trigger pulses are of constant frequency and are applied at long time intervals (low frequency), the gates generated are wide. On the other hand, when the trigger pulses are of constant frequency and are applied at short time intervals (high frequency), the gates generated are narrow. In all cases, however, two input trigger pulses are required to complete one cycle of operation, resulting in an output gate frequency one- - half that of the input trigger frequency.

Although the turn-on and turn-off input trigger pulses (which can be applied from different sources as well) can be of either positive or negative polarity, a negative trigger is preferred. A reason for this requirement is that if a tube is biased far beyond cutoff, a high-amplitude positive pulse is required to drive the tube from cut off into conduction. On the other hand, a low-amplitude negative pulse will immediately cut off conduction of a tube. In addition, the circuit used to generate a low-amplitude pulse requires less power.

When a transistor is operating in the saturation region, a phenomenon known as minon"ty carn"er storage occurs. Because the collector-base voltage is limited in its excursion by the resistance in the collector circuit, the collector cannot accept all of the minority carriers injected by the emitter, and, as a result, an excess of minority carriers is built up in the base region. In a PNP transistor that is in a state of saturation, an excess of holes is built up in the base; before the transistor can be turned off, this excess must be removed. Thus, the turn-off operation is a function of the amount of minority carrier storage. Minority carrier storage is one limiting factor in the switching speed of the multivibrator; other factors that limit the switching speed are the operating level of the transistors, collector capacitance, and external circuit elements.

Minority carrier storage can be prevented by limiting the excursion of the collector voltage of a switching stage to an area outside the saturation region of the transistor. In this case, the collector current is not limited by the collector circuit resistance, but rather by the maximum current limitation of the transistor. This is the basis of operation of the "nonsaturating multivibrator"; this circuit is discussed in detail later in this section, as are several other semiconductor bistable multivibrator circuits and bistable multivibrator triggering techniques.

The rectangular-gate output of the bistable multivibrator can be either positive or negative in polarity. Each gate is formed by the combination of positive and negative step functions produced by turning the multivibrator on and off. The negative-going step is inherently faster than the positive-going step. When connecting other circuits to the bistable multivibrator output, precautions should be taken so as to prevent the shunting capacitance from causing undesirable effects on the rise and fall times of the step function.

BASIC FLIP-FLOP (ECCLES-JORDAN) MU LTIVIBRATOR (ELECTRON TUBE)

Application.

The basic flip-flop (Eccles-Jordan) multivibrator produces a square-or rectangular-wave output for use as gating or timing signals, or for on-off switching operations in binary counter circuits.

Characteristics.

Circuit assumes one of two stable states: one tube normally conducting with the other tube normally cut off, and vice versa.

Requires two input triggers to complete one cycle of operation; the circuit assumes a stable state upon completion of each half-cycle of operation.

For a constant-frequency input, the output frequency is one-half that of the input trigger frequency.

Input triggers can be either positive or negative; positive trigger affects normally cut-off tube, and negative trigger affects normally conducting tube.

Symmetrical triggering occurs when the same trigger pulse is applied simultaneously; unsymmetrical triggering occurs when triggers are applied separately.

Symmetrical or unsymmetrical output gate depends on timing sequence of input trigger pulses; input triggers from different sources (turn-on and turn-off triggers) produce unsymmetrical gate output.

Plate-to-grid feedback coupling is direct (through resistors), with bypass capacitors used to speed up switching from one stable state to the other.

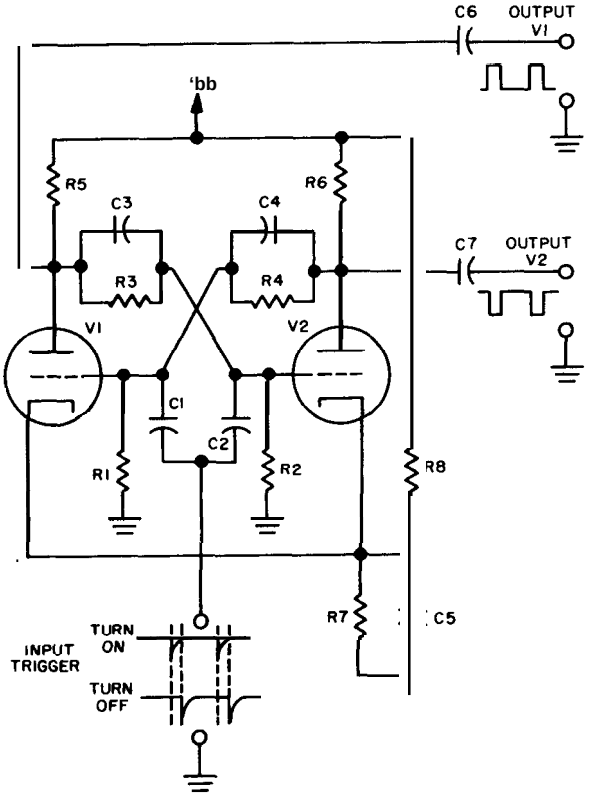
Circuit can be made to assume the same stable state whenever voltages are applied by incorporating a definite imbalance within the circuit or by using a manually controlled "reset" signal.

Tubes can be grid-biased by connecting to negative supply, or cathode-biased by connecting cathodes through voltage divider to positive supply.

Circuit Analysis.

General. The basic flip-flop (Eccles-Jordan) Multivibrator is capable of producing a square- or rectangular-wave output pulse (gate) in response to two input triggers. This type of multivibrator has two stable (bistable) states – one tube is normally conducting while the other tube is normally held cut off – and will function for only one-half cycle upon the application of an input trigger. Feedback from the plate of one tube to the grid of the other is direct through a coupling resistor bypassed with a capacitor, whose function is to reduce or eliminate the effects of tube interelectrode capacitance. Because two input triggers (turn-on and turn-off) are required to complete one cycle of operation, the output-gate frequency of the bistable multivibrator is one-half the input trigger frequency. The output gate length is determined by the time interval of the turn-on and turn-off input trigger. Output signals can be taken from the plate of either or both electron tubes.

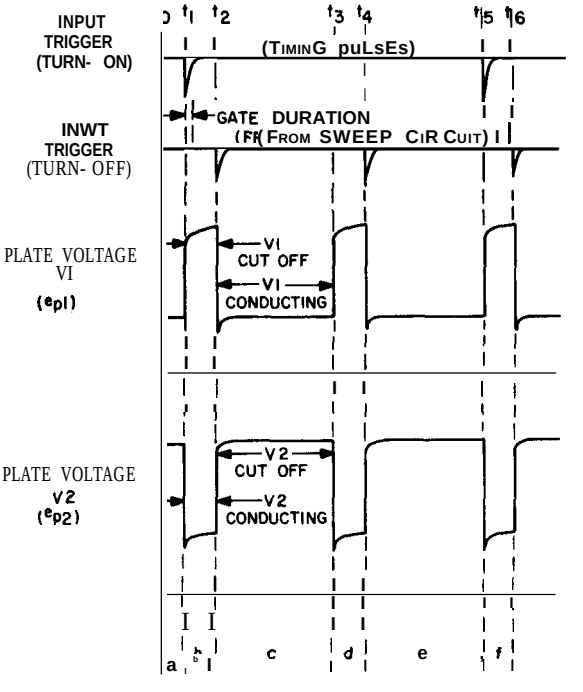
Circuit Operation. The accompanying circuit schematic illustrates two triode electron tubes in the basic



Basic FlipFlop Multivibretor

multivibrator circuit. Electron tubes VI and V2 are identical-type triode tubes; although the accompanying schematic illustrates two separate triodes, a twin-triode is frequently used in this circuit. Resistors R1 and R2 are the grid resistors for V1 and V2, respectively. Resistor R3 provides the direct coupling from the plate of V1 to the grid of V2, and resistor R4 provides the direct coupling from the plate of V2 to the grid of V1. Feedback resistors R3 and R4 are bypassed with capacitors C3 and C4, respectively. These capacitors permit faster switching action from one tube to the other by reducing the effects of tube interelectrode capacitance. Resistors R5 and R6 are the plate-load resistors for V1 and V2, respectively. Capacitors Cl and C2 are the input-trigger coupling capacitors for VI and V2, respectively; they provide symmetrical triggering. Capacitors C6 and C7 are the output-gate coupling capacitors for V1 and V2, respectively. Operating bias for this bistable multivibrator, which is cathode-biased, is determined by the combination of the cathode and respective grid circuit voltage dividers. The cathode circuit voltage divider consists of common cathode resistor R7, bypassed with capacitor C5, and resistor R8; the voltage divider for the grid circuit of V1 consists of resistors Rl, R4, and R6, and the voltage divider for the grid circuit of V2 consists of resistors R2, R3, and R5.

Consider now the operation of the basic flip-flop multivibrator by referring to the preceding circuit illustration and the following illustration of the idealized theoretical waveforms. Also, in order to more fully analyze the timing sequence, assume that the circuit under consideration is for a radar application wherein it is desirable to have the gate length contolled by the display circuit. Thus, the radar sweep circuit provides the turn-off trigger to return the multivibrator to its initial stable state.



Theoretical Waveforms for Basic FlipFlop Multivibrator

When voltage is first applied to the circuit, there is a slight conduction through both tubes. Because of the inherent imbalance of the circuit, however, one tube will conduct slightly more than the other. For example, if initially the current through V1 should be slightly greater than that through V2, the voltage drop across plate-load resistor R5 will be greater than the drop across plate-load resistor R6. This results in a lower plate voltage for V1, which is applied through resistor R3 to the grid of V2, thus causing the voltage at this grid to become more negative and reduce the current through V2. When the plate current through V2 is reduced, the current through plate-load resistor R6 likewise is reduced; therefore, the voltage drop across resistor R6 decreases, resulting in a rise in the plate voltage of V2. The positive-going plate voltage of V2 is applied through resistor R4 to the grid of V1, making this grid more positive. The regenerative action just described continues rapidly until V2 is cut off and VI is at maximum conduction. Thus, the circuit is in one of its two stable states of equilibrium, as represented by time interval *a* on the waveform illustration. Note that the output at the plate of V1 is at its most negative excursion (V1 is conducting) while the output at the plate of V2 is positive (V2 is cut off). Since there is no internal R-C time constant timing circuit to drive the nonconducting tube out of cutoff, the circuit remains in this stable condition until an input trigger pulse is applied.

Assume now that a negative trigger pulse of sufficient amplitude is applied simultaneously to both grids through input capacitors Cl and C2. This trigger pulse, which is the turn-on input trigger from the radar timing circuits, is applied at t_1 as illustrated on the waveform diagram. Because V2 is already cut off, the input trigger has little effect on this tube; however, the same negative trigger pulse drives the grid of V1 below cutoff, causing this normally conducting tube to decrease conduction. As soon as V1 reduces conduction, its plate voltage rises toward the plate-supply voltage, $+E_{bb}$. The positive-going signal at the plate of V1 is now coupled through resistor R3 and applied to the grid of V2, driving V2 into conduction. Thus, at instant t_1 a switching action occurs; V2 now conducts heavily, as indicated by the waveform at its plate, and V1 is cutoff. The multivibrator remains in this condition, which is its second stable state as depicted by time interval b, until another trigger is applied.

When the desired gate duration is attained, the negative turn-off trigger from the radar sweep circuits is applied (at t_2) and the gate is terminated. The negative-going turn-off trigger cuts off conduction of V2 and causes a switching action that returns the multivibrator to its original stable state, in which VI is conducting and V2 is cut off. The circuit remains in this condition (time interval c) until another negative trigger from the radar timing circuits is applied at t_3.

Close examination of the waveform illustration reveals that the length of the output gates is determined by the time interval between the turn-on and turn-off triggers. if the frequency of the turn-off trigger is made lower, the time interval between the triggers will increase; hence, the gate length will likewise increase. Conversely, the gate length will decrease if the turn-off trigger frequency is increased. Thus, the bistable multivibrator provides a positive or negative gate output in response to a timing (turn-on) input trigger pulse, with the gate being terminated by a turn-off trigger pulse. If a single constant-frequency trigger is used for both the turn-on and turn-off functions, the circuit will produce a symmetrical square-wave output having a frequency one-half that of the input-trigger frequency.

In the symmetrical-input bistable multivibrator being considered, positive input trigger pulses of sufficient amplitude can also be used to initiate the switching action between tubes V1 and V2. When the positive trigger pulse is applied simultaneously to the grids of the tubes, there will be no effect on the operation of the conducting tube. However, the plate current of the cut-off tube will be increased, causing its plate voltage to fall. The fall in plate voltage, when coupled to the grid of the conducting tube, drives this tube into cutoff.

Although it is true that either negative or positive input trigger pulses can cause the switching action to occur, triggering with negative pulses is preferred. For example, if the cut-off tube is biased with a high negative potential, a high-amplitude positive pulse is required to drive the tube into conduction, and only the most positive portion of the pulse has any effect. On the other hand, a low-amplitude negative pulse applied to the conducting tube immediately drives

this tube into cutoff, causing an instantaneous switching action.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuit and whether it is of the proper polarity and amplitude. Lack of an input trigger at the grid of V1 or V2 can be due to an open coupling capacitor, C 1 or C2, or to failure of the external input-trigger source.

Failure of the plate voltage supply, $+E_{bb}$, will disrupt the operation of the circuit, as will an open cathode circuit. With tubes (or a single twin-triode tube) installed in the circuit, the filament and plate voltages should be measured, as well as the bias voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether plate-load resistor R5 or R6 and cathode-bias resistor R7 or R8 is open. If coupling resistor R3 or R4 is open there will be no feedback signal to cause the muhivibrator switching action. If bypass capacitor C3 or C4 is open feedback will still occur, but the interelectrode capacitance of the tube may cause undesirable effects on the wavefront of the feedback signal. An open output coupling capacitor, C6 or C7, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective tube; however, it can also be caused by a decrease in the applied plate voltage or an increase in the resistance of the associated plate-load resistor, R5 or R6. A leaky or shorted output coupling capacitor, C6 or C7, will form a voltage divider with the input resistor of the following stage. If the input resistor of this following stage is returned to ground or to a negative supply, the voltage at the plate of both VI and V2 will be reduced, and the operation of the following stage will be upset by the change in voltage applied to its grid. Also, the additional current through plate-load resistor R5 or R6 may cause the resistor to burn out.

Incorrect Frequency or Gate Width. The basic flip-flop multivibrator has no components governing the frequency or width of its output-gate signal; these are both governed by the input triggers applied to the circuit. Therefore, any change in the output-gate frequency or width is a result of improper operation of the turn-on and/or turn-off trigger generating circuits.

BASIC FLIP-FLOP MULTI VIBRATOR (SEMICONDUCTOR)

Application.

The basic flip-flop multivibrator produces a square-or rectangular-wave output for use as gating or timing signals in radar sets. It is also used in switching-circuit applications, and for computer logic operations which include counting, shift-registers, clock pulses, and memory circuitry. This circuit is often used for relay-control functions, and for a variety of similar applications in radar and communications systems.

Characteristics,

Circuit assumes one of two stable states: one transistor normally conducts while the other transistor is cut off, and vice versa.

Requires two input triggers to complete one cycle of operation; the circuit assumes a stable state upon completion of each half-cycle of operation.

For a constant-frequency input, the output frequency is one-half that of the input trigger frequency.

Input trigger can be either positive or negative (positive trigger may be applied to base of conducting transistor, and negative trigger may be applied to base of cut-off transistor in common-emitter circuit configuration).

Symmetrical triggering occurs when the same trigger pulse is applied simultaneously; unsymmetrical triggering occurs when triggers are applied separately.

Symmetrical or unsymmetrical output gate depends on timing sequence of input trigger pulses; input triggers from different sources (turn-on and turn-off triggers) produce unsymmetrical output gate.

Collector-to-base feedback coupling is direct (through resistors), with bypass capacitors used to speed up switching from one stable state to the other.

Circuit can be made to assume the same initial stable state whenever voltages are applied by incorporating a definite imbalance within the circuit, or by using a manually controlled “reset” signal.

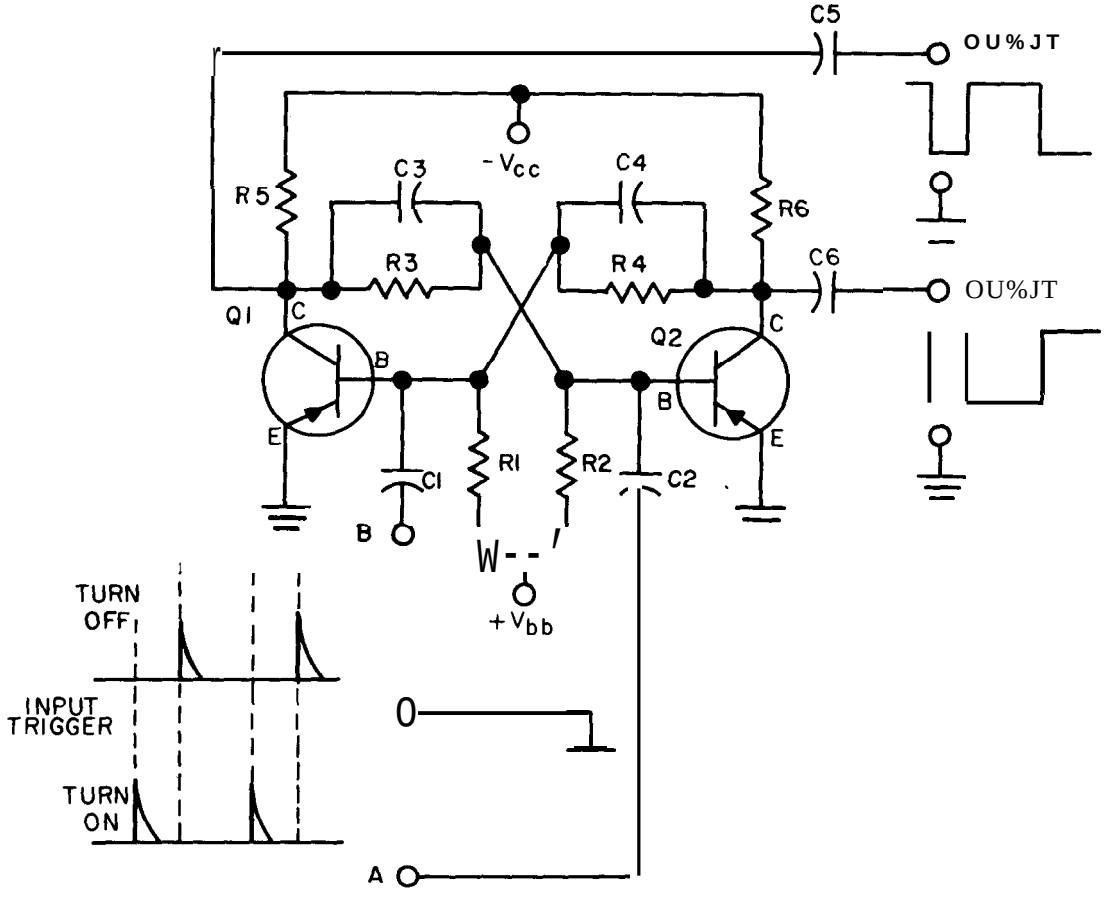
Output is taken from collector of either transistor in common-emitter circuit configuration.

Output impedance is low when transistor is in conducting (on) state; output impedance is approximately equal to collector load resistance when transistor is in cutoff (off) state.

Circuit Analysis.

General. The basic flip-flop multivibrator is capable of producing a square- or rectangular-wave output pulse (gate) in response to two input triggers. This type of multivibrator has two stable (bistable) states – one transistor is normally conducting while the other transistor is normally held cut off – each one functions for only one-half cycle when triggered. Feedback from the collector of one transistor to the base of the other is direct through a coupling resistor bypassed by a capacitor. The capacity shunts the high-frequency components of the pulse from collector to base around the coupling resistor so that the rapid change taking place at one collector is coupled, with minimum attenuation, to the base of the other transistor. Because two input triggers (turn-on and turn-off) are required to complete one cycle of operation, the output gate frequency of the flip-flop multivibrator is one-half the input trigger frequency. The output gate length is determined by the time interval between the turn-on and turn-off triggers. Output signals are taken from the collector of either or both transistors in the common emitter circuit configuration.

Circuit Operation. The accompanying circuit schematic illustrates two transistors in a basic flip-flop multivibrator circuit. Transistors Q1 and Q2 are



Basic Flip-Flop Multivibrator Using PNP Transistors

identical PNP transistors used in a common-emitter circuit configuration; either junction or point-contact transistors may be used in this circuit. Resistors RI and R2 are the base-biasing resistors for Q1 and Q2, respectively. Resistor R3 provides the direct coupling from the collector of Q1 to the base of Q2, and resistor R4 provides the direct coupling from the collector of Q2 to the base of QI. Feedback resistors R3 and R4 are bypassed with capacitors C3 and C4, respectively; these capacitors permit faster switching action from one transistor to the other. Resistors R5 and R6 are the collector-load and output resistors for Q1 and Q2, respectively. Capacitors Cl and C2 are the input trigger coupling capacitors for Q1 and Q2, respectively; they provide unsymmetrical triggering. Capacitors C5 and C6 are the output-gate coupling capacitors for Q] and Q2, respectively. An output waveform can be taken from the collector element of either transistor, or output waveforms can be taken from the collector elements of both transistors simultaneously.

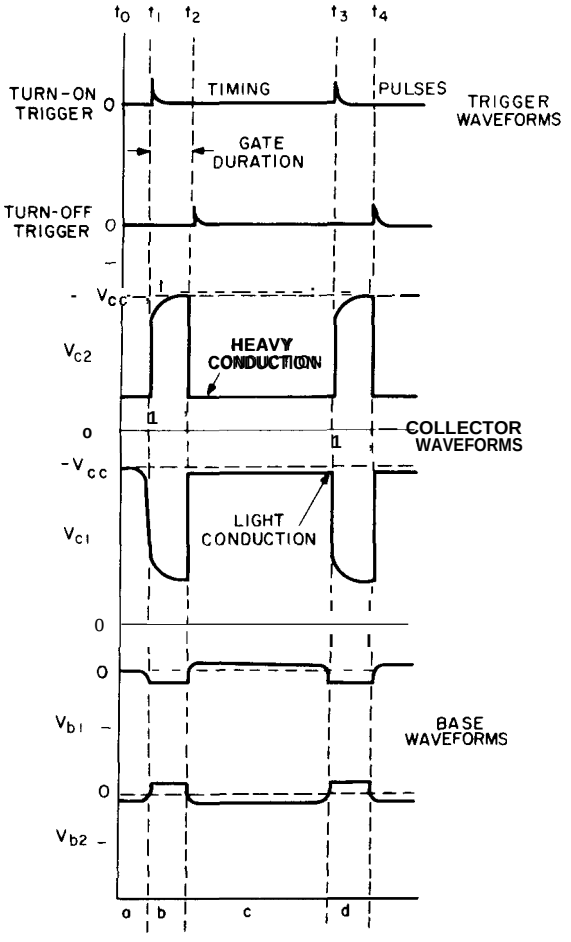
Fixed bias for the PNP transistors of this flip-flop multivibrator is obtained from two separate d-c voltage sources via voltage-divider networks. Resistors R1, R4, and R6 form one voltage divider between the positive d-c ($+V_{BB}$) and negative d-c ($-V_{cc}$) supply voltages. The resistor values are selected so that the voltage at the top of RI is negative with respect to the grounded P-type emitter of Q1; thus, the emitter of Q1 is forward biased with respect to the N-type base. Another voltage divider, consisting of resistors R2, R3, and R5 between the positive and negative supply voltages, forward biases the emitter of Q2 in the same manner. That is, the voltage at the top of R2 (at the N-type base of Q2) is negative with respect to the P-type emitter of Q2. Because of the voltage-divider action, the voltage at the collector of each transistor is more negative than the voltage at its base; thus, the collector-base junction of each PNP transistor is reverse biased.

When voltage is first applied to the circuit, the current which flows in each collector load resistor (R5 and R6) is determined by the effective resistance offered by transistors Q1 and Q2 for a given value of base-bias voltage. Although the multivibrator shown in the schematic appears to be a balanced circuit, and in spite of the use of close-tolerance components, there is always minor differences in internal resistance within the transistors. As a result of this inherent imbalance, the initial collector current (resulting from the forward-bias conditions set up by the emitter-base junction resistances and bias resistors R1 and R2) for each transistor is different, and the immediate effect produced by regenerative action between the coupled stages is that one transistor conducts while the other is cut off.

For the purpose of this explanation, assume initially that more collector current flows through transistor QI than through transistor Q2; thus, as the collector current of Q1 increases, the negative voltage at the collector of Q1 decreases with respect to its emitter, or ground. Thus, the collector of Q1 becomes less negative and this, in effect, acts as a positive -going pulse, which is directly coupled through resistor R3 to the base of transistor Q2. The positive-going pulse at the base of Q2 makes the base positive with respect to the emitter (ground) and, as a result, Q2 is reverse-biased and approaches cutoff. The collector current of Q2 decreases because of the reverse-bias action between its base and emitter, and the voltage at the collector of Q2 increases, rising towards the value of the supply voltage. In other words, as the collector of Q2 becomes more negative a negative-going pulse is developed across R6, which is directly coupled through resistor R4 to the base of transistor Q1. The negative-going pulse at the base of Q1 makes the base negative with respect to its emitter (ground), and increase the forward bias on the base, causing the collector current of Q1 to further increase. This regenerative process continues until Q1 is driven into saturation (as a result of the increased forward-bias), and Q2 is cut off (as a result of the increased reverse-bias). Thus, with the initial application of dc power, one transistor is turned on while the other is cut off, and each transistor is then held in this particular state of operation by the feedback from the other transistor until the off-trigger arrives.

For the following discussion of basic flip-flop multivibrator circuit operation, refer to the preceding circuit schematic and the following illustration of the idealized theoretical waveforms. Assume that transistor Q1 has been initially turned on and is conducting heavily in a saturated state, while transistor Q2 remains cut off. Thus, the circuit is resting in one of its two stable states of equilibrium as discussed above. The initial turn-on period is represented by time interval *a* on the waveform illustration, while the steady state conducting condition of Q1 is represented by time interval b. Therefore, the output at the collector of Q1 is at its most positive excursion,

while the output at the collector of **Q2** is at its most negative excursion (Q2 is cutoff). Since there is no internal time constant circuit provided to permit the nonconducting transistor to be automatically raised above cutoff (the fixed bias network ensures that it is held below cutoff), the circuit remains in this stable condition until a positive off-trigger is applied Q1.



Theoretical Waveforms for Basic Flip-Flop Multivibrator (Using PNP Transistors)

At time t_2, the positive turn-off trigger is applied to terminal B, and the base of Q1 is instantaneously driven below cutoff. Collector current flow through Q1 reduces, and heavy collector current flow through Q2 develops a positive-going output voltage across R6, which is also applied through R4 and C4 to reverse bias the base of Q1. This additonal reverse-bias quickly causes Q1 collector current to cease, and the collector voltages rises quickly towards the supply value producing a negative-going output through C5. At the same time, this negative-going collector voltage is fed back through R3 and C3 to the base of Q2 as a forward bias. This continuous feedback action of reverse bias on Q1 and forward bias on Q2 continues until the collector voltage on Q2 bottoms, or saturation is reached. The circuit now rests in its second stable state, (during time interval c) with Q1 nonconducting while Q2 conducts heavily. The switching action is speeded up by capacitors C3 and C4 which allow the instantaneous changes to be immediately applied to the associated base element to produce the steep leading and trailing edges of the waveform. The circuit remains in this condition (time interval c) until another turn-on trigger of positive polarity is applied to terminal A.

At time t_3, the positive turn-on trigger is applied to C2 and the base of Q2 which is forward biased and heavily conducting. The instantaneous positive bias produced by the input signal cancels the existing forward bias and reverse-biases Q2, stopping collector current flow. As the collector current of Q2 ceases, the collector voltage of Q2 rises towards that of the supply and produces a negative-going output signal. Meanwhile, this negative output voltage is also fed back to the base of Q1 through feedback resistor R4 which is bypassed by C4. The instantaneous negative swing through C4 quickly drives the base of QI in a forward-biased direction, and causes Q1 to conduct. As Q1 conducts, an output voltage of positive-going polarity is developed across R5, and is fed back through R3, bypassed by C3, to the base of Q2 driving it still further towards cutoff. Thus Q2 is held cut off, while Q1 once again conducts heavily near saturation. This is the starting condition and the other stable "operating point (time interval d on the waveform).

Close examination of the waveform illustration reveals that the length of the output gates is determined by the time interval between the turn-on and turn-off triggers. If the frequency of the turn-off trigger is made lower, the time interval between the triggers will increase; hence, the gate length will decrease if the turn-off trigger frequency is increased. Thus, the bistable multivibrator provides a positive or negative output gate in response to a timing input (turn-on) trigger pulse, with the gate being terminated by a

turn-off trigger pulse. If a single constant-frequency trigger is used for both the turn-on and turn-off functions, the circuit produces a symmetn"cal square wave output, with a frequency one-half that of the trigger frequency. A single pulse can be used for triggering because either the leading or the trailing edge of the trigger can be used. When conducting, and the leading edge is applied, a positive trigger operates to reverse bias the conducting transistor while the feedback causes the nonconducting transistor to be turned on. Conversely, if the trailing edge of the trigger pulse is applied to the nonconducting transistor, it produces a forward-biased condition and starts the transistor conducting, while feedback from the transistor produces a reverse bias to stop the first transistor from operating. This action is true as long as the trigger is a sharp pulse of short duration. If of long duration, an unsymmetrical output will be produced.

In the symmetrical-input bistable multivibrator under discussion, negative trigger pulses of sufficient amplitude can also be used to initiate the switching action between transistors Q1 and Q2. When the negative pulse is applied simultaneously to the base of the transistors, there will be no effect on the operation of the conducting tube. However, the collector current on the cut-off transistor will be increased, causing the collector voltage to decrease. The decrease in collector voltage when coupled to the grid of the nonconducting transistor drives this transistor into full conduction. In turn, feedback through this newly turned on transistor biases off the originally conducting transistor.

Although it is true that either negative or positive input trigger pulses can cause the switching action to occur, triggering with positive pulses is preferred. For example, if the cut-off transistor is biased with a highly positive potential, a high-amplitude negative pulse is required to drive it into conduction, and only the most negative portion of the pulse has any effect. On the other hand, a low amplitude positive pulse applied to the conducting transistor immediately drives this transistor into cutoff, causing a relatively instantaneous switching action.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuit, and whether it is of the proper amplitude and polarity. Lack of an input trigger at the base of Q1 or Q2 can be due to an open coupling capacitor, C 1 or C2, or to failure of the external input-trigger source. If the input signal does not appear on the base side of the capacitor use an in-circuit capacitance checker to check C 1 or C2 for proper capacitance or an open circuit.

Failure of the base bias or collector bias supply will disrupt operation of the circuit as would an open feedback circuit. Use a voltmeter to check the base bias, collector, and supply voltages. Normal voltage indications on these elements also indicates that neither RI nor R2 is open and, likewise, R3 and R4 also. If either C3 or C4 is opened, the circuit will still operate as a direct-coupled unit and operation will be somewhat slowed up, but an output will still be obtained. If normal signals appear on the collectors but not at the output, coupling capacitor C5 or C6 is probably open. Use an in-circuit capacitance checker to verify the capacitance value and to check for an open or shorted condition.

Reduced Output. A reduction of output is usually caused by low collector voltage, improper bias, or defective transistor. A change in the resistance of the associated collector load resistor R5 or R6 will also affect the output amplitude. Check the resistance with an ohmmeter. A leaky or shorted output coupling capacitor, C5 or C6, will form a voltage divider with the input resistor of the following stage. If the input resistor of the following stage is returned to ground or to a bias supply, the collector voltage on either Q1 or Q2 will be changed and operation of the following stage will be upset by the change in voltage on its grid. In addition, this may possibly cause additional collector current flow through collector resistor R5 or R6 and may cause the resistor to burn out.

Incorrect Frequency or Gate Width. The 'basic flip-flop multivibrator has no parts governing the frequency or width of the output gate signal; these are both governed by the input triggers applied to the circuit. Therefore, any change in the output-gate frequency or width is a direct result of improper operation of the turn-on and/or turn-off trigger generating circuits.

PENTODE FLIP-FLOP (ECCLES-JORDAN) MU LTIVIBRATOR

Application.

Same application as basic flip-flop (Eccles-Jordan) multivibrator (electron tube).

Characteristics.

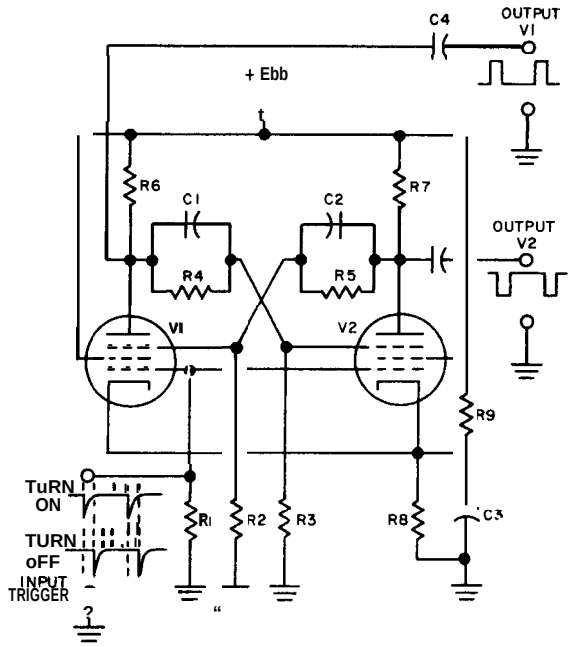
Same characteristics as basic flip-flop (Eccles-Jordan) multivibrator (electron tube), except it uses plate-to-supressor grid feedback coupling instead of plate-to-grid feedback coupling.

Circuit Analysis.

General. The pentode Eccles-Jordan (flip-flop) multivibrator is capable of producing a square- or rectangular-wave output pulse (gate) in response to two input triggers. The circuit has two stable (bistable) states – one tube is normally conducting while the other tube is normally held cutoff. Like the triode Eccles-Jordan multivibrator, discussed earlier in this Section of the Handbook, the circuit operation is controlled by the application of an input trigger pulse which causes the conduction to switch from one tube to the other. Thus, the multivibrator will function for only one-half cycle upon the application of each input trigger. Feedback from the plate of one tube to the suppressor grid of the other is direct through a coupling resistor bypassed with a capacitor, whose function is to reduce or eliminate the effects of tube interelectrode capacitance.

The feedback connection to the opposite suppressor gird, instead of the control grid, frees the control grid for application of the trigger pulses. Because two input triggers (turn-on and turn-off) are required to complete on cycle of operation, the output-gate frequency of the bistable multivibrator is one-half the input trigger frequency. The output gate length is determined by the time interval of the turn-off input triggers. Output signals can be taken from the plate of either or both electron tubes.

Circuit Operation. The accompanying circuit schematic illustrates two pentode electron tubes in an Eccles-Jordan bistable multivibrator configuration.

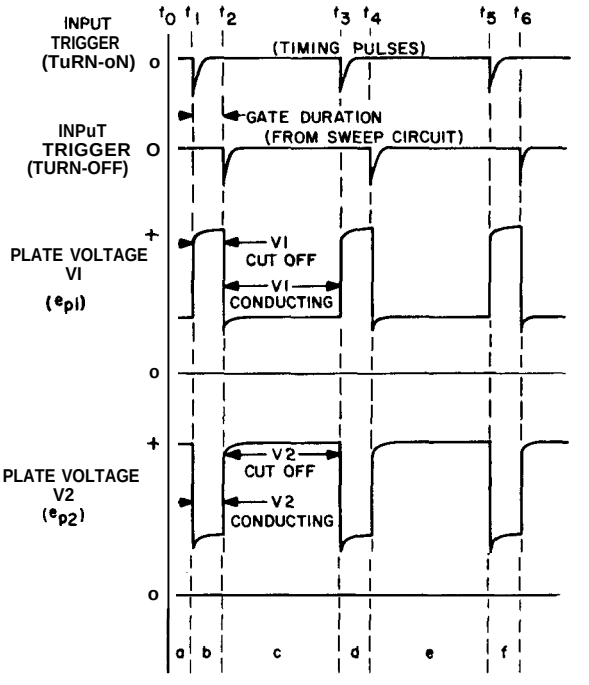


Pentode Eccles-Jordon (FlipFlop) Multivibrator

Electron tubes VI and V2 are identical sharp cutoff pentode-type tubes. Resistor R1 is a common grid resistor for both tubes. Resistors R2 and R3 are the suppressor grid resistors for V1 and V2, respectively. Resistor R4 provides direct-coupled feedback from the plate of V1 to the suppressor grid of V2; resistor R5 provides direct-coupled feedback from the plate of V2 to the suppressor grid of VI. Feedback resistors R4 and R5 are bypassed with capacitors Cl and C2, respectively. These capacitors permit faster

switching action from one tube to the other by reducing the effect of tube interelectrode capacitances, Resistors R6 and R7 are the plate-load resistors for VI and V2, respectively; the screen grids are tied directly to the supply voltage, $+E_{bb}$. Suppressor grid voltage for V1 is obtained from a voltage divider consisting of resistors R2, R5, and R7; suppressor grid voltage for V2 is obtained from a voltage divider consisting of resistors R3, R4, and R6. Capacitors C4 and C5 are the output coupling capacitors for V1 and V2, respectively. Operating bias for this bistable multivibrator, which is cathode-biased, is obtained from a voltage divider consisting of common cathode resistor R8, bypassed with capacitor C3, and resistor R9. A comparison of the pentode and triode Eccles-Jordan multivibrator circuits reveals their similarities and differences.

Consider now the operation of the pentode Eccles-Jordan multivibrator by referring to the preceding circuit illustration. Since the output-gate waveforms of the pentode circuit are similar to those of the triode Eccles-Jordan multivibrator presented earlier in this Section of the Handbook, reference to the triode circuit waveforms can be made for this pentode circuit as well. The waveforms are reproduced in the following figure for convenience.



Theoretical Waveforms for Pentode Eccles-Jordan (Flip Flop) Multivibrator

When voltage is first applied to the circuit, there is a slight conduction through both tubes. However, because of the inherent imbalance of the circuit, one tube will conduct slightly more than the other. For example, if initially the current through V1 should be slightly greater than that through V2, the voltage drop across plate-load resistor R6 will be greater than the drop across plate-load resistor R7. This results in a lower plate voltage for VI, which is applied through resistor R4 to the suppressor grid of V2. The negative-going signal on the V2 suppressor grid reduces the plate current of this tube, thus reducing the current through plate-load resistor R7 and causing a voltage rise at the plate of V2. This positive-going voltage is coupled through resistor R5 to the suppressor grid of V1, further increasing the plate current of V1. Suppressor grid current flows at a slight positive suppressor grid voltage, but decreases at a high positive suppressor grid voltage, such as when the positive-going signal is applied from the plate of V2. The plate current of V1 increases further, and a regenerative action occurs instantaneously to drive V1 into heavy conduction and V2 into cutoff. Thus, the multivibrator is in one of its stable states, as depicted during time interval *a* in the waveform illustration referenced previously. Since there is no internal R-C time constant timing circuit to drive the nonconducting tube out of cutoff, the circuit remains in this stable state until a timing pulse is applied to the control grids to cause the switching action.

Assume now that a negative trigger pulse of sufficient amplitude is applied simultaneously to both control grids. The trigger pulse, applied at t 1, has little effect on the operation of V2 since this tube is already cut off. However, the same negative trigger drives the grid of VI below cutoff, causing this tube to reduce conduction. As soon as V1 reduces conduction, its plate voltage rises toward the plate supply voltage, $+E_{bb}$. The positive-going signal at the plate of VI is now coupled through resistor R4 and applied to the suppressor of V2 driving V2 into conduction. Thus, at instant t_1 a switching action occurs, with the result that V2 now becomes the conducting tube and V1 is cut off. Thus, the circuit is in the second of its two stable states, as depicted during time interval b. The multivibrator remains in the condition wherein V2 is conducting and VI is cut off until the next negative trigger pulse is applied to cause another switching action.

When the desired gate duration is attained, the negative turn-off trigger is applied (at t_2) and the gate is terminated. The negative-going turn-off trigger cuts off conduction of V2 and causes a switching action that returns the multivibrator to its original stable state wherein VI is conducting and V2 is cut off. The circuit remains in this condition (time interval c) until another negative trigger from the timing circuits, the turn-cm trigger, is applied at t_3.

As in the triode Eccles-Jordan multivibrator, the length of the output gates of the pentode configuration is determined by the time interval between the turn-on and turn-off triggers. The gate length will increase if the turn-off trigger frequency is decreased; conversely, the gate length will decrease if the turnoff trigger frequency is increased. If a single constant frequency trigger is used for both the turn-on and turn-off functions, the circuit will produce a symmetrical square-wave output having a frequency one-half that of the input-trigger frequency.

Although positive trigger pulses could be used to "drive" the pentode Eccles-Jordan bistable multivibrator, negative trigger pulses are preferred; a small-amplitude negative pulse when applied to the conducting tube will immediately drive this tube into cutoff to cause an instantaneous switching action. The output of the multivibrator is taken from either or both plate circuits through an output coupling capacitor (C4 or C5). A cathode follower should be used couple the positive gate output to a circuit that requires grid current, since the multivibrator may occasionally fail.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuit and whether it is of the proper polarity and amplitude. Lack of an input trigger at the grid of V1 or V2 can be due to failure of the external input-trigger source or to the coupling from the trigger source to the multivibrator.

Failure of the supply-voltage source, $+E_{bb}$, will disrupt the operation of the circuit, as will an open cathode circuit. With tubes installed in the circuit, the filament, plate, screen grid, and suppressor grid voltages should be measured, as well as the bias voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether any of the respective electrode resistors are

491-044 0-79-50

open (resistors R2 through R9). If coupling resistor R4 or R5 is open, there will be no feedback signal to affect the multivibrator switching action; in addition, the dc operating potential from the associated sup pressor grid will be removed. If bypass capacitor Cl or C2 is open, feedback will still occur, but the inter-electrode capacitance of the tube may cause undesirable effects on the wave front of the feedback signal. An open output coupling capacitor, C6 or C7, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective tube; however, it can also be caused by a decrease in the applied voltage or an increase in the resistance of the associated plate-load resistor, R6 or R7. A leaky or shorted output coupling capacitor, C4 or C5, will form a voltage divider with the input resistor of the following stage. If the input resistor of this following stage is returned to ground or to a negative supply, the voltage at the plate, screen grid, and suppressor grid of both V1 and V2 will be reduced, and the operation of the following stage will be upset by the change in voltage applied to its grid. Also, the additional current through the resistors associated with the electrodes mentioned previously may cause the resistors to burn out.

Incorrect **Frequency and Gate Width.** The pentode Eccles-Jordan (flipflop) multivibrator has no components governing the frequency or width of its output-gate signals; these are both governed by the input triggers applied to the circuit. Therefore, any change in the output-gate frequency or width is a result of improper operation of the turn-on and-or turn-off trigger generating circuits.

DIRECT COUPLED (OR BINARY) MU LTIVIBRATOR (SEMICONDUCTOR)

Application.

The direct-coupled (or binary) multivibrator produces a square or rectangular output waveform primarily for use in computer circuit and switching operations such as computer logic, counting and shift register operations, clock pulse generation and memory circuit.

Because of its simplicity is also serves a variety of similar applications in radar and electronic equip ments.

Characteristics.

Usually employs self bias.

Provides two outputs (one is the inverse of the other).

Requires a turn-off or reset trigger to change state.

Requires a minimum number of parts.

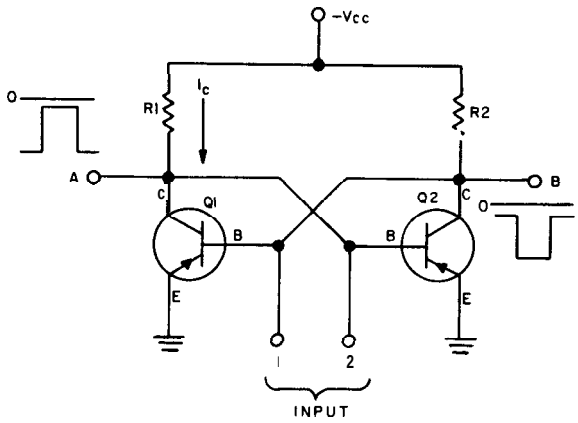
Operates at low levels (10-15 millivolt input con. trols 200-300 millivolt output).

Circuit Analysis.

General. The dc coupled or binary (count-by-two circuit) multivibrator offers design simplicity and a minimum of parts which leads to its frequent use in logic circuitry. It is basically, a bistable multivibrator with two states of stable operation. In the on-state, one transistor continuously conducts while the other remains cut off. In the off-state, the previously conducting transistor is cut off and the previously nonconducting transistor is switched on. The change of state is accomplished only by a separate trigger. There is no R-C timing network to permit automatic charge or discharge to control the switching rate. Design is usually such that the conducting transistor operates in a saturated condition. Thus the base voltage is higher than the emitter and the collector voltages, and all element voltages are low in value with only a fraction of a volt difference between them. Consequently, the conducting transistor has a low value of dissipation, and the output is also low. As a result, the dc multivibrator usually requires a stage of external amplification if other transistors are to be driven by it. When operated as a saturated flipflop it requires a higher turn-off power than that of the nonsaturating type (discussed later in this section of the Handbook). Since no emitter resistors are used, the circuit is somewhat sensitive to temperature changes. above 60 degrees Centigrade.

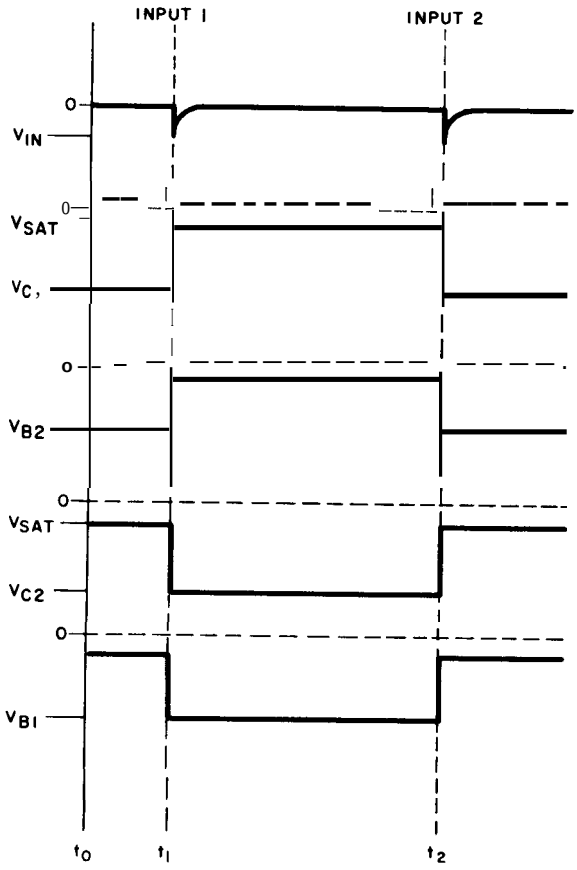
Circuit Operation. The following schematic illustrates a basic dc flip-flop. Note that only two resistors (R1 and R2) are used, which serve both as collector resistors and as feedback resistors, and

across which the output is developed. For simplicity, the control trigger circuitry is not shown.



Basic PNP Direct-Coupled (Binary) Flip Flop

Initially a forward bias is applied to both transistors by connecting the base of Q1 and Q2 to R2, and Rl, respectively (the negative supply voltage through the resistor places a forward negative bias on the transistor). In the absence of a trigger pulse both transistors tend to conduct. However, the first one to establish a flow of collector current produces a positive-going collector swing which is applied to bias the opposite transistor below cutoff. Because of the inherent slight difference in base resistance between similar transistors, one transistor will always conduct more heavily than the other. Assume for the sake of discussion that Q1 is conducting and Q2 is driven to cutoff. Since this circuit operates at collector saturation, a heavy current flows from the supply through resistor Rl, and transistor QI to ground. The flow of i_c as shown on the schematic produces a positive voltage drop across R1. This positive-going voltage is fed back directly to the base of Q2 as a reverse bias which immediately stops conduction through Q2. The heavy flow of i_c drops the collector voltage of Q1 to almost zero (it is saturated). Meanwhile, since Q2 stops conducting its collector voltage rises to nearly the full negative supply value. Since the base of Q1 is connected to the collector end of R2, this negative-going feedback voltage is applied to the base of Q1 as a large forward bias. The base voltage on Q1 is now higher than that of the collector, and since the emitter is grounded and effectively at zero potential, the base voltage is rdso higher than the emitter. Thus the base voltage is the dominating voltage which holds Q1 conducting until a turn-off trigger arrives. The circuit is now operating between intervals tl and t2 as shown on the following waveform illustration.

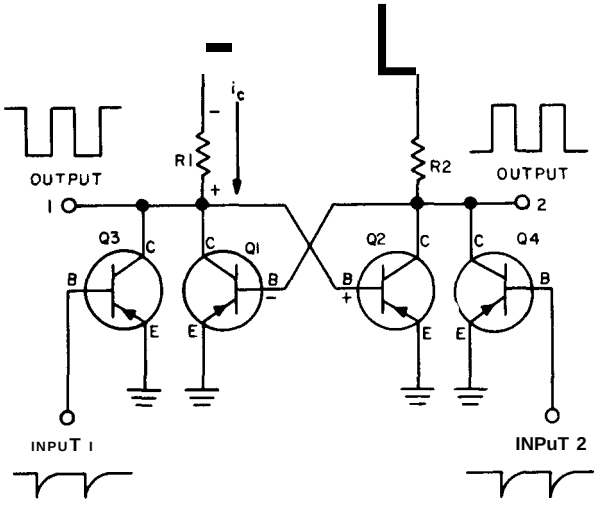


Typicel Waveforms

At time t_2 the turn-off trigger arrives, and a negative input pulse is applied via input 2. Consequently, the negative input on the base drives Q2 in a forward direction (the small saturation voltage fed from the collector of Q1 is easily overcome by the negative input pulse), and Q2 conducts. Immediately, current flow through R2 causes a positive swinging voltage to be applied to the base of Ql, stopping conduction through R1. As conduction ceases through R1 the collector voltage of Q1 rises towards the full negative supply value, and feeds back an increasing negative

voltage to the base of Q2. Thus, Q2 is quickly switched into conduction while Q1 is turned-off. At time T_2 the second stable state is accomplished, and now the circuit awaits another turn-off trigger at time t_3. This is merely a repeat of the sequence of operation at time t_1. Namely, a negative trigger is applied to input 1 which drives the base of Q1 in a forward direction, causes collector current flow through R1 and feeds back a positive-going voltage to the base of Q2 causing it to stop conducting. Instantaneously, the collector voltage of Q2 rises towards the negative supply value, and drives the base of Q1 into heavy conduction. The circuit is now resting in the initial state, with Q1 conducting heavily and Q2 cut off.

The circuit schematic of a practical binary multivibrator is shown in the following illustration, with control circuitry. Except for the operation of transistors Q3 and Q4, circuit operation is identical and corresponding parts are labelled identically so that the previous discussion applies.



Typical PNP Binary Multivibrator

Transistor Q3 and Q4 merely act as switches, when a negative trigger is applied to their base they conduct, and when no trigger is present they are held nonconducting. The control transistor connected to the conducting multivibrator transistor is held at cutoff by the low saturation voltage of the collector to which it is connected, while the other is held cutoff by the high reverse bias at the non-conducting collector. Since their emitters are comected directly to ground, when triggered, they develop a shut-off pluse which stops the conducting transistor from operating and causes the switching. For example, assume Ql heavily conducting, with its base held negative by the feedback from R2. Q4 is resting reverse biased awaiting the control trigger. When the negative control trigger (input 2) arrives, the base of Q4 is driven negative and this forward bias causes the transistor to conduct through R2. Flow of collector current in Q4 develops a positive swinging pulse across R2 and drives the base of Q1 positive to cutoff. Thus Q1 is stopped from conducting. Transistor Q3 operates similarly, assuming Q2 conducting and Q1 cut off, the negative input to Q3 (input 1) causes collector conduction and produces a positive pulse across RI, thereby driving Q2 base positive to cutoff, and switching Q1 into conduction by the feedback developed as the collector of Q2 rises towards the negative supply at cutoff.

Failure Analysis.

Partial or No Output. A no-output condition can only be caused by a lack of bias voltage because of a blown fuse or defect in the supply, or because both transistors Q1 and Q2 or load resistors R] and R2 are defective. If either Q1 or Q2 is operable and either R1 or R2 is not open, a single unstitched output will be obtained, since the circuit has two states of operation. First check the supply voltage with a high resistance voltmeter to ascertain that a blown fuse or defective power supply is not at fault. Then check the collector voltage to ground. Transistors Q1 and Q3 will show either a high negative voltage or practically zero voltage depending on whether or not Q1 is conducting, while Q2 and Q4 will produce exactly the opposite indication under normal operation. If both Q1 and Q2 indicate either a low voltage or a high voltage, one or both of the transistors is at fault. Use an in circuit transistor checker to locate the defective one. In the absence of a transistor checker use an ohmmeter, and check the forward and reverse resistance of the emitter and collector junctions with the bias removed. The forward resistance should be considerably lower than the reverse resistance. Replace any defective transistors with known good ones. Since control transistors Q3 and Q4 shunt the multivibrator transistors, if defective, the output will also be shunted to ground. If inoperative, there will still be a single output and the stage will not change state.

4

If they are simultaneously shorted, there will be no output and both Q1 and Q2 collector voltage will be almost zero. If only one is shorted there still will remain a single output which cannot be switched by application of an input trigger.

Reduced Output. A reduced output is usually caused by low collector voltage, improper bias, or a defective transistor. Any change in the resistance of collector load resistors RI or R2 will also affect the output amplitude. Use a high resistance voltmeter to check the supply and collector voltages, and measure the resistance of R1 and R2 with an ohmmeter. If the voltages are normal and both R1 and R2 are of proper value the transistor must be at fault. Check the beta of both transistors with an in-circuit checker to determine which has a loss of gain, or use an oscilloscope to locate the low output waveform and associated transistor.

Incorrect Frequency or Gate Width. The direct-coupled multivibrator has no parts governing the internal frequency or width of the output gate signal; these are solely controlled by the input triggers applied to the circuit. Therefore, any change in output gate frequency or width can only be a direct result of improper operation of the turn-on or turnoff trigger generating circuits, not the multivibrator.

SQUARING MU LTIVIBRATOR (SEMICONDUCTOR)

Application.

The squaring multivibrator, also known as the Schmitt trigger or emitter-coupled bistable multivibrator, is primarily used to supply a square or rectangular output when triggered by a sine-wave, sawtooth, or other irregularly shaped waveforms.

Characteristics.

May be self or fixed biased.

Has two stable (bistable) states of operation (one transistor conducts while the other is cut off, and vice versa).

Provides a symmetrical output gate regardless of input waveform.

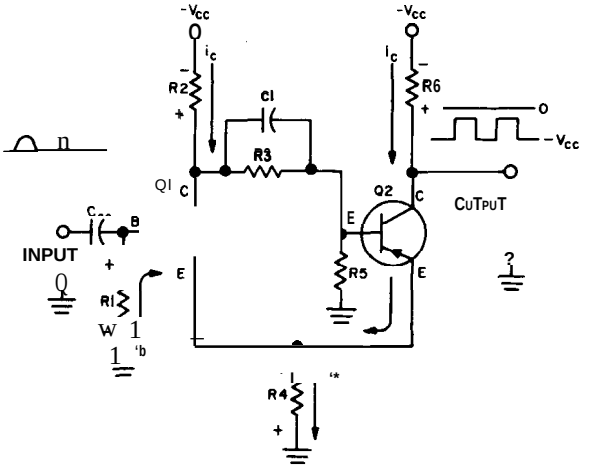
Collector to base feedback provides one switching path, while common emitter coupling feedback provides the other switching path.

Use common emitter configuration.

Circuit Analysis.

General. The Schmitt circuit differs from the conventional bistable multivibrator circuit in that one of the coupling (feedback) networks is replaced by a common emitter resistor (the equivalent of cathode coupling in the electron tube). The additional regenerative feedback developed by the common emitter-feedback coupling arrangement provides quicker action and straighter leading and trailing edges on the out put waveform than in other mr.dtivibrators. Because of the relatively instantaneous switching action of this arrangement, the waveform of the input trigger has no effect on the output so that essentially square-wave output signals are rdways produced.

Circuit Operation. The schematic of a typical Schmitt type squaring circuit is shown in the following illustration.



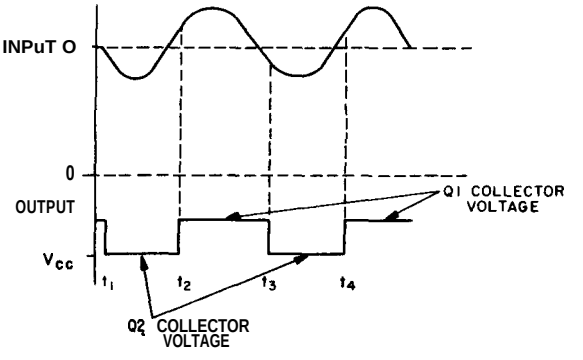
PNP Squaring Multivibrator

Transistor Q2 is the initially conducting transistor, which is supplied with forward base bias by resistor network R2, R3, and R5 connected as a voltage divider between the negative voltage supply and ground. Capacitor C_{cc} and base resistor RI form a conventional R-C input coupling circuit. Resistor R4 is the feedback (coupling) resistor which is common

to both emitters, and R6 is the collector resistor of Q2 across which the output waveform is developed. Capacitor C3 bypasses feedback resistor R3 to help speed up switching action.

Initially, transistor Q2 conducts heavily because of the large forward bias supplied by the voltage divider consisting of collector resistor R2, feedback resistor R3, and base resistor R5, series-connected between the negative supply and ground. A reverse collector bias is applied Q1 through R2, and a reverse ernitter-bias is developed across the common emitter resistor R4 by Q2 current flow. Base current flow through R1 is rdso in a direction which produces a reverse base on Ql, so that Q1 cannot conduct until triggered. Thus, Q1 remains cutoff, while Q2 conducts. With Q2 conducting, a positive-going output voltage is developed across collector resistor R6 which lowers the effective collector voltage of Q2 to almost zero. No output coupling capacitor is shown since the circuit may be direct coupled to the following driver stage, if desired.

Assume now a sine-wave input signal is applied to c_{cc}. During the positive half-cycle of operation the positive input voltage applied across R1 keeps Q1 reverse-biased so that it cannot conduct. Since in this condition the output is developing a positive signal similar to that through initial conduction, as explained previously, it is evident that the input and output are in phase. When the input signal swings negative during the opposite half-cycle of operation, a negative voltage appears across R1 as Ccc discharges. The case of Q1 is thereby driven negative and forward biased, starting collector current flow through R2. The direction of electron flow is such that the collector end of R2 becomes positive (as marked on the schematic), and this instantaneous positive swing is coupled through Cl to the base of Q2, appearing as a positive reverse bias which instantly stops current flow through Q2. The reduction of collector current flow through R6 produces a voltage of opposite polarity to that shown on the schematic, that is a negative output voltage, as the collector of Q2 rises towards the supply voltage (time t_1 to t_2 on the following waveform illustration).



Typical Input and Output Waveforms

Although R3 connects the collector of Q1 to the base of Q2, and any voltage appearing on the collector of Q1 will also eventually appear on Q2 base, a speed up of this action is obtained by bypassing R3 with capacitor Cl. Thus, the high frequency components of the collector signal are not slowed up by the resistance of R3 so that switching action is faster than without Cl.

Consider now the effect of the common coupling resistor (R4) in the emitter circuit. Initially the heavy current through Q2 produced a negative drop across R4, as marked on the schematic. This negative emitter bias which is degenerative, because no bypass capacitor is employed, also tends to prevent Q2 current flow. However, the base bias of Q2 is much larger and the degenerative emitter voltage produced across R4 has little effect on Q2 collector current flow. However, Q1 is already at cutoff, and this additional negative emitter bias ensures that it remains so

until sufficient base input is applied (on the next half-cycle) to overcome this reverse bias.

With the collector current flow of Q2 reducing, the degenerative voltage developed across R4 also reduces, which is the same as applying an increasing positive voltage between emitter and ground. Thus, while the base of Q1 is driven in a forward-biased direction by the input signal, a regenerative feedback is developed in the emitter circuit by the reduction of Q2 current flow. Consequently, transistor Q1 is quickly driven into heavy conduction near saturation. The resulting instantaneous positive swing developed across R2 is instantly applied through Cl to the base of Q2, and quickly drives Q2 to cutoff. The circuit now rests in its second stable state (interval t_1 to t_2) until another trigger arrives to drive Q2 into conduction and cut off QI.

When the input signal again swings in a positive direction (time interval t_2), the positive voltage appearing across R1 causes a reverse bias to be applied Q1 base and reduce collector current flow through R2; this produces a negative swinging voltage across R2, which is applied to the base of Q2 through capacitor Cl. The negative swing forward-biases Q2 and starts it conducting, and develops a positive-going voltage swing across R6 to provide an in-phase output voltage. Simultaneously, the increased negative emitter (reverse) bias developed across feedback resistor R4 further stops conduction in Q1. This regenerative feedback action quickly drives Q2 to collector saturation and Q1 to cutoff, whereupon the rising negative collector voltage of Q1 applied to the base of Q2 through Cl and ,R3 holds Q2 strongly conducting despite the degenerative emitter voltage developed across R4 (time interval t_2 to t_3). This is the initial order of conduction and the transistor awaits the next trigger (at time t_3) to turn off Q2 and turn on QI. Because of the extreme regenerative action of the emitter-coupled circuit, once started, the switching action is quickly accomplished, and the shape of the input trigger has no effect in determining the output waveform. Cutoff and turn-on is sharp and the sides of the waveform are steep. The width of the output waveform like the other bistable multivibrators is controlled by the difference in time between the off and on pulses. When symmetrical and equal a true square wave is produced.

Failure Analysis.

Constant or No Output. Lack of supply voltage, an open common emitter resistor, or defective transistors are about the only three items which can cause a no output condition, since at least one steady output can always be obtained if any voltage is present. Check the supply voltage with a high resistance voltmeter to make certain that a blown fuse or defective supply are not at fault. Since R4 connects both transistors to ground and they are reverse collector biased, no conduction will occur if R4 is open, and a steady negative output will be obtained. A zero emitter to ground voltage reading will indicate that R4 should be replaced. If a steady positive, or near zero but constant voltage is obtained, Q1 is probably defective. On the other hand if Q2 is shorted the same indication would occur. Likewise, if Q2 is open a steady negative output voltage would be obtained through R6. It is evident that it is rather difficult because of the feedback and direct connections in this type of circuit to obtain a specific indication which conclusively points to only one cause of trouble. Therefore, a simple voltage check plus a resistance analysis of the few parts involved should quickly locate the defective component. If the voltage and resistance are correct but an unswitchable steady output is still obtained, check that an input trigger is being received on both sides of coupling capacitor Ccc, using an oscilloscope.

Reduced Output. A reduced output can occur because of low supply voltages, improper bias voltage, or defective transistors. Check the supply and bias voltage with a high resistance voltmeter. Use an incircuit transistor checker, or check for a low forward-resistance and a high reverseresistance with an ohmmeter.

Incorrect Pulse Width or Frequency. Like the other bistable multivibrators, an effect on frequency or pulse width is controlled by the time difference between the on- and off-triggers. Thus any faulty operation of this type is due solely to defects in the trigger generating circuits and not the multivibrator.

SATURATING MU LTIVIBRATOR (SEMICONDUCTOR)

Application.

The saturating multivibrator is used to supply a rectangular gate, or trigger, in radar and control applications, and irr the logic switching circuits of computers and similar devices.

Characteristics.

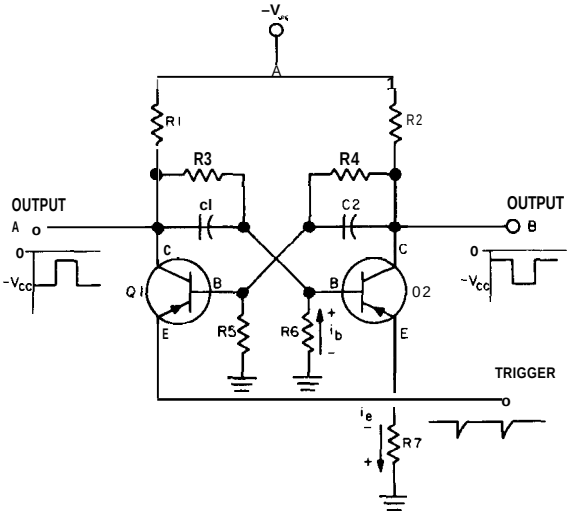
Usually uses fixed bias.

Provides two outputs simultaneously, one the inverse of the other. Requires a turn-on or turn-off trigger to change state.

Has two (bistable) stable states (one transistor conducts while the other remains cut off and vice versa).

Output power is considerable lower than that of the nonsaturating type.

Operating speed is slower than the non-saturating multivibrator.



Saturated PNP Multivibrator

Circuit Analysis.

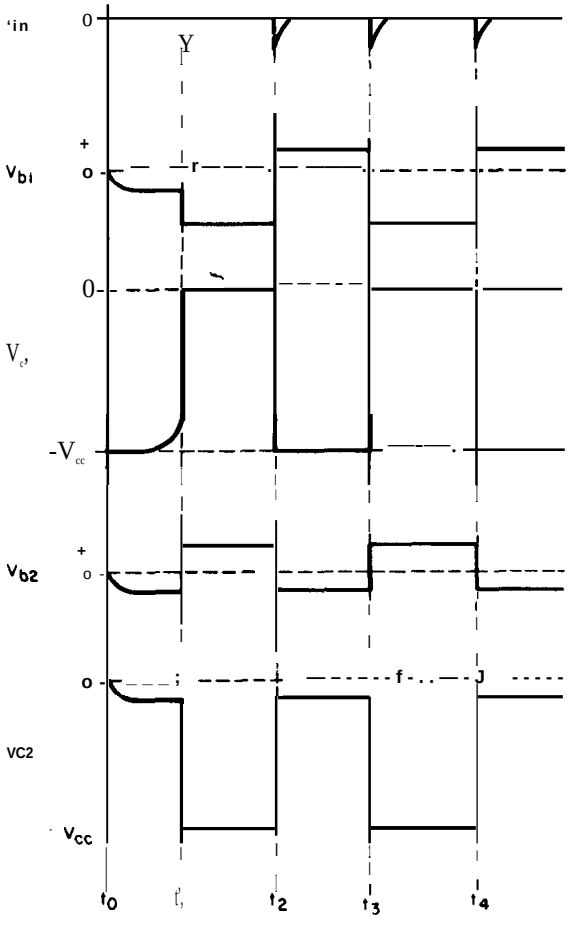
General. In the saturating multivibrator, the emitter and collector voltages are lower than the base voltage and there is only a few tenths of a volt difference between them. Consequently, it takes more driving power in this saturating circuit, as compared with the nonsaturating circuit, to drive the stage out of saturation (a larger trigger is required). The output voltage is also less. Thus, while a certain amount of stability may be imparted by saturated operation the gain and speed suffer. The gain is limited by the low saturation voltages, and the speed by the amount of time required to obtain hold dispersion (the extremely heavy saturation current injects extra holes in the base, which require a finite recovery time to remove them). As a result, the saturated circuit is used where its simplicity makes it more economically feasible than the non-saturating type.

Circuit Operation. The schematic of a typical saturated multivibrator is shown in the accompanying illustration.

Fixed bias is applied by a voltage divider arrangement, consisting of RI, R3, and R6 for transistor Q2, and R2, R4, and R5 for Q1, connected between the negative supply and ground. Feedback resistors R3 and R4 are bypassed by capacitors Cl and C2, respectively, to speed up response. An output is taken from each collector, and the input trigger is applied across emitter resistor R7, which is common to both transistors. This circuit arrangement is that of the conventional bistable multivibrator arranged for common emitter triggering.

In the quiescent condition, with no trigger applied, both transistors conduct immediately when the supply voltage is applied, since they are both forward biased through voltage dividers to the negative sup ply. Although the circuit is symmetrical, that is, the collector, feedback, and base resistors are all of equal values to minimize any unbalance, there still exists a

slight difference in base resistance between transistors of the same types. Thus, one transistor always tends to conduct more heavily than does its counterpart, and through feedback from the collector to the opposite base drives the associated transistor to cutoff, and itself to full conduction. Assume for the sake of discussion the normally-on transistor is Ql, while Q2 is the normally-off transistor. From time t. to t_1 (as shown on the following waveform illustration) the initial conduction is established as previously explained, so that a time t_1 transistor QI is conducting while Q2 is cutoff. Since the turn-off input trigger at this time is stopping Q2 there is no effect and the circuit rests in its initially-on state until time t_2.



Typical Waveforms

During the interval from t_1 to t_2 a continuous positive (reverse) bias exists at the base of Q2 due to base current flow from ground through R6, producing a voltage drop of the polarity shown on the schematic (this current is actually produced by reverse collector current I_{ceO}). Thus, with reverse base bias and a reverse collector bias, Q2 remains cut off until the next turn-on trigger arrives. Since no collector current flows through R2 the collector of Q2 rises towards the value of the negative supply voltage and drives Q1 base in a forward-biased direction, causing heavy conduction through Q1. The heavy collector current drops the voltage across R1 to almost zero, and a positive-going output is produced at A, while a negative output from Q2 is produced at terminal B. Once saturated, the collector voltage of Q1 is less than the base voltage fed back from Q2. With high current but low voltage, the power dissipation of the transistor is well within ratings (one advantage of saturated operation is the low collector dissipation involved). They heavy emitter current flow through the common, emitter-coupling resistor R7 places a large degenerative voltage on the emitter of Q2 which effectively reverse-biases Q2. Thus Q2 is held in its off-state, regardless of whether or not the off period is long enough for Cl to discharge. The only effect on operation that Cl has is that of speeding up the switching operation by shunting the high frequency transients around R3 to help speed up turn-on, or turn-off, switching action.

When the negative trigger is applied at t_2 the emitter of Q1 is driven negative, which is the same as driving the base positive to reverse bias the transistor. Since transistor Q2 is already reverse-biased, this trigger has no effect on Q2, only on Q1. Consequently, the collector and emitter current of Q1 is reduced. This reduction of collector current produces a negative-swinging voltage across collect resistor R1, and through Cl to the base of Q2. The instantaneous negative swing applied to the base of Q2 drives Q2 in a forward-biased direction, and causes collector current flow through collector resistor R2. The voltage drop across R2 produced by the increasing collector current reduces the collector voltage, effectively producing a positive-swinging voltage at the collector, which is fed back through capacitor C2 to the base of Q1. The positive-swinging voltage drives the base of Q1 instantaneously in a reverse-biased direction and causes a further drop in collector current. The

regenerative feedback action continues smoothly and quickly until Q2 is driven into collector saturation (collector voltage bottoms), while QI is cut off. While this regenerative feedback and switching action occurs, a degenerative voltage is developed across common resistor R7 in the emitter circuits of both transistors. Although this degenerative emitter voltage normally is of such polarity as to oppose the increase of current, it is not of as great an amplitude as the feedback voltage developed across R5 which is driving Q1 to cutoff, or the feedback voltage developed across R1 which is driving Q2 into conduction. It does, however, aid in obtaining collector current cut off on Q1 since the transistor is already being driven in that direction, and eventually reaching saturation. Because the heavy collector saturation current of Q1 produces extra holes in the base of Q1, transistor Q1 does not stop conduction immediately when its base voltage is driven positive and base current flow is stopped. But instead, the collector current continues to flow for a finite interval, even though there is no forward bias on Ql, until the holes are removed from the base of Q1 and cut-off prevails. With no collector current flow, the collector of Q1 rises in a negative direction towards the full supply voltage, and a negative output is produced at terminal A. Meanwhile, as Q2 conducts heavily saturated, the collector current is ahnost zero, and a positive output voltage is produced at terminal B by the voltage drop across collector resistor R2 of Q2. Conditions are now exactly opposite the original state and Q2 rests in the on-state (interval t_2 to t_3), while Q1 rests in the cutoff state awaiting a negative turn-on trigger at time t_3.

When the turn-on trigger arrives at time t3, the emitter of QI and Q2 is driven negative. Since Q1 is already in a non-conducting state the trigger cannot further stop conduction so it has no effect on the operation of Q1. However, the trigger does drive Q2 in a reverse-biased direction (a negative emitter trigger has the same effect as a positive base trigger), and causes a reduction of collector current flow through R12. Immediately a negative-swinging voltage is deveIoped across R2 and applied through Cl to the base of Q1, which drives Q1 in a forward direction towards saturation. The increasing collector current flow through RI, again produces a positive-swinging collector voltage which is applied through Cl to the base of Q2, further driving Q2 in a reverse biased direction and further reducing collector current flow. This regenerative switching action is smooth, continuous and relatively fast so that except for a slight delay caused by hole storage, as explained previously for the opposite condition of conduction in Q1, the switching is considered to be almost instantaneous. When Q1 reaches saturation and Q2 is completely cutoff, minimize hole storage time and produce speedy operation, even as high as 20 MHz. Thus, the tendency is to use saturated circuity generally for its simplicity and economy. Non-saturated circuits are usually only used when output power requirements call for more power than can be produced with saturated circuits.

Failure Analysis.

General. When making voltage checks use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

Partial or Steady Output. Failure of one half of the circuit to operate will produce a partial output in the form of a steady single polarity output. Failure of the supply voltage, or emitter resistor R7, are about the only two possibilities of obtaining no output at all. Because of the feedback connections it becomes rather difficult to isolate the trouble by symptom along. It is quicker to make a voltage check and determine if the supply voltage is present, and that no fuse or power supply is at fault. Then use an ohmmeter to the stage again rests in the original conducting state awaiting a turn-on trigger for Q2 to change operation (interval t3 to t4). Meanwhile, a positive output is developed across R2 and applied output terminal B, while a negative output is developed across RI and applied to terminal A.

Practically all the non-clamped multivibrators are of the saturated type, since clamping the waveform to operate within the normal operating region of the transistor when use as an amplifier is necessary. As long as the base drive is allowed to draw collector current until the transistor collector voltage bottoms, saturation will always occur. Therefore a produce the unchanging steady current represented by the flat top of the output pulse there must be no further change of collector current. In the simple multivibrator this is achieved by collector current saturation, and in the

more complicated types of multivibrators by clamp ing diodes. At the time transistors were first discovered and applied to this type of circuit, hole storage time effects caused a serious limitation in the speed of operation at which practical multivibrators could be made to operate. At the present state of the art, however, special switching transistors have been developed which check for continuity and proper resistance values to locate the defective part.

If either collector resistor R1 or R2 is open, no collector voltage will appear on the associated transistor, Q1 or Q2, respectively, and the bias voltage divider will be open. Therefore, the other transistor will be effectively cutoff biased by the floating base, and the normal reverse collector bias. With no conduction, a single negative output will be produced while the other output will be zero due to the open collector circuit. In the event emitter resistor R7 which is common to both transistors opens, there will be no flow of current through either transistor, but a negative output will appear at both output terminals since the transistors will, in effect, operate as if both were biased to cutoff. Thus, both collector voltages will rise to the full value of the supply. Therefore, if either transistor fails, or both fail, a negatime output will be produced.

Normal voltage indications on the base and collector elements of the transistors usually indicates that any associated series resistors have continuity and proper value. However, it is just as easy to check the resistance of each resistor with an ohmmeter because of the few parts involved, Since it is important to check that the proper polarity and amplitude of input trigger exists and that it is present, use an oscilloscope to observe the waveforms. When the waveforms are improper or missing it locates the general area of the trouble, which must then be further localized by voltage and resistance checks.

Reduced Output. A reduced output is usually caused by low collector voltage, improper bias, or a defective transistor. A change in the associated collector load resistor, R1 or R2, will also affect the output amplitude. Use an oscilloscope to observe the waveforms and determine where the reduced amplitude exists. Then check for proper bias and collector voltage in that portion of the circuit, and make certain that the collector resistance is normal. If normal voltages are present and the collector resistance is within tolerance, and a low output amplitude still exists, it must be because of reduced transistor current.

Incorrect Frequency or Gate Width. Since the multi-vibrator has no parts which govern the frequency or width of the output signal, these are both governed by the input triggers' applied to the circuit. Hence, any change in these parameters must be the direct result of improper operation of the turn-on or turn-off trigger generating circuits.

NONSATURATING MU LTIVIBRATOR (SEMI-CONDUCTOR)

Application.

The nonsaturating multivibrator is used to supply a rectangular gate or trigger in radar and control equipments, and in the logic switching circuits of computers and similar devices. Particularly where a large power output is required.

Characteristics.

Usually uses fixed bias.

Provides two simultaneous outputs, one is the inverse of the other.

Requires a turn-on or a turn-off trigger to change state.

Has two stable operating states (bistable).

Output frequency is one-half that of the trigger frequency.

Output power is greater than that of the saturating type.

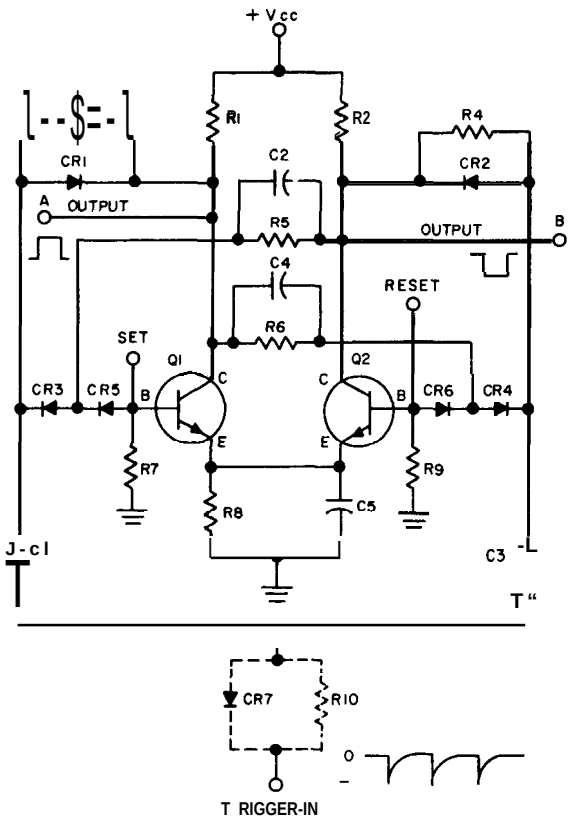
Operating speed is faster than the saturating multivibrator.

Uses clamping diodes to prevent saturation effects.

Circuit Analysis.

General. The nonsaturating multivibrator uses clamping diodes to stop collector saturation, and steering diodes to make certain the proper trigger is received, thus avoiding false triggering. In the circuit discussed below breakdown diodes are also used to prevent forward biasing of the collector which would cause saturation. Consequently, the transistors operate in the normal operating region (over the linear portion of their transfer curve). Basically the circuit is that of a conventional emitter-coupled bistable multivibrator, with the steering, clamping, and breakdown diodes added.

Circuit Operation. The schematic of a typical nonsaturating multivibrator is shown in the accompanying illustration.



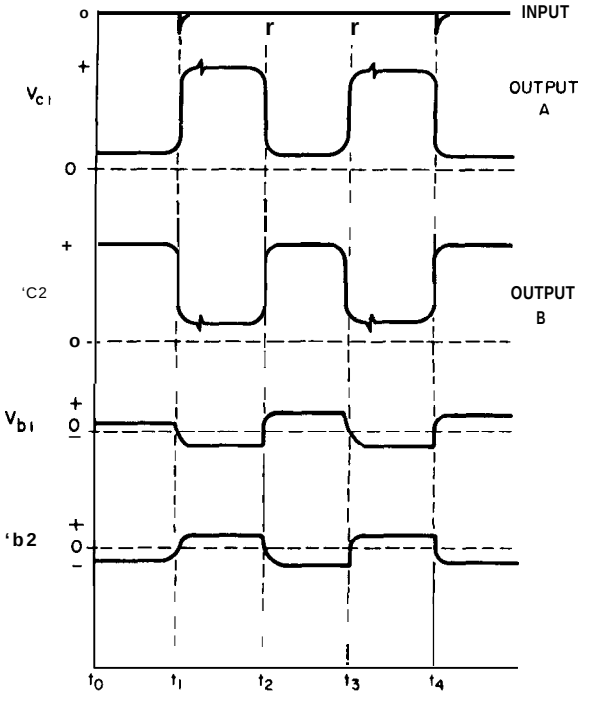
NPN Nonsaturating Multivibrator

Resistors R1 and R2 are the collector resistors of Q1 and Q2, respectively. The collector to base feedback networks are C2 and R5, and C4 and R6, with the common coupling-emitter resistor R8, bypassed by C5 to prevent degeneration. Resistors R7 and R9 are the base return resistors. The clamping diodes are CR1 and CR2 which shunt R3 and R4. Diodes CR3 and CR'4 are the respective steering diodes of Q1 and Q2. Breakdown diodes CR5 and CR6 are saturation limiters which prevent the collector voltage of Q1 and Q2 from being forward biased when conducting. Input triggering pulses are injected at input terminal I (connected for parallel triggering), while terminals A and B are the output terminals from which the square wave output is taken. Transistor Q2 is considered to be the normally-on transistor, while Q1 is normally-off. When the negative input trigger is applied to the base of Q2, these conditions are reversed and Q2 is turned off, while Q1 is turned on. When the next negative trigger is applied to the base of Q1, the circuit reverts back to the initial state of operation, with Q1 off, and Q2 on.

In the absence of an input signal, both transistors initially conduct. Although the multivibrator circuit is symmetrical (corresponding resistors have the same value), there is always a slight difference in collector resistivity between transistors of the same type, so that one transistor will conduct more heaviiy than the other. In turn, the heavier-conducting transistor produces a feedback voltage which cuts off the light-conducting transistor. Assume for the sake of discussion that Q1 is initially in the off-condition while Q2 is in the on-condition.

In the quiescent condition, then, Q1 is effectively at cutoff, or at its lowest limit of conduction held by a negative, reverse-bias feedback voltage from the collector of Q2 via R-C network R5, C2 (NPN transistors require a negative bias voltage for cutoff). With no collector current flowing through RI, the collector of Q1 is at a high positive voltage near the supply value (reverse-biased collector), and both steering diode CR3 and clamping diode CR1 are held in a reverse-biased condition. At the same time, the negative feedback voltage produced by collector current flow through R2, and applies through C2 and R5 holds breakdown diode CR5 in a forward-biased condition but cuts off the base of Q1. In a similar manner, the emitter bias developed across R8 and C5 holds the emitter-base junction of Q1 in a reverse-biased condition preventing conduction. Meanwhile, a positive feedback voltage from the collector of Q1 is applied via C4 and R6 to the base of Q2 through breakdown diode CR6. Because of the high reverse voltage (collector of Q1 is near supply level), breakdown diode CR6 conducts in a reverse direction and maintains a constant forward bias on Q2, which causes heavy current flow but not collector saturation. The heavy collector current flow through collector resistor R2 develops a negative-going voltage which is applied to terminal B as an output, simultaneously with the positive output from terminal A. As Q2 collector current increases, the voltage drop across R2 increases also, the collector voltage of Q2 reduces becoming less positive. Since steering diode CR4 is connected to the collector of Q2 through R4, when the collector voltage drops lower than the positive feedback voltage developed across RI (which is

applied through R6 to the anode of diode CR4) the diode becomes forward-biased and conducts, and as the collector voltage drops further CR2 eventually conducts. The collector of Q2 is now connected through the two diodes to the cathode of breakdown diode CR6 and the junction of R6. As long as the breakdown diode maintains a constant potential between the base and collector of Q2, the collector voltage cannot fall lower than the base voltage. Therefore, the collector cannot be forward biased and saturation cannot occur. Although the collector current may still increase if additional base current drive is supplied, the collector potential remains constant at the freed minimum value. The operating range of Q2 (and later Ql) then, is from the minimum value of collector voltage to almost the full supply voltage at cutoff. The stage is now in its initial conducting or on-state with Q2 conducting and Q1 off, and rests in this condition until a turn-off trigger is received.



Multivibrator Waveforms

At time t_1 in the preceding waveform illustration, a negative trigger is applied to steering diode CR4, but since it is already conducting the trigger has no effect and the stage rests in the initially-on condition (interval t_1 to t_2). At time t_2, the next negative trigger is applied through Cl to the cathode of diode CR3 and simultaneously to CR4 via C3. Since Q1 is nonconducting and the base is already negative, no effect is felt on Q1. However, when the negative pulse passes through CR4 and CR6 and appears on the base of Q2 it instantly partially reverse-biases the conducting transistor and causes a reduction in Q2 collector current flow through R2. As the collector current decreases, the drop across R2 is reduced and collector voltage becomes more positive. This positive-going voltage is applied as feedback through C2 and R5, causing breakdown diode CR5 to conduct in a reverse direction, and driving the base of Q1 in a forward-biased direction. Collector current now flows through R1 and produces a negative-going voltage which is applied through feedback network C4 and R6 to the base of Q2 through breakdown diode CR6. Thus Q2 is driven further in a reverse-biased direction, and a larger turn-on voltage is fed back again to the base of Q1 by the increasing collector current flow through RI. The regenerative feedback continues smoothly and rapidly until Q1 is fully conducting while Q2 is turned-off. The circuit now rests in its second stable state (interval t_2 to t_3) until triggered off again at time t_3. When Q1 conducts, diodes CR3 and CR] are activated similarly to diodes CR2 and CR4 in the discussion of Q2 operation, so that CR5, CR3, and CR1 continue to conduct, while a negative output pulse is produced at terminal A. With Q2 held at cutoff by feedback from Q1, a positive square-wave output pulse is obtained at terminal B as the collector voltage of Q2 rises toward the full supply vrdue. In this instance, the emitter bias developed across R8 by conduction of Q1 keeps Q2 emitter reverse-biased, while breakdown diode CR5 maintains a constant difference in potential between the base and collector of Q1. Thus, while additional current may be drawn through Q1 if the base current drive increases, the collector voltage remains steady at its minimum clamped potential. If additional current is required, it is supplied through the shunt diode circuit from the cut-off side of the circuit via R2, and R5. Since any additional base current supplied at this time would cause only.. a small increase of collector current this shunting action will not appreciably reduce the output voltage developed across R2. But what is more important, is that additional collector current through R1 cannot occur and drop the collector of

Q1 to zero and cause saturation. At time t_4, the next negative trigger is applied through Cl, and CR3, and CR5, to the base of Q1, reducing the flow of collector current because of the reverse bias it applies subsequently, the previously discussed cycle of feedback through C4 and R6 occurs, driving the base of Q2 into conduction, and produces additional feedback through C2 and R5 to drive the base of Q1 in the off-direction. Thus time t_4 corresponds to the initial trigger at t_1 which was previously considered ineffective, since Q2 was already assumed to be turned on.

When a positive trigger pulse is applied through Cl or C3, it reverse-biases the steering diodes and cannot reach a triggering point in the circuit. After the pulse ceases, the positive charge on the capacitor is quickIy discharged through either CR1 or CR2. Any similar effect produced by the trailing edge of a negative trigger is also eliminated in this fashion providing a fast recovery time. Diodes CR7 and resistor RIO, shown in dotted lines in the schematic, are trigger shaping devices to allow speedy triggering, they are not necessarily a part of the multivibrator. Resistor R1O is used to slow up any positive trigger so that false triggering cannot occur. Diode CR7 acts as a gate for negative triggers and shunts them around R1O to avoid any attenuation, while forcing any positive excursions to travel through R1O. Feedback capacitors C2 and C4 function only to pass the high frequency component of the switching transients from collector to base without attenuation. Thus the switching action is speeded up, and the output waveform has steep leading and trailing edges rather than sloping sides produced by slow switching action.

Although clamping and steering diodes provide improved operation, it is possible to design nonsaturating multivibrators using the standard saturated multivibrator circuit with different values of component parts. In this case, parts values are chosen so that saturation does not occur. It is also of interest to note that, while the saturated circuits use heavy currents at very low voltages the dissipation is less than that involved in the nonsaturating circuit, which uses near-saturation currents at higher voltages with a consequent increase in average collector dissipation. Therefore, the nonsaturating circuit usually requires transistors with higher ratings.

Failure Analysis.

General. While making voltage checks, use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges. Be careful also to observe the proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junction will cause a false low-resistance reading.

Partial or No Output. It is necessary that the proper polarity and amplitude trigger be applied before the circuit will switch from one state to another. However, it will rest in one stable state and produce a single output if unable to respond to a trigger, or if disabled. Use an oscilloscope to determine that the proper trigger is applied, and then check the element voltages to determine if the circuit is otherwise normal. Check the supply voltage first to make certain the fault is not in a blown fuse or defective power supply. With the normal voltages present and a proper trigger at the input, if switching will not occur check steering diodes CR3 and CR4 to see if they pass the pulse. If not, replace the defective diode with a known good one. Should emitter resistor R8 which is common to both Q1 and Q2 open, neither will function but a dual positive output will be obtained from terminals A and B since they will rise to the full value of the supply voltage. Failure of breakdown diodes CR5 and CR6 will allow saturation to occur, but will not prevent obtaining an output. When the collector voltage is found to be lower than the base voltage the associated breakdown diode is inoperative and should be replaced with one known to be good.

Low Output. Low collector voltage, improper bias, failure of the breakdown diodes, or the transistors themselves can cause a low output. If emitter bypass capacitor C5 is open, degeneration will cause a reduction of output. Use an in-circuit capacitance checker for this test. A change in the associated collector load resistors, R1 or R2, will also effect the output amplitude. Use an oscilloscope to observe the output waveform and determine where the reduced amplitude exists. Then check for the proper bias and collector voltage in that portion of the circuit. If normal voltage is present and the collector resistor is within tolerance, but low output amplitude still exists it must be caused by reduced collector current.

Incorrect Frequency or Gate Width. Since the multivibrator has no parts which govern the frequency or width of the output signal, these are both governed by the input triggers applied to the circuit. Hence, any change in these parameters must be the direct result of improper operation of the turn-on or turn-on or turn-off trigger generating circuits.

RELAY CONTROL MU LTIVIBRATOR (SEMICONDUCTOR)

Application

The relay control multivibrator is used in computers and electronic switching circuits to control a relay or similar electromechanical device where the ratio of the on-off currents is 10 or more.

Characteristics.

Usually uses fixed bias.

Requires a turn-on and a turn-off trigger to change state.

Has two stable states (bistable).

Operates at a frequency of one half the trigger pulse frequency.

Is a saturating type of multivibrator.

Uses steering diodes for stability.

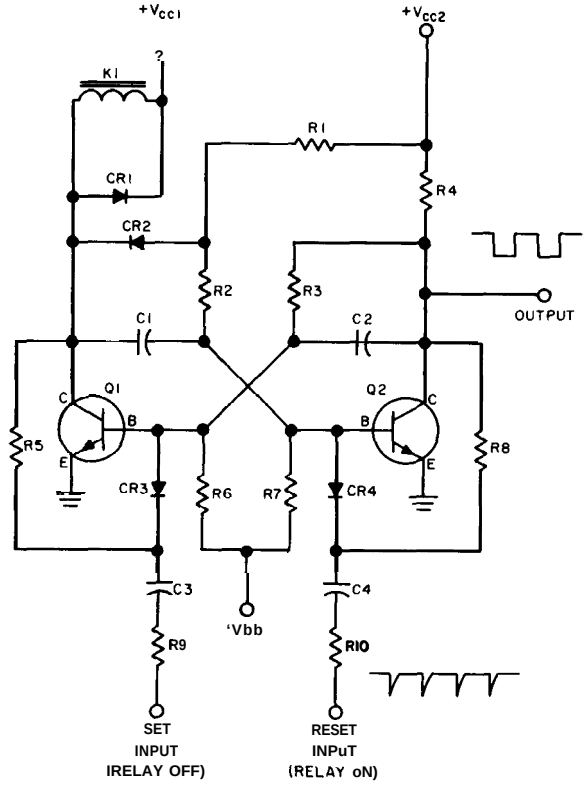
Inductive kickback from the relay coil is prevented by a diode clipper.

Operating speed is limited by the relay operating speed.

Circuit Analysis.

General. In the relay control multivibrator, one transistor is used to operate the relay, with a pull-in to drop-out current ratio of approximately 15 to 1. A rectangular output is simultaneously obtained from the other transistor; a positive output is obtained with the relay closed, and a negative output with the relay open. Steering diodes are provided to prevent false triggering and a protective diode is placed across the relay operating coil to prevent inductive operating transients from affecting the transistor to which the relay is connected.

Circuit Operation. The schematic of a typical relay control multivibrator is shown in the following illustration. As can be seen from the schematic, relay K1 is operated by transistor Q1, while Q2 provides a rectangular output voltage. The negative input trigger is applied through attenuating resistors R9 or R1O and capacitors C3 or C4 to turn off the conducting transistor. Resistor R4 is the collector resistor for Q2, while the relay coil of K1 functions similarly for Q1. The feedback network for Q1 consists of C2 and R3, while Q2 is held in conduction by a voltage divider arrangement of R1 and R2 together with bias resistor R7. Diode CR2 prevents the collector voltage swing of Q1 across relay coil K1 from supplying the feedback to operate Q2. Resistors R6 and R7 are the base bias resistors. Note that fixed bias is supplied from a separate base bias source, and that two different collector supplies are used, with that of Q1 (Vcc_1) being the lowest.



NPN Ralay Control Multivibrator

Normally, transistor Q2 is the conducting transistor while Q] is cut off. Initially both transistors will conduct, but with bias voltage divider R1, R2, and R7 connected between the high positive voltage of V_{CC_2} and negative base bias supply Vbb, a positive (forward) bias exists on Q2 base. Therefore, Q2 conducts heavily and develops a negative-going voltage

across collector resistor R4, which is fed back through C2 and R3 to the base of QI, driving it into cutoff. As the voltage across K1 coil rises to the supply value of Vcc_1, diode CR2 is reverse biased and prevents any feedback from the collector of Q1 to the base of Q2. The negative feedback voltage on Q1 base holds NPN transistor Q1 is a non-conducting condition with only a small reverse-collector current flow through K1 relay coil. At this time, any voltage drop across K1 places a positive bias on protective diode CRI to keep it reverse-biased and nonconducting. As long as the cathode of diode CR2 remains at the positive level of Vcc_1, and as long as the voltage drop across RI keeps the anode lower than the cathode voltage, CR2 also remains in a nonconducting condition.

When a negative trigger is applied to the reset input terminal through R10 and C4, the base of Q2 is momentarily driven negative by the conduction of steering diode CR4, and causes Q2 to stop conducting. Thus, as the forward bias on Q2 is reduced by the input trigger, the collector current voltage drop across R4 reduces (becomes positive-going).

The feedback of the positive-swinging collector voltage through C2 and R3 to the base of Q1 produces a forward bias which causes Q1 collector current to increase. The flow of Q] collector current through the relay coil of K1 is of a polarity which keeps CR] reverse-biased. CR2 also remains reverse biased, until the collector potential of Q1 drops below the anode potential applied through R1 and R2. As Q2 collector current decreases and Q1 collector current increases the base of QI is further driven towards saturation by the feedback from R4. Eventually, relay K1 pulls in, and transistor QI is in saturation, while transistor Q2 is cut off. At this time a positive voltage is developed at the output terminal of Q2 as the collector voltage of Q2 rises to the supply value of Vcc_2. At saturation the collector voltage of Q1 is less than the base voltage (only a few tenths of a volt) and CR2 is forward-biased. Electron current flow from ground through Q1 and CR2 to R1, and voltage supply Vcc_2 produces a negative reverse bias voltage which is fed back through R2 to Q2 base to hold Q2 in a nonconducting state. This is the second stable state, with Q1 on and Q2 off.

When a negative trigger is applied through R9 and C3 from the set-input of Q1, sterring diode CR3 temporarily conducts and produces a momentary reverse bias on the base of Q1, causing Q1 collector current to reduce. The reducing collector current allows the voltage on the cathode of CR2 to rise in a positive direction towards supply voltage Vcc_1 and eventually reverse-biases the diode. The positive voltage fed back to the base of Q2 through R1 and R2 now causes Q2 to again conduct. Thus Q2 quickly reaches the initial stable conducting state with QI cut off by the negative feedback through C2 and R3. When the collector current flowing through relay coil of K1 is reduced to zero, the inductive field about the coil collapses and causes CR1 to momentarily conduct when a negative trasient appears on the cathode. The negative inductive kick is thereby effectively clipped off, protecting Q1 from the inductive surge voltage.

Steering diodes CR3 and CR4 will now' allow a positive trigger pulse to appear on the base of either Q1 or Q2, thus false triggering is prevented. Resistors R9 and R1O are not always required, in fact, they are really not a part of the multivibrator. They are used to provide a high impedance input instead of the approximate 300 ohm impedance offered by the coupling capacitors alone. These resistors also prolong the discharge time of the trigger, ensuring that the switching action occurs before the trigger is removed. With the steering diode cathodes connected back to their associated collector through R5 and R8, the conducting transistor maintains the diode in an almost forward biased condition (in saturation the collector is almost the same value as the base voltage – within tenths of a volt). Thus the large trigger pulse instantly turns the diode on and triggers the conducting transistor off. If a negative trigger pulse was accidentally applied to the nonconducting transistor, the large collector to base reverse bias would prevent the diode from being forward biased, and the trigger would be ineffective.

Since the output voltage is in-phase with the closing of the relay it may be used to signal the position of the relay or to trigger an associated circuit. The prime purpose of this multivibrator circuit, however, is to control the relay. Since the relay is a mechanical device, it operates at slower speeds than the electronic circuit; thus the relay operating speed determines the maximum switching speed.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges. Be careful to observe proper polarity when

checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output or Partial Output. Total** loss of output could only result from lack of supply voltage, since an output will be produced even if both transistors are inoperative. Although the relay will not operate if Q1 is defective or has a defective circuit part, a positive voltage equal to the V_{CC_2} supply will still be obtained from Q2, if inoperative, or a negative output if operable. Use an oscilloscope to determine that the proper input trigger exists and passes through the correct steering diode (an open diode can prevent triggering). Then measure the supply voltage and check the collector voltage on both transistors. With the correct collector bias supply voltage and base bias voltage present, the collector of the conducting transistor should measure very low (a few tenths of a volt), while the cut off transistor will have a high collector voltage almost the same as that of the supply voltage. If both collector voltages are low, either relay coil K1 or collector resistor R4 is open, or the transistor(s) are shorted. Check the resistance of R4 and K1 coil.

Where an output is obtained but no switching occurs, in addition to defective steering diodes, either R9, R1O, C3 or C4 can be open. Hence the necessity to use the oscilloscope to determine if the input trigger appears at the transistor base terminal. The circuit will operate without feedback capacitors Cl and C2 but will be somewhat slowed down, and will most probably cause sloping leading and trailing edges on the output waveform at high switching speeds.

Erratic Operation. Since the circuit is controlled by an external trigger it is important to observe the trigger with an oscilloscope to be certain that the trigger itself is not erratic. If the trigger appears normal in shape and amplitude, check operation of the steering diodes and the resistance of R5 and R8. If the resistance of R5 or R8 increases with age, or they become open, the biasing of the steering diodes and the discharge time of R9, C3 or R1O, C4 will be changed. Such condition might also be caused by defective transistors. Check the resistors with an ohmmeter, and the diodes and transistors with an in-circuit checker, if possible.

Incorrect Frequency or Gate Width. Since the multivibrator has no parts which govern the frequency or width of the output signal, these are both governed by the input triggers applied to the circuit. Hence, any change in these parameters must be the direct result of improper operation of the turn-on or turn-off trigger generating circuits.

Low Output. Low collector voltage, improper bias, or defective transistors can cause a low output voltage. A change in collector resistor R4 will also affect the output amplitude. Use an oscilloscope to check the output wavefrom and determine where the reduced amplitude exists. Then check for the proper bias and collector voltages in that portion of the circuit. If normal voltages are present and the collector resistor is within tolerance, but low output amplitude still exists, it can only be because of reduced collector current.

PART 7-3. MONOSTABLE

MONOSTABLE (ONE-SHOT) MULTI VIBRATORS

General.

The term monostable multivibrator refers to one class of multivibrator or relaxation oscillator circuits that function in a stable condition until the application of a trigger pulse. At this time the circuit switches rapidly and goes through one complete cycle of operation, after which it reverts to its original stable condition, in which it remains until the application of another trigger pulse. The monostable (or one-shot) multivibrator is essentially a two-stage resistance-capacitance-coupled amplifier, and not an oscillator in the strict sense of the word, with one stage normally cut off and the other stage normally conducting. The one shot multivibrator operates in much the same manner as the free-running, or astable, type discussed earlier in this Section of the Handbook, except that this circuit requires an input trigger to initiate the multivibrator action and produce the output signal.

The monostable multivibrator produces a square- or rectangular-wave output pulse, more commonly called a “gate”, having fast rise and fall times and extreme flatness on top; the pulse is produced only in response to an input trigger. The output frequency is determined by the frequency of the input trigger, and the duration of the gate length is determined by the circuit design. The one-shot multivibrator can be used at pulse-repetition rates from zero to maximum which is determined by the gate length and the R-C time constant of the circuit. A nominal range of gate time duration is from 30 to 2500 microseconds,

491-044 0-73- 51

which will accommodate trigger pulses in the range of 200 to 2000 pps.

In applications requring different gate lengths, the gatedeterrnining components can be switched in value to produce the desired gate length. Also, the monostable multivibrator may supply both positive and negative gates to as many as four branches. A precaution is that the positive-gate output should not be applied to a circuit requiring grid current as the multivibrator may occasionally fail; the use of a cathode follower or buffer circuit will eliminate this disadvantage. Because the monostable multivibrator is not well suited for controlling the gate length with a turn-off trigger pulse, a bistable multivibrator should be used when this type of control is desired.

Although the output from the monostable multivibrator is sometimes differentiated to provide a pulse either at the leading edge or the trailing edge of the gate waveform, in most cases only the leading edge of the waveform must be extremely fast; the trailing edge is usually not used for critical timing applications. A negative-going leading edge is used whenever possible since such a gate can be obtained rather easily from any tube electrode except the cathode. In addition, a negative gate at the plate of a multivibrator tube will always be generated at a lower impedance than a positive gate at the same plate.

TRIODE PLATE-TO-G RIO-COUPLED MONOSTABLE MU LTIVIBRATOR

Application.

The triode plate-to-grid-coupled monostable multivibrator produces a square-wave or rectangular-wave output for use as gating or timing signals.

Characteristics.

Circuit assumes a stable state in which one tube normally conducts and the other tube is normally cut off.

Requires an input trigger to cause circuit operation; circuit returns to stable state upon completion of one cycle of operation.

Input trigger can be either negative or positive; negative trigger affects tube that is normally conducting, and positive trigger affects tube that is normally cut off.

Produces square-wave or rectangular-wave output gates for both positive and negative polarity in response to an input trigger.

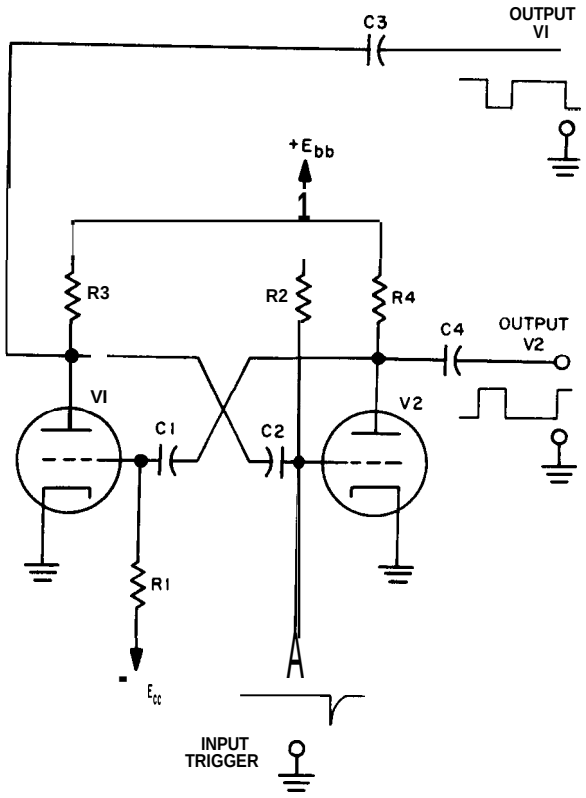
Output gate length is determined by R-C time constant in grid circuit and by the applied voltage; output frequency is determined by input trigger frequency.

Circuit Analysis.

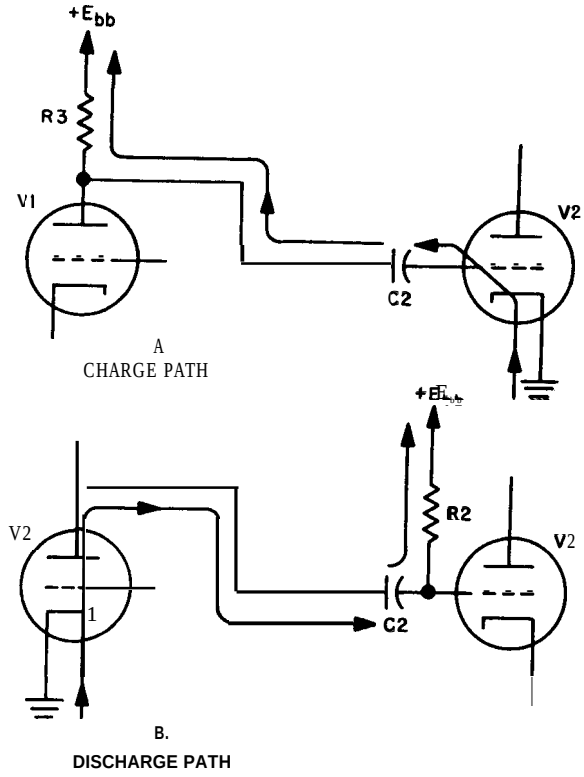
General. The triode plate-to-grid-coupled monostable multi vibrator is a two-stage resistance-capacitance-coupled amplifier capable of producing a square-wave or rectangular-wave output pulse (gate) in response to an input trigger The monostable multivibrator has only one stable state, in which one tube normally conducts while the other tube is normally cut off, and will function for only one complete cycle upon the application of the input trigger. To achieve the stable condition, the grid of the normally conducting tube is usually returned to B+, while the grid of the tube that is normally cut off is returned to ground or to a negative voltage source. Feedback from the plate of one tube to grid of the opposite tube is through R-C coupling. Because the monostable multivibrator operates for only one cycle in response to an input-trigger pulse, the output frequency of this circuit is dependent upon the input trigger frequency; the output gate length is determined by the R-C time constant of the plate-to-grid feedback network and the applied voltage. Output signals can be taken from the plate of either or both electron tubes.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a plate-to-grid-coupled monostable multivibrator configuration. Electron tubes V1 and V2 are identical-type triode tubes; although the accompanying schematic illustrates two separate triodes, a twin-triode is frequently used in this circuit. Capacitor Cl provides coupling from the plate of V2 to the grid of V1, and capacitor C2 provides coupling from the plate of V1 to the grid of V2. Resistor R1 returns the grid of V1 to the negative voltage (bias) supply, –Ecc, and resistor R2 returns the grid of V2 to the positive voltage supply, +Ebb. Resistors R3 and R4 are the plate-load resistors for V1 and V2, respectively. Capacitors C3 and C4 are the output coupling capacitors for V1 and V2, respectively. The tube that

is normally cut off is VI, and the tube that is normally conducting is V2.



Triode Plate-to-Grid-Coupled Monostable Multivibrator

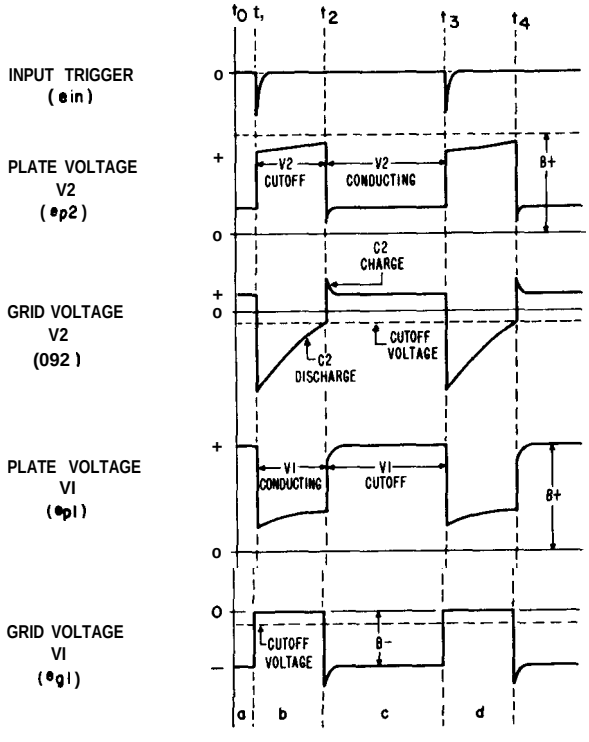


Charge and Discharge Paths for Capacitor C2

The following simplified schematic diagram illustrates the charge and discharge paths for feedback capacitor C2. The cutoff time of V2 is determined by the discharge of capacitor C2 through resistor R2 toward the positive voltage supply, +Ebb. Although the conduction resistance of V1 is included in the discharge path of C2, it is small as compared with the resistance of R2, and can therefore be neglected. The cutoff time of VI is determined by the period of the input trigger pulse. If the R2-C2 time constant is made exactly one-half the period of the trigger pulse, the multivibrator produces a symmetrical square-wave output; if the R2-C2 time constant is made longer or shorter than one-half the trigger pulse period, an asymmetrical rectangular-wave output is produced.

Consider now the operation of the triode plate-to-grid-coupled monostable multivibrator by referring to the preceding circuit illustrations and the following illustration to the idealized theoretical waveforms. When voltage is first applied, V2 goes into conduction and VI cuts off. This action results from the fact that the grid of V2 is returned through resistor R2 to a positive voltage, while the grid of V1 is returned through resistor R1 to a negative voltage. Thus, at time t. (start of time interval a) on the waveform illustration, the grid voltage of V2 (eg_2) is slightly positive, causing conduction through V2, and a decrease in its plate voltage (ep_2). The negative-going voltage at the plate of V2 is coupled through capacitor Cl to the grid of V1, thus aiding in cutting off this tube (waveform eg_1). Also, at to, coupling capacitor C2 charges through the low cathode-to-grid internal resistance of V2 (approximately 1K) and the V1 plate-load resistor, R3. The voltage at the plate of

VI is represented by the ep_1 waveform. At to, then, the plate-to-grid-coupled monostable multivibrator assumes its stable state, in which V2 normally conducts and V1 is normally cut off; the circuit remains in this condition until a trigger pulse is applied.



Theoretical Waveforms for Triode Plata-to-Grid Coupled Monosteble Multivibrator

Assume now that a negative trigger pulse of sufficient amplitude to cut off the tube is applied directly to the grid of V2. The effect of this trigger pulse (e_{in}, applied at t_1) is to drive V2 into cutoff. As a result of the decreased conduction through V2, the plate voltage of v2 (ep_2) rises toward the supply voltage, and the positive-going signal is coupled through capacitor Cl to the grid of Vl, thus raising the grid voltage (eg_1) above cutoff and driving V1 into conduction. The plate voltage of V1 (ep_1) decreases, and the negative-going signal is coupled through capacitor C2 to the grid of V2 to drive V2 further into cutoff. Thus, at t_1 a switching action occurs and the multivibrator is in a "temporary" stable state in which V1 conducts and V2 is cutoff.

During this temporary stable state (time interval b), capacitor C2 discharges through resistor R2 toward the potential of the positive voltage supply. This causes the grid voltage of V2 (eg_2) O to rise toward the potential of the positive voltage supply until the point is reached where the grid voltage of V2 can no longer hold the tube cut off. At that instant, t_2, V2 once again conducts and the negative-going signal at its plate is coupled through capacitor Cl to the grid of VI which again cuts off V1. The voltage waveform at the plate of V1 (ep_1) is rounded off, and the waveform at the grid of V2 (eg_2) has a small positive spike of the same time duration as a result of the charging of coupling capacitor C2 when V2 again conducts. The plate voltage waveform of V2 (ep_2) has a small negative spike at the same time duration as the positive spike on the V2 grid voltage waveform (eg_2). Hence, at t_2, the multivibrator reverts to its original stable condition, in which V2 conducts and V1 is cut off; the circuit remains in this condition (time interval c) until another negative trigger pulse is applied at t_3.

Close examination of the waveforms reveals that the monostable multivibrator goes through one complete cycle of operation for each input trigger pulse. Also, the time of application of the trigger pulse determines when V1 is driven into conduction, and the R-C time constant of R2-C2 and the applied voltage determines when V2 is driven into conduction. Thus, the monostable multivibrator output frequency is determined by the input trigger frequency, and the output gate width is determined by the discharging of capacitor C2 through resistor R2 toward the potential of the positive voltage supply.

A negative trigger pulse applied to the grid of the normally conducting tube, as was done in this case, is not the only method by which the multivibrator circuit can be triggered. A negative trigger pulse applied directly to the plate of VI and coupled through capacitor C2 to the grid of V2 serves the same purpose. A positive trigger pr.dse applied directly to the plate of V2 or to the grid of V1 will also trigger the circuit. In some practical-circuit applications, a positive trigger is applied to the grid of a "trigger-inverter" stage whose plate is comected in parallel with the plate of VI; the inverted trigger is then coupled through capacitor C2 to the grid of V2 as a negative trigger pulse. In any event, a cycle of

multivibrator operation is initiated by diving the normally conducting tube into cutoff, or by driving the tube that is normally cut off into conduction.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuit and whether it is of the proper polarity and amplitude. Lack of an input trigger at the grid of V2 can be due to failure of the externrd input-trigger source.

Failure of the positive voltage supply, +Ebb, will disrupt the operation of the circuit, as will an open cathode circuit. With tubes (or a single twin-triode tube) installed in the circuit, the filament and plate voltages should be measured, as well as the grid bias voltage, to determine whether the applied voltages are within tolerance and whether plate-load resistor R3 or R4 or grid-bias resistor R1 or R2 is open. If coupling capacitor Cl or C2 opens, there will be no feedback signal to effect the multivibrator switching action. An open output coupling capacitor, C3 or C4, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective tube; however, it can also be caused by a decrease in the applied plate voltage or an increase in the resistance of the associated plate-load resistor, R3 or R4. A leaky or shorted output coupling capacitor, C3 or C4, will form a voltage divider with the input resistor of the following stage. In this input resistor is returned to ground or to a negative voltage supply, the voltage at the plate of both VI and V2 will be reduced, and the operation of the following stage will be upset by the change in voltage applied to its grid. Also, the additional current through plate-load resistor R3 or R4 may cause the resistor to bum out.

Incorrect Frequency or Gate Width. The plate-to-grid-coupled monostable multivibrator has no components governing the frequency of its output-gate signal; this frequency is governed by the input trigger applied to the circuit. Therefore, any change in the output-gate frequency is a result of improper operation of the trigger generating circuits. A change in the output-gate width, however, will result if there is a change in the value of either resistor R2, capacitor C2, or the applied voltage. A change in the resistance or capacitance of the R2-C2 timing control circuit will have the greatest effect on the gate width; changes in the applied voltage will affect the gate width to a lesser degree.

TRIODE COMMON-CATHODE-RESISTOR-COUPLED MONOSTABLE MULTI VIBRATOR

Application.

The triode common-cathode-resistor-coupled monostable multivibrator produces a square-wave or rectangular-wave output for use as gating or timing signals.

Characteristics.

Circuit assumes a stable state, in which one tube normally conducts and the other tube is normally cut off.

Requires an input trigger to cause circuit operation; circuit returns to stable state upon completion of one cycle of operation.

Input trigger can be either negative or positive; negative trigger affects tube that is normally conducting, and positive trigger affects tube that is normally cut off.

Produces square-wave or rectangular-wave output gates of both positive and negative polarity in response to an input trigger.

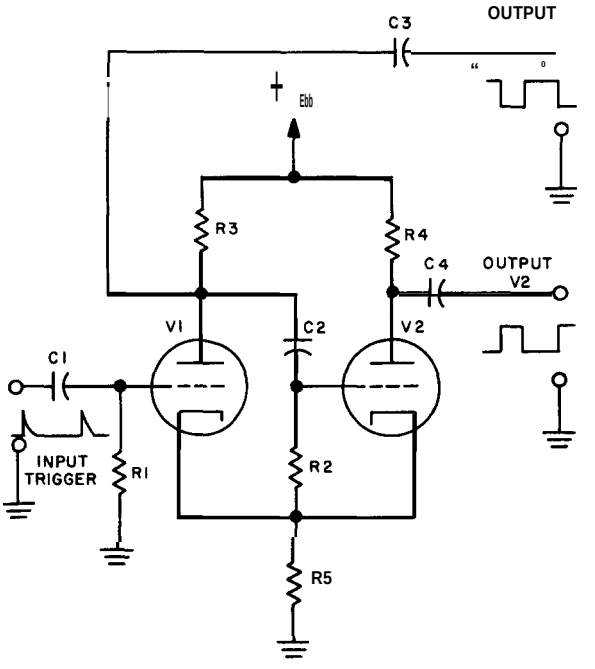
Output gate length is determined by R-C time constant in grid circuit and by the applied voltage; output frequency is determined by input trigger frequency.

Circuit Analysis.

General. The triode common-cathode-resistor-coupled monostable multivibrator is functionally similar to the Triode Plate-to-Grid-Coupled Monostable Multivibrator discussed previously in this Section of the Handbook. The circuit has only one stable state, in which one tube normally conducts while the other tube is normally cut off, and will function for only one complete cycle upon the application of an input trigger pulse. To achieve the stable condition, the grid of the normally conducting tube is usually returned to its cathode or to B+ while the grid of the tube that is normally cut off is returned to ground or to a negative voltage (bias) supply. R-C coupling is provided from the plate of V1 to the grid of V2, but the coupling from V2 to V1 is effected across a common cathode resistor. Because the monostable multivibrator operates for only one

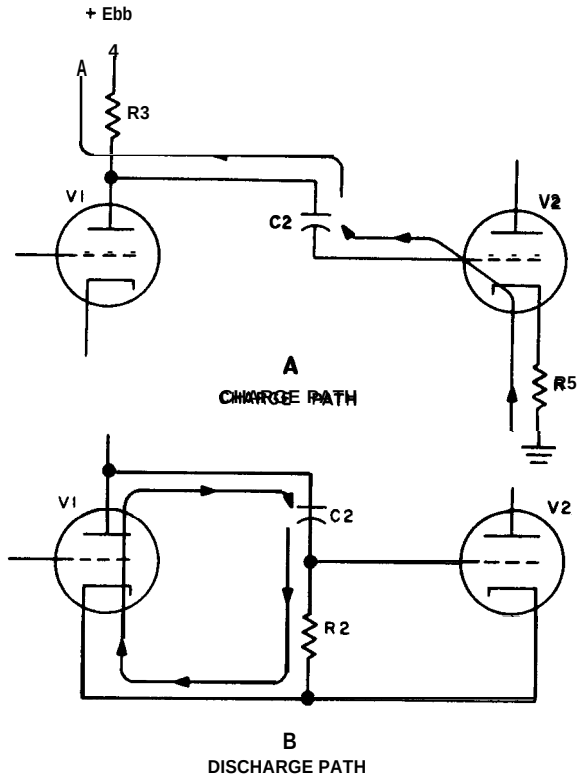
cycle in response to an input trigger pulse, the output frequency of this circuit is dependent upon the input trigger time constant of the grid circuit and by the applied voltage. Output signals can be taken from the plate of either or both electron tubes.

Circuit **Operation. The** following circuit schematic illustrates two triode electron tubes in a common-cathode-resistor-coupled monostable multivibrator configuration. Electron tubes VI and V2 are identical-type triode tubes; although the accompanying schematic illustrates two separate triodes, a twin-triode is frequently used in this circuit. Capacitor Cl is the input coupling capacitor for application of a positive trigger to the grid of VI. Capacitor C2 provides coupling from the plate of V1 to the grid of V2. Resistor R1 returns the grid of V1 to ground, and resistor R2 returns the grid of V2 to the common cathode connection. Resistors R3 and R4 are the plate-load resistors for V1 and V2, respectively. Resistor R5 is the common cathode bias and coupling resistor for coupling from V2 to V1. Capacitors C3 and C4 are the output coupling capacitors for V1 and V2, respectively. The tube that is normally cut off is V1, and the tube that is normally conducting is V2.



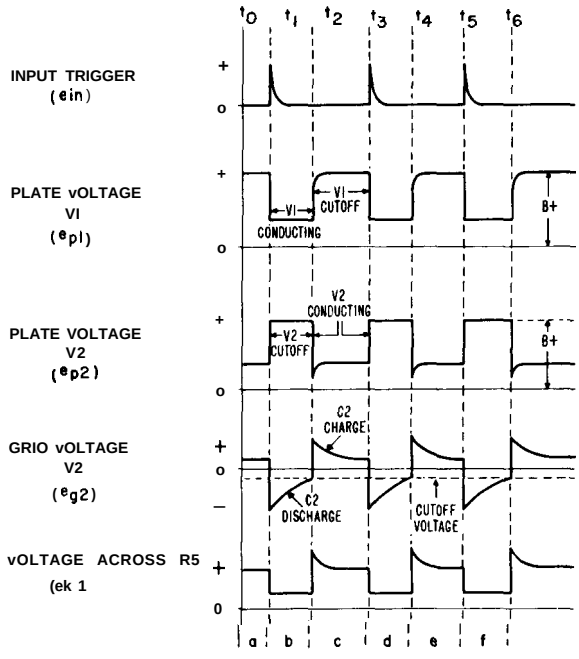
Triode Common-Cathode-Resistor-Coupled MonoStable Multivibrator

The following simplified schematic diagram illustrates the charge and discharge paths for capacitor C2. The cut-off time of V2 is determined by the discharge of capacitor C2 through resistor R2. Although the conduction resistance of VI is included in the discharge path of C2, it is frequency; the output gate length is determined by the R-C small as compared with the resistance of R2, and can therefore be neglected. The cutoff time of V1 is determined by the period of the input trigger pulse. If the R2-C2 time constant is made exactly one-half the period of the trigger pulse, the multivibrator produces a symmetrical square-wave output; if the R2-C2 time constant is made longer or shorter than one-half the trigger pulse period, an asymmetrical rectangular-wave output is produced.



Charga and Dischargs Paths for Capacitor C2

Consider now the operation of the triode common-cathode-resistor-coupled monostable multivibrator by referring to the preceding circuit illustrations and the following illustration of the idealized theoretical waveforms. When voltage is first applied, V2 goes into conduction and VI cuts off. This action results from the fact that the grid of V2 is returned through resistor R2 to the cathode, initially placing this grid at the same potential as the cathode, and thus allowing V2 to conduct heavily. The plate current flow of V2 through common cathode resistor R5 makes the voltage at the top of the resistor positive with respect to ground, producing a bias voltage of sufficient amplitude to hold V1 cut off (since its grid is returned to ground through resistor RI), and still permit V2 to conduct. Thus, at time t. (start of time interval a) on the waveform illustration, the grid voltage of V2 (eg_2) is slightly positive, causing conduction through V2; as a result, the plate voltage (ep_2) of V2 decreases because of plate current flow through plate-load resistor R4. Also, as a result of V2 plate current, there is a positive voltage (ek) developed across common cathode resistor R5, which provides the bias to cut off VI. The positive-going voltage at the plate of VI (ep_1) is coupled through capacitor C2 to the grid of V2, driving the grid further positive. Also, at to, coupling capacitor C2 charges through the low cathode-to-grid internal resistance of V2 (approximately 1 K) and the plate-Iload resistor, R3, of V1. At to, then the common-cathode-resistor-coupled monostable multivibrator assumes its stable state, in which V2 normally conducts and V1 is normally cut off; the circuit remains in this condition until a trigger pulse is applied.



Theoretical Waveforms for Triode Common-Cethode-Resistor-Coupled Monostable Multivibrator

Assume now that a positive trigger pulse of sufficient amplitude to cause the tube to conduct is applied to the grid of V1 through coupling capacitor Cl. The effect of this trigger pulse (e_{in}, applied at t_1) is to drive V1 into conduction, thus causing an increase in current through V1 and a decrease in the

plate voltage (ep_1) of VI. This negative-going voltage is applied instantaneously through capacitor C2 to the grid of V2, driving the grid voltage of V2 (eg_2) below cutoff. When the V2 plate current ceases, the voltage drop (ek) across cathode resistor R5 decreases to the level where it decreases the bias on VI, permitting this tube to conduct more heavily. Thus, at t_1, a switching action occurs and the multivibrator is in a "temporary" stable state, in which V1 conducts and V2 is cut off.

During this temporary stable state (time interval b), capacitor C2 begins to discharge, causing the grid voltage of V2 (eg_2) to become less negative. The discharge path of C2 is downward through grid resistor R2 and then upward through the low cathode-to-plate conduction resistance of V1. At this time VI alone is conducting; its plate current is limited by its own cathode bias, which is not sufficient to cut off VI. As the voltage (eg_2) on the grid of V2 becomes less negative, because of the discharging of capacitor C2, it soon reaches the point, at t_2, where is is no longer of sufficient amplitude to hold V2 in cutoff. Consequently, V2 once again conducts, and the flow of V2 plate current through common cathode resistor R5 increases the voltage drop (ek) across this resistor, again increasing the bias of VI and reducing the flow of plate current through V1. As the conduction through VI decreases, the plate voltage (ep_1) of VI rises toward the potential of the positive voltage, supply, +Ebb. The positive-going signal at the plate of VI is coupled through capacitor C2 to the grid of V2, driving this grid positive (waveform eg_2, at t_2). Thus, capacitor C2 stops discharging and again begins charging. The voltage waveform at the grid of V2 (eg_2) has a' small positive spike of the same time duration, as a result of the charging of coupling capacitor C2 when V2 again conducts. The plate voltage waveform of V2 (ep_2) has a small negative spike, and the voltage waveform across common cathode resistor R5 (ek) has a small positive spike of the same time duration as the positive spike on the V2 grid voltage waveform (eg_2). Hence, at t_2, the multivibrator reverts to its original stable condition in which V2 conducts and VI is cut off; the circuit remains in this condition (time interval c) until another positive trigger pulse is applied at t_3.

Close examination of the waveforms reveals that the monostable multivibrator goes through one complete cycle of operation for each input trigger pulse. Also, the time of application of the trigger pulse determines when V1 is driven into conduction, and the R-C time constant of R2-C2 and the applied voltage determine when V2 is driven into conduction. Thus, the monostable multivibrator output frequency is determined by the input trigger frequency, and the output gate width is determined by the discharging of capacitor C2 through resistor R2 toward the potential of the positive voltage supply.

A positive trigger pulse applied to the grid of the tube that is normally cutoff, as was done in this case, is not the only method by which the multivibrator circuit can be triggered. A negative trigger pulse applied directly to the cathode of V1 or applied to the grid of V2 and coupled to the cathode of V1 through the cathod-follower action of R5 serves the same purpose. In some practical-circuit applications, a positive trigger is applied to the grid of a "trigger-inverter" stage whose plate is connected in parallel with the plate of V1; the inverted trigger is then coupled through capacitor C2 to the grid of V2 as a negative trigger pulse. In any event, a cycle of multivibrator operation is initiated by driving the normally conducting tube into cutoff, or by driving the tube that is normally cut off into conduction.

Failure Analysis.

No Output. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuit and whether it is of the proper polarity and amplitude. Lack of an input trigger at the grid of V1 can be due to an open coupling capacitor, Cl, or to failure of the external input-trigger source.

Failure of the positive voltage supply, +Ebb, will disrupt the operation of the circuit, as will an open cathode circuit. With tubes (or a single twin-triode tube) installed in the circuit, the filament and plate voltages should be measured, as well as the bias voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether plate-load resistor R3 or R4 or cathode bias resistor R5 is open. If coupling capacitor C2 opens, there will be no feedback signal to effect the multivibrator switching action. An open output coupling capacitor, C3 or C4, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective tube; however, it can also be caused by a decrease in the applied voltage or an increase in the resistance of the associated plate-load

resistor, R3 or R4. A leaky or shorted output coupling capacitor, C3 or C4, will form a voltage divider with the input resistor of the following stage. If the input resistor of this following stage is returned to ground or to a negative voltage supply, the voltage at the plate of both V1 and V2 will be reduced, and the operation of this folIowing stage will be upset by the change in voltage applied to its grid. Also, the additional current through plate-load resistor R3 or R4 may cause the resistor to bum out.

Incorrect Frequency or Gate Width. The common-cathode-resistor-coupled monostable multivibrator has no components governing the frequency of its outputgate signal; this frequency is governed by the input trigger applied to the circuit. Therefore, any change in the output-gate frequency is a result of improper operation of the trigger-generating circuits. A change in the output-gate width, however, will result if there is a change in the value of either resistor IV?, capacitor C2, or the applied voltage. A change in the resistance or capacitance of the R2-C2 timing control circuit will have the greatest effect on the gate width; changes in the applied voltage will affect the gate width to a lesser degree.

BASIC ONE-SHOT TRANSISTOR MU LTIVIBRATOR

Application.

The basic one-shot transistor multivibrator is used to provide a delay function for compatible logic circuits, or is used as gate in computers, electronic control or communication equipment.

Characteristics.

Usually uses fixed bias.

Requires an on-trigger, but will automatically turn itself off.

Operates at the same repetition frequency as that of the trigger.

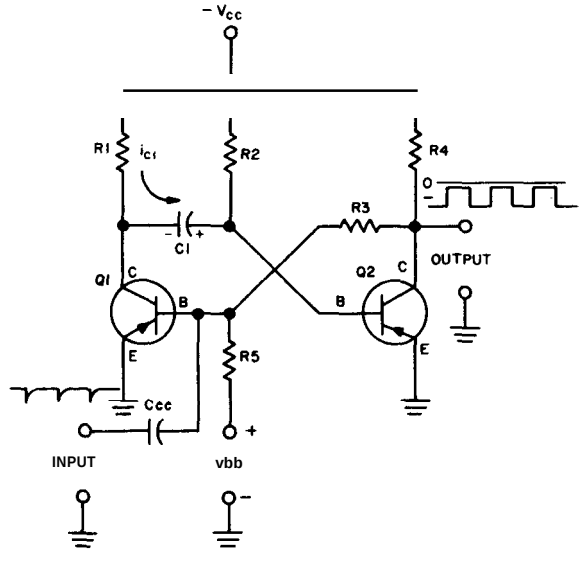
Has one stable state (monostable).

Isa saturating type of multivibrator.

Circuit Analysis.

General. The basic one-shot multivibrator is a triggered circuit, which requires a trigger pulse to initiate action. Once the trigger pulse initiates the action, the circuit automatically completes one full cycle of operation. Either the stable state of cutoff or saturation is used. Normally, one transistor is operated saturated while the other is at cutoff. When the circuit is triggered by an external pulse, the operating point is moved from the initial stable region to the other stable (operating) region. The time constant of the circuit elements determines how long the circuit will remain in the stable (operating) region. At the end of the time constant, the operating point then moves back to the original stable region.

Circuit Operation. The schematic of a typical basic monostable (one-shot) multivibrator is shown in the accompanying illustration.



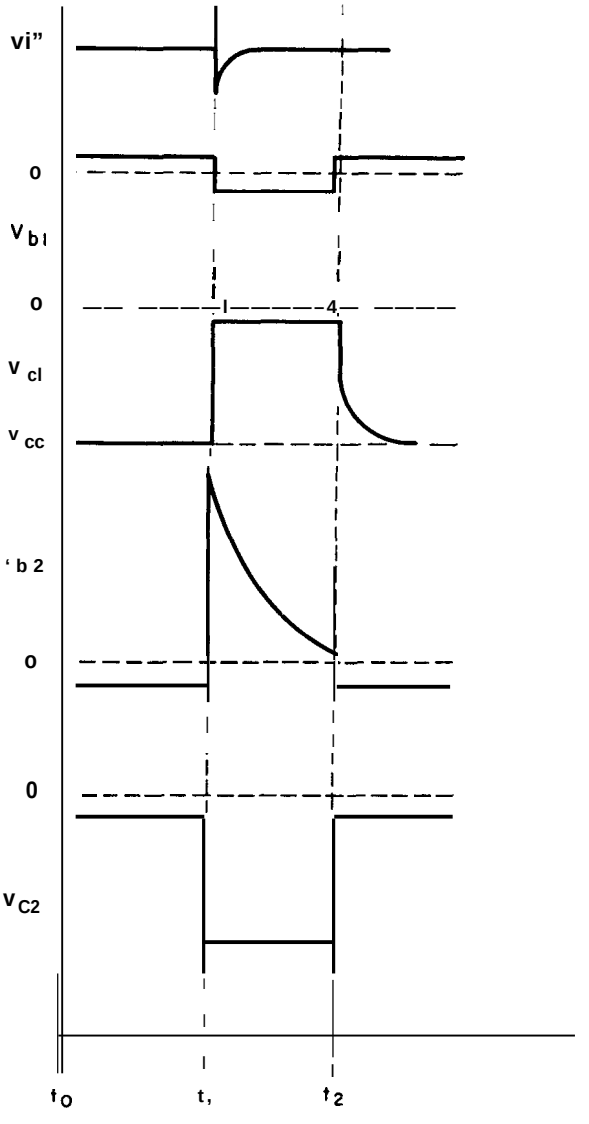
Basic PNP One-Shot Multivibrator

Fixed forward bias is applied to the base of Q2 by resistor R2, while the voltage divider consisting of R4, R3, and R5 forma fixed bias divider between the base bias supply and the collector supply and ground. Thus Q1 is biased slightly positive, and is cut off by this reverse-bias. Resistor R4 also is the collector resistor for Q2, and R1 serves a similar function for Q1. Resistor R3 serves as the collector-to-base feedback resistor for Ql, while Cl is the feedback capacitor for Q2. Both emitters are grounded and a cross-connected, grounded-emitter circuit is used. The input is applied through coupling capacitor Ccc, while the output is taken directly from the collector of Q2.

If desired, the output load could also be capacitively coupled.

In the quiescent condition, transistor Q2 conducts heavily while transistor QI is cut off. This action occurs initially because of the large negative forward bias placed on the base of Q2 by resistor R2, which is connected back to the negative supply. Thus an application of power Q2 quickly saturates, and developes a positive-swinging output across R4, which is fed back to the base of Q1 through resistor R3, holding the transistor at cut off. During the on-period of Q2, feedback capacitor Cl is charged positively, through R1 and the low base-emitter saturation resistance of Q2. The low saturation resistance of Q2 base-emitter junction acts as a switch, connecting R1 and Cl in series with the negative supply source and ground.

When the negative trigger is applied to Q1 base through coupling capacitor Ccc (time t_1 in the following waveform illustration), transistor Q1 is driven into conduction by this forward bias. The flow of Q1 collector current through RI reduces the effective collector voltage and produces a positive-swinging voltage across R4, which is applied through feedback capacitor Cl as a positive reverse bias to cut off Q2. As the collector current of Q2 reduces, the voltage across collector resistor R4 rises toward that of the negative collector supply, and an increasing forward-bias is fed back to the base of Q1 through feedback resistor R3. Thus Q2 is cut off and Q1 is turned on. Operation is now reversed and the output from Q2 is a negative voltage. Since Cl is positively charged, when disconnected from ground by Q2 being driven into cut off, the capacitor holds the base of Q2 highly positive (reverse-biased) while it discharges. The discharge path is through the low collector-to-emitter saturation resistance of QI, and ground on one side, and through R2 to the negative supply on the other side. The discharge is shown by the typical RC discharge curve on the trailing edge of the Vb_2 waveform (time t_1 to t_2) in the waveform illustration. Q2 remains nonconducting until the base voltage drops to zero and the base of Q2 goes slightly negative at time t_2. Q2 immediately starts to conduct, and the flow of collector current through R4 produces a positive-swinging voltage, which is applied through feedback resistor R3 to drive Q1 in a reverse-biased direction and stop conduction through Q1. This action occurs quickly, and a positive square wave now appears at the output of Q2. The quiescent state of operation continues until the next trigger (time t_2), whereupon the switching action described above is again repeated.



Monostable Multivibrator Waveforms

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of

shunting resistance employed on the low voltage ranges. Be careful to observe proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output.** Lack of supply voltage, an open collector resistor, R4, or a defective transistor can cause a no-output indication. Measure the supply and collector voltages with a high resistance voltmeter, if the supply voltage is normal but the collector voltage is low or zero, either R4 is open or Q2 is shorted. Checking the resistance of R4 with an ohmmeter will determine if Q2 needs replacement.

Continuous **Output.** If bias resistor R2 increases with age or opens, the base of Q2 will tend to float in a zero-biased condition. The collector of Q2 will rise to the supplY value, and a continuous output with no switching action will occur. The same indication will also occur if R3 is open, since Q1 will be biased beyond cut off and the trigger will not be large enough to initiate action. At the very best, an attempt to switch may be noticed, with the circuit reverting back to the cut off condition when the trigger ceases. Such action is best observed with an oscilloscope. Should R5 open, a negative (forward-bias) will be placed on Ql, and both Q1 and Q2 will conduct with a continuous positive output from Q2. On the other hand if Q1 is stopped from conducting by a short across R5, Q2 will continue to operate alone, also producing a continuous positive output. Because of the few resistors in the circuit a quick check with an ohmmeter will determine if they are satisfactory. Should Cl be open circuited, no feedback can be applied from the collector of Q1 to the base of Q2 and switching will not occur, again Q2 will rest in a conducting position with a positive output near zero. If Cl becomes short circuited, R1 and R2 will be paralleled and a higher forward bias will be applied. Q2 base, holding it in conduction and preventing operation. Use an in-circuit capacitance checker to check the capacity of Cl. If the resistors are satisfactory, together with Cl, then Q1 must be defective if a continuous output still occurs.

Low Output. Low collector voltage, improper bias, or defective transistors can cause a low output voltage. A change in collector resistor R4 will also affect the output amplitude. Use an oscilloscope to check the output waveform and determine where the reduced amplitude exists. Then check for the proper bias and collector voltages in that portion of the circuit. If normal voltages are present and the collector resistor is within tolerance, but a low output amplitude still exists, it can only be because of reduced collector current.

Incorrect Frequency. Since the multivibrator has no parts which govern the frequency of operation, it is governed by the applied input trigger. Hence any change in frequency must be the result of improper operation of the turn-on trigger generating circuits.

Incorrect Pulse Width. While the frequency is governed by the input trigger, the length of time the circuit operates before flipping back to the initial stable condition is determined by the circuit time-constant governed by the charge and discharge of Cl through R2, and also R1. Thus if the value of Cl changes or that of R1 or R2 changes, or if the saturation resistance of transistor Q2 changes appreciably, a different pulse width may be expected. Observation of the output pulse on an oscilloscope will show any change in width. Measure the value of Cl with an in-circuit capacitance checker, and check the resistance of R1 and R2. If these parts appear satisfactory replace Q2 with a known good transistor. Any delays in switching are the result of minority carrier injection into the base at saturation, which requires a finite discharge time until the circuit can be triggered. Should a noticeable delay in switching occur after the circuit has been operating properly, check all parts values.

PHANTASTRON MU LTIVIBRATOR

Application.

The phantastron multivibrator is used to generate a rectangular-wave output having extreme linearity and accuracy, for use as gating or timing signals.

Characteristics.

Operation is similar to that of a monostable multivibrator.

Pulse width or delay varies linearly with the applied control voltage.

Requires an electron tube of the pentode or pentagrid type.

Circuit operation turn-on is by application of negative trigger to the plate, or positive trigger to the suppressor, of a pentode or the additional control grid of a pentagrid tube; turn-off is automatic by internally generated waveform.

Output can be taken from the cathode, screen, or plate, and may be either positive or negative, as selected.

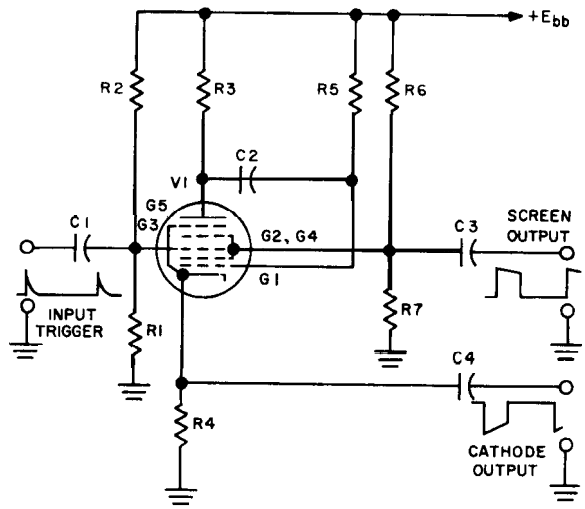
Provides either a low-impedance or high-impedance output, as determined by output connections.

Circuit Analysis.

General. The phantastron circuit is considered to be a relaxation oscillator similar to the multivibrator in operation; the screen-coupled and cathode-coupled phantastron circuits are analogous to the plate-to-grid< oupled and cathode-coupled monostable multivibrators, respectively. A difference in the operation of the circuits is that the monostable multivibrator derives its timing from an exponential waveform developed by an R-C network, whereas the phantastron uses a basic Miller-type sweep generator to produce a linear timing waveform. The phantastron is usually turned on by the application of a gating or trigger pulse, and is turned off automatically by an internally generated waveform. Both a positive and a negative rectangular-wave output with well-defined leading edges may be obtained from the phantastron, depending on the output connections.

For a thorough analysis of Miller circuit operation, and the operation of the screen-coupled, and fast-recovery pentode phantastron circuits, refer to the discussion of time delay circuits in the Special Circuits Section of this Handbook.

Circuit Operation. The following schematic illustrates a pentagrid tube (type 6SA7 or equivalent) in a cathode-coupled phantastron multivibrator configuration. Although the schematic illustrates a pentagrid tube, a sharp-cutoff pentode, such as the 6AS6 or its electrically equivalent premium-type miniature 5725 or subminiature 5636, could be used as well, provided that the necessary circuit modifications are incorporated as illustrated and described in the Special Circuits Section of this Handbook.



Pentagrid Phantastron Multivibrator

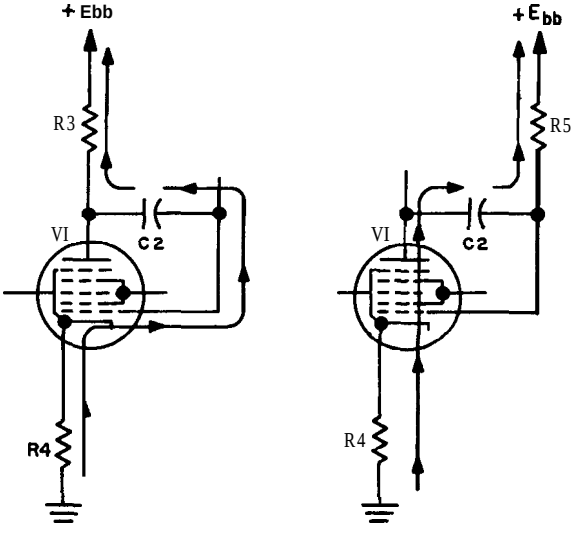
The functions of the electrodes of the pentagrid tube used in this circuit are as follows: Grid 1, which is the control grid, controls the total tube (cathode) current. Grids 2 and 4, connected internally, act as the screen grid. The cathode, the control grid (grid 1), and the screen grid (grids 2 and 4) correspond to the normally conducting tube of the cathode-coupled monostable multivibrator. (For analysis of Triode Common-Cathode-Resistor-Coupled Monostable Multivibrator operation, refer to the applicable discussion given earlier in this Section of the Handbook.) Grid 3, which is additional control grid, controls the division between screen and plate current; a negative voltage on this grid reduces plate current and increases screen current; a positive voltage has the opposite effect. Also, grid 3 has the effect of changing the cathode current, since some of the

d

electrons returned toward the cathode by its action pass through the screen grid and reduce the space charge near the cathode, thereby causing the increase of screen current to be less than the corresponding decrease in plate current. Grid 5, connected internally to the cathode, is suppressor grid. The cathode, the additional control grid (grid 3), and the plate correspond to the normally cutoff tube of the cathode-coupled monostable multivibrator.

The circuit components of the pentagrid-tube phantastron multivibrator serve the following functions: Resistors RI and R2 forma voltage divider from the positive voltage supply (+Ebb) to ground, setting the bias level of grid 3 and thereby initially holding plate current cut off. Resistor R3 is the plate-load resistor. The cathode-bias resistor, R4, also serves as the cathode-load resistor. Resistors R6 and R7 form a voltage divider from the positive voltage supply (+Ebb) to ground, setting the operating voltage level of the screen grid. Resistor R5 returns the control grid to the positive voltage supply, setting the bias level that initially permits the screen grid to conduct heavily. Operation of the circuit occurs at the rate determined by the discharge of feedback capacitor C2 through resistor R5; in some circuits this grid-return resistor, which usually has a value exceeding 1 megohm, is made variable to set the maximum delay or pulse width of the output gate. Capacitor C2 also provides feedback from plate to grid to allow rapid response to any changes in the plate voltage. Capacitor Cl couples the input trigger to grid 3; this trigger initiates (or turns on) the phantastron action. Capacitors C3 and C4 are the output coupling capacitors for the screen grid and cathode, respectively; a positive gate is obtained from the screen grid, and a negative gate from the cathode. If desired, a linear sawtooth waveform can be obtained from the plate of the phantastron circuit.

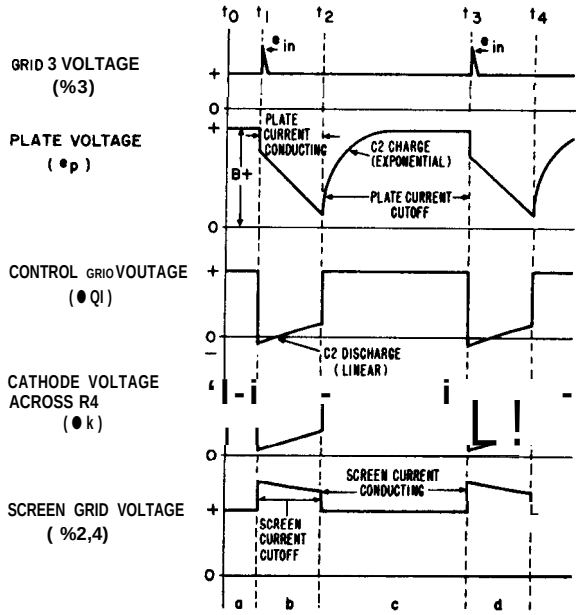
The following simplified schematic diagram shows the charge and discharge paths for capacitor C2. The charge path (part A of the illustration) is from ground through cathode resistor R4, the low cathode-to%rid conduction resistance of VI, to the right side of the capacitor, and then from the left side of the capacitor through plate-load resistor R3 and the positive voltage supply back to ground. This path causes capacitor C2 to charge at an exponential rate during the time that plate current is cut off and the tube is drawing heavy screen current and only slight control grid current. The discharge path (part B of the illustration) for capacitor C2 is from its right side through grid-bias resistor R5 and the positive voltage supply (+Ebb) to ground, and then from ground through cathode resistor R4 and the low cathode-to-plate conduction resistance of V1 to the left side of the capacitor. This path causes capacitor C2 to discharge at a linear rate during the time that screen current is low (near cutoff) and the tube is drawing heavy plate current. The linear discharge of capacitor C2 results from the Miller effect of tube VI, producing a much longer discharge circuit than could be obtained from R5-C2 alone. That is, although the discharge rate of capacitor C2 is determined by the time constant of R5-C2, the discharge capacitance is not the value of C2 alone, but is effectively the value of C2 times the quantity unity plus the gain of V1 (1 + A), which is the Miller effect.



Charge and Discharge Paths for Capacitor C2

The operation of the phantastron muhivibrator can be more easily understood by referring to the preceding circuit illustrations and the accompanying waveform illustration during the following discussion. When voltage is first applied, the plate section of the tube is in cutoff and there is heavy screen grid current. The conduction of screen current

is a result of the operating voltage on this electrode, as determined by voltage divider resistor R6 and R7. The voltage is sufficiently positive to attract electrons emitted by the cathode as a result of the positive bias on the control grid (positive voltage return to B+ through resistor R5); this permits the flow of cathode current at this time. In addition to permitting heavy screen current, the positive control grid draws current and charges capacitor C2 through the path described previously. The total screen and control grid current through cathode-bias resistor R4 produces a voltage drop across this resistor. Comparison of the ek and eg_3 waveforms reveals that the positive potential at the top of resistor R4 is now greater than the positive potential at grid 3, which is obtained from the action of voltage divider resistors RI and R2. A bias voltage is therefore established between grid 3 and the cathode; this bias is sufficient to cut off plate current, while having no effect on screen or control grid current. Because there is no plate current, the plate potential is maximum positive (at B+), as depicted by the ep voltage w“aveforrn during time intervrd a. Notice, also, during time interval a, that the screen voltage (eg_{214}) is at a minimum as a result of heavy screen current, the cathode voltage (ek) is positive, and the control grid voltage (eg_l) is positive because the positive-going signal at the plate is fed back through capacitor C2. This, then, is the stable state of the phantastron multivibrator; the circuit remains in this condition (heavy screen current and plate current cut off) until a positive trigger pulse is applied to grid 3 at t_1.



Theoretical Wavaforms for Pentagrid Phantastron Multivibrator

When the positive trigger (e_{in}) is applied through capacitor Cl to grid 3, it overcomes the bias on this grid and permits plate current to flow. This current, in turn, causes an immediate drop in the plate voltage developed across plate-load resistor R3. The

negative-going signal at the plate is coupled through capacitor C2 to the control grid, where it drives the grid sufficiently negative to reduce the total cathode current. Since the total cathode current is reduced, the screen current is also reduced; thus a positive-going voltage is produced at the screen grid. Through cathode-follower action, the negative-going signal at the control grid is coupled to the cathode, where it reduces the bias between the cathode and grid 3. With a decrease in this bias voltage there is an increase in plate current, resulting in a further drop in plate voltage. The action just described is cumulative and instantaneous, so that when the positive trigger is applied to grid 3 at t_1, there is an immediate increase in plate current and a sharp fall in plate voltage, a decrease in screen current and a sharp increase in screen voltage, a decrease in total cathode current and sharp decrease in cathode voltage, and the control grid is driven negative. All of the voltage relationships are depicted at t_1 on the waveform illustration.

The fact that the plate current increases while the cathode current decreases is possible because the screen current is now decreasing. Therefore, the rise in plate current results from the fact that the plate draws current which had previously gone to the screen grid. That is, the bias between the cathode and grid 3 is decreasing, which is a regenerative action, causing the plate current to increase. Simultaneously, the bias between the cathode and control grid is increasing, which is a degenerative action, causing the total tube current (and screen grid current) to decrease. The screen grid current is only reduced–not cut off completely; if it were cut off completely, the plate current would also be cut off and circuit would not function. Hence, there must be a point were the regenerative and degenerative effects are equal and the current stabilizes for an instant. This is the instant (at t_1, when the sharp drop in plate voltage ceases) at which capacitor C2 begins its linear discharge action.

As capacitor C2 discharges during time interval b, it loses electrons from its right side, in effect making this side of the capacitor (and the control grid as well) more positive to reduce the bias between the control grid and the cathode. The reduction in control grid bias permits a heavier flow of plate current through the tube, which gradually raises the voltage drop across cathode-bias resistor R4 (ek waveform) and lowers the plate voltage (ep waveform), as illustrated during time intervals b. The rate of change in tube current is governed by the discharge rate of capacitor C2 through resistor R5. Thus, in discharging, the control grid side of capacitor C2 gradually becomes more positive, causing an increase in plate current that produces a constant decrease in plate voltage. The positive voltage increment on the control grid is always slightly greater than the negative-going plate signal it produces; therefore, the the grid potential gradually rises and the plate potential gradually drops, as depicted by the respective grid (eg_1) and plate (ep) waveforms during time interval b.

An important characteristic of this circuit is the extreme linearity of the rate of change in the plate voltage and grid voltage during time interval b. The positive-going grid increases tube conduction, thereby decreasing the internal resistance of the tube. A decreasing resistance in series with a capacitor results in a linear voltage discharge of the capacitor, instead of the exponential discharge obtained when a fixed value of resistance is in series with a capacitor. The phantastron plate voltage during time interval *b* is, therefore, a linear downward-sloping voltage, and the grid voltage is a linear upward-sloping voltage.

The action described during time interval b continues until the plate voltage becomes so low (only a few volts) that the tube can no longer amplify the changes in plate voltage. At this instant, t_2, capacitor C2 stops discharging and the control grid is rapidly driven positive, causing the tube current to increase at a very fast rate. The rapid rise of current through cathode-bias resistor R4 produces a high positive potential on the cathode, which, in relation to the positive potential at grid 3, is a bias sufficient to cut off plate current. Since the total tube current is increasing at this instant, the additional current must flow in the screen grid circuit. The action now occuring is regenerative; as the plate voltage goes positive because of plate-current cutoff, the control grid goes positive and causes an increase in tube current, which produces a higher voltage drop across resistor R4 to increase the bias on grid 3 and further cut off plate current. Thus, the phantastron multivibrator has returned to its original stable state of plate current curoff and maximum screen grid current, as illustrated during time interval c, until the next trigger pulses at t_3 again causes a cycle of phantastron action. Before the phantastron is ready for the next cycle of operation, however, capacitor C2 must

4

charge through the relatively long exponential R-C time constant circuit of R3-C2. Because of the relatively slow recharging of C2, a long period must pass after completion of the phantastron gate before the application of the next trigger pulse. The long charge time of C2 is depicted on the plate voltage (ep) waveform during time interval c.

As mentioned previously, when the phantastron is triggered (turned on) there is a sudden drop in the screen current. This produces on the screen grid a positive-going voltage with a steep leading edge (e_{g214} waveform). As the tube current gradually increases, producing the linear drop in plate voltage, the screen current increases in the same manner, but by a much smaller amount. The screen waveform will therefore decrease linearly by a small amount until the point of plate-current cutoff (described previously) is reached. At the instant of plate-current cutoff, the screen current increases sharply, causing a sharp drop in screen voltage, as depicted by the trailing edge of the eg_{214} voltage waveform; this is the positive-gate output waveform coupled through capacitor C3 to the screen output terminals. The resultant negative-gate output, ek, taken across cathode resistor R4, is coupled through capacitor C4 to the cathode output terminals. This negative-gate waveform also has steep leading and trailing edges, with the flat portion falling off in amplitude at a linear rate.

From the circuit action just described, it is evident that changing the value of the applied voltage will determine the point, and the time, at which the plate voltage "bottoms", with respect to the time of application of the input trigger. Changing the value of either feedback capacitor C2 or grid resistor R5 will also affect the pulse width by controlling the rate of discharge of capacitor C2. For example, increasing the value of either resistor R5 or capacitor C2 will increase their R-C time constant, thereby causing capacitor C2 to discharge more slowly and increase the width of the delay gate. A decrease in the value of either resistor R5 or capacitor C2 will have the oppostie effect on the width of the delay gate. In some phantastron circuits the grid resistor, R5 in this case, is made variable so as to control the maximum width of the delay gate.

Variations o f the phantastron multivibrator include separate diodes for input trigger application and clamping the plate voltage at a predetermined level, and a cathode follower in the charging circuit of feedback capacitor C2. The diode in the input trigger circuit acts as a trigger injector and also as a disconnecting diode to effectively isolate the trigger circuit after the phantastron action has started. The "plate-voltage catching", or clamping, diode establishes the maximum level of plate voltage, and since the turnoff level is fried, effectively controls the time during which the phantastron produces the linear delay gate. The cathode follower is added to reduce the time required for recharging the feedback capacitor, C2 in this case, between gates; the plate circuit of the pentagrid tube merely raises the grid voltage of the cathode follower, and conduction through this tube charges the capacitor at a much faster rate than through the normal plate-load-resistor charge path. The latter typee of circuit is knowrt as a "fast-recovery phantastron". All the variations in phantastron circuitry mentioned in this paragraph are described in more detail in the Special Circuits Section of this Handbook.

Failure Analysis.

No Ouput. The input trigger should be checked with an oscilloscope to determine whether it is being applied to the circuitry and whether it is of the proper polarity and amplitude. Lack of an input trigger at the additional control grid (grid 3) can be due to an open input coupling capacitor, Cl, or to failure of the external input-trigger source. It is also possible for excessive bias to make the circuit inoperative because the input trigger amplitude is not sufficient to overcome the bias and initiate the phantastron action. Such a condition is indicated when an input trigger can be seen with an oscilloscope on grid 3 of the pentagrid tube and voltage appears on all tube elements, but either the control grid or cathode voltage is higher than normal. This is most likely to occur when a negative voltage source is used with a common bleeder network to obtain the bias (as in a screen-coupled circuit). Since this cathode-coupled pentagrid circuit develops its own bias, an excessive current drain or short-circuit condition would be needed to increase the bias to the non-operating point.

Failure of the positive voltage supply, +Ebb, will disrupt the operation of the circuit, as will an open cathode circuit. With a tube installed in the circuit, the filament, plate, screen, and grid 3 voltages should be measured, as well as the bias voltage developed across the cathode resistance, to determine whether

the applied voltages are within tolerance and whether an associated electrode resistor is open. If feedback capacitor C2 is open, there will be no feedback signal to promote the phantastron action. An open output coupling capacitor, C3 or C4, will prevent the output-gate signal from reaching the following stage.

Reduced Output. A reduction in output is generally caused by a defective tube; however, a low screen gate output can also be caused by a decrease in applied voltage or a change in resistance value in the screen circuit. Low cathode gate output indicates low cathode current, which is the sum of all tube element currents, and thus may be caused by any one of numerous conditions (decreased tube conductance, reduce plate or screen voltage, etc). Usually, a voltage check will locate the defective circuit and component. A leaky or shorted output coupling capacitor, C3 or C4, will form a voltage divider with the input resistor of the next stage. If the input resistor of this next stage is returned to ground or to a negative supply, the voltage at the screen grid or cathode will be reduced, and the operation of the stage will upset by the change in voltage applied to its grid.

Distorted or Unstable Output. Distortion is in-dicated by a nonlinear waveform or an inaccurate time delay. Linearity and accuracy of the output gate waveform development is the basic property of this circuit, with the controlling elements being the applied d-c control voltage and the R-C time constant in the feedback circuit. Control voltage trouble may occur when the circuit uses a separate external control voltage from a separate power supply, since power supply fluctuations can easily change the operating level and, therefore, the gate duration. A change of time constant due to changes in circuit values or to feedback capacitor failure or leakage will change the rate of operation and hence the gate length; this should be most noticeable for the longer gate lengths. False triggering due to pickup of noise or stray pulses in the control cabling (on remote units) may affect both the turn-on and turn-off of the gate. This instability, or jitter, can also be caused by power supply fluctuations. An oscilloscope waveform check at each electrode is usually the best method of checking for the cause of the jitter, which can then be traced to its source.

Incorrect Frequency. The phantastron multivibrator has no components governing the frequency of its output gate signal; this frequency is governed by the input trigger applied to the circuit. Therefore, any change in the output gate frequency is a result of improper operation of the trigger generating circuits.

SECTION 8
SWEEP GENERATORS

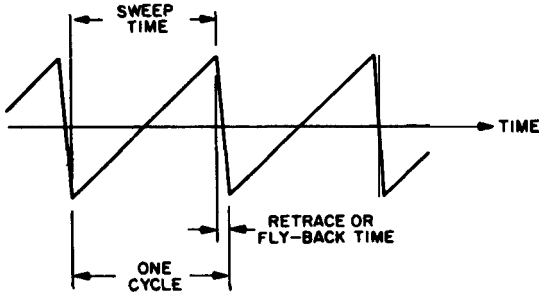
PART 8-1. SAWTOOTH

SAWTOOTH WAVE, GAS-TUBE SWEEP GENERATOR CIRCUITS

General.

A sawtooth *wave* is defined as a periodic wave which varies in amplitude between two values to provide a waveform pattern resembling the teeth of a saw.

The sawtooth waveform has many applications in television, radar, and special test equipment. It is commonly used as the time base for cathoderay tubes which employ electrostatic deflection of the electron beam. For this type of deflection, the horizontal deflection circuits require a linear time base, that is, a type of voltage waveform which is directly proportional to time. The following illustration shows a sawtooth voltage waveform.



Typical Sawtooth Waveform

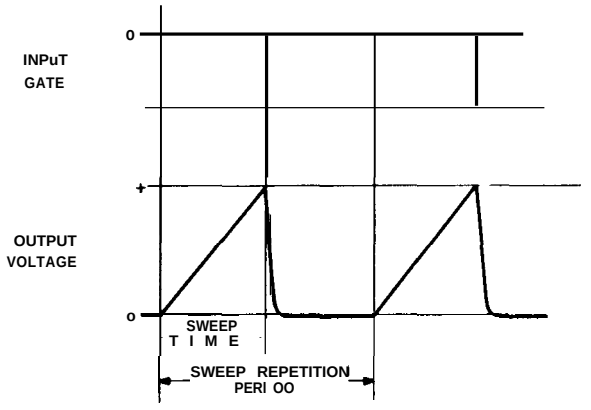
The useful portion of the sawtooth waveform is called the sweep time, and the remaining portion is called the retrace, or *fly-back,* time. The sweep voltage developed by the sweep-generator circuit is used to move (deflect) the spot across the fluorescent screen of the cathode-ray tube at a uniform rate. During the retrace, or fly-back, portion of the waveform, the spot is returned very rapidly to the initial starting point of the sweep, ready for another sweep trace to be generated. The waveshape of the retrace portion, during the period of time between the end of one sweep and the beginning of the next, is usually not very important insofar as the cathode-ray tube display is concerned. This is because the rate at which the spot returns across the fluorescent screen is usually too rapid to be visible or because a blanking pulse is applied to the cathode-ray tube to supress the spot during the retrace period. The sweep portion of the sawtooth waveform, however, must be very nearly a linear (straight-line) function of time.

The simplest forms of sawtooth sweep generator make use of the principle of charging and discharging a capacitor to obtain the desired output waveform. By using only the most linear portion of the exponential charging curve of a capacitor, the gas-tube sweep generator can produce a reasonably linear sawtooth waveform; however, perfect linearity of the sweep is difficult to obtain with this type of sweep generator.

TRIODE SAWTOOTH-WAVE SWEEP GENERATOR CIRCUITS

General.

Triode sweep generators use externally controlled electron-tube sweep circuits which produce symmetrical sawtooth waveforms for the duration of the trigger gate. As shown in the accompanying illustration, the output voltage rises at a linear (constant) rate during the negative input gate, and then drops back to zero between input gates.



Triode Sweep Generator Waveforms

The duration of the linear portion of the output waveform is known as the sweep time, and is determined by the duration of the input gate. The time from the beginning of one sawtooth wave (sweep) to the beginning of the next sawtooth wave is known as the sweep-repetitwn period, and is determined by the repetition period of the input gate. The term *linearity* is used to describe the straightness of the sweep portion of the sawtooth waveform. The more closely the sweep approaches a straight (but sloping) line, the greater the linearity.

In triode sawtooth-wave sweep generator circuits, the electron tube is used as a switch to control the charge and discharge of a capacitor which produces the desired sawtooth output waveform. During the negative input gate, the triode acts as an open switch and allows the capacitor to charge, producing the linear sweep. At the end of the input gate, the triode acts as a closed switch, causing the capacitor to discharge very quickly, and preventing it from recharging until the next input gate is applied to initiate the next sweep cycle.

Two triode sawtooth-wave sweep generator circuits are in general use: The basic Triode Sawtooth Sweep Generator and the Bootstrap Sweep Generator. The major difference between the two circuits is in the linearity of the sawtooth output waveform. While the output of the basic circuit is sufficiently linear for most applications, the bootstrap circuit provides an extremely linear output for applications where the waveform distortion in the basic circuit cannot be tolerated. Each of these circuits is discussed in detail in the following paragraphs of this section of the Handbook.

SEMICONDUCTOR SAWTOOTH-WAVE CIRCUITS

General.

Although electron tube sweep generator circuits are divided into two classes, the vacuum (hard) tube sweep-generator and the gaseous (soft) tube sweep-generator, they are not so divided for semiconductors. Actually, the semiconductor sweepgenerator circuits are analogous to the gaseous (soft) tube circuits, utilizing special transistors which are comparable to the thyratron type of electron tube.

Two general types of transistors are used, that is, the unijunction or double-based diode with three terminals and the four-layer diode having only two terminals. These transistors may be used as switches or as relaxation oscillators, and can produce other than sawtoothed waveforms if desired. The discussion in this section, however, will be limited to the production of sawtoothed waveforms by use of the relaxation oscillator form of circuit. The advantages and utility of these semiconductor circuits lie in their extreme simplicity and their use of relatively few components; plus the fact that one unijunction is considered the equivalent of two normal transistors. In most cases only a capacitor and a transistor are required to produce a sawtooth sweep. Where adjustable frequencies of periodic recurrence are desired, a resistor may be added, with the RC combination governing the period of oscillation. The basic principle of operation is that of charge and discharge of a capacitor, controlled by the semiconductor operating as a negative resistance oscillator.

Operation is normally restricted to frequencies from a lower frequency of approximately one or two cycles per minute to an upper frequency which lies between 500 KHz and 1 MHz for presently available transistors. In some experimental units the upper frequency has exceeded 1 MHz but not 3 MHz. Although the upper frequency limit of the transistor is not as high as that of the electron tube, the range is sufficient for normal applications of sawtooth waves. The recovery time is shorted for semiconductors than the deionization time of tubes (on the order of 30 microseconds as compared with 100 microseconds or

more), which offers some advantage over the electron tube.

NEON GAS-TUBE SWEEP GENERATOR

Application.

The sawtooth-wave sweep-generator circuit using a neon gas tube is one form of relaxation oscillator. This type of circuit is occasional used where a simple "free-running" sweep generator will provide a satisfactory sawtooth waveform for use in certain noncritical test-equipment circuits and in cathode-ray tube circuits employing electrostatic deflection.

Characteristics.

Free-running, **relaxation-oscillator** type.

Output is sawtooth waveform.

Output sweep frequency is determined by **R-C** circuit, type of neon gas tube used, and voltage applied to circuit. Sweep frequencies up to 10 KHz can be produced.

Neon gas tube is used as switch to control charge and discharge of capacitor.

Circuit Analysis.

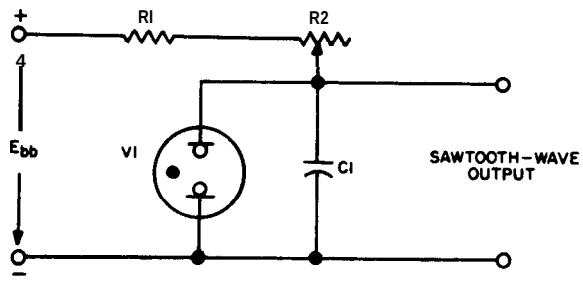
General. In the discussion of time constants given in the introduction to the **Amplifier** Section of this Handbook, the typical charging curve for an R-C circuit was illustrated. If a capacitor is charged through a resistance from a constant-voltage source, an exponential voltage curve is obtained across the terminals of the capacitor. Eventually the charge on the capacitor rises to a value equal to the applied voltage. The initial portion of the **R-C** charging curve is reasonably straight, with very little curvature, and if only a small part of the initial portion of the charging curve is utilized, the degree of linearity obtained is considered to be satisfactory for many sweep applications.

In order to develop a sawtooth voltage, it is necessary to charge the capacitor and then quickly discharge it to complete the charge-discharge cycle; the cycle is then repeated over and over to produce the desired sawtooth output waveform. A means must be provided to quickly discharge the capacitor once it has received a partial charge. At extremely low frequencies a mechanical switch can be used to short the capacitor terminals and discharge the capacitor; however, such a switching system becomes impractical at the higher frequencies.

The neon gas tube (or neon bulb) is a practical and simple device which can act as an electronic switch to discharge the capacitor. A neon gas tube has a negative resistance characteristic and, because of this characteristic, as soon as the tube is ionized, heavy current will flow through it. If the tube is connected directly across a source of voltage which is sufficiently high to ionize the gas, the current rises rapidly to a value which can damage the tube. However, in a typical sweep-generator circuit, the resistance in the circuit limits the current and prevents it from damaging the gas tube; furthermore, the tube conducts primarily to discharge the capacitor.

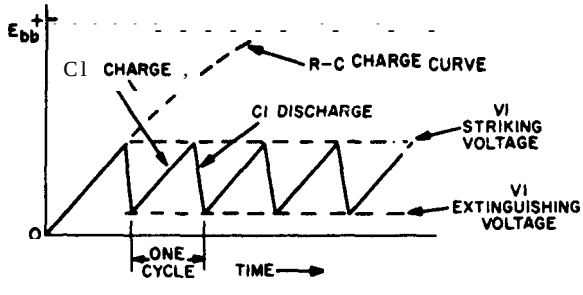
The value of the terminal voltage necessary to cause ionization of the gas tube is termed the striking, or *firing*, voltage. When the tube ionizes, its internal resistance becomes very low and will allow a heavy current flow as long as the voltage applied to the tube is sufficient to maintain ionization. However, when the voltage drops to a low value, conduction ceases. The value of voltage at which conduction ceases and the tube deionizes is termed the extinguishing, or recovery, voltage. Approximate values of striking and extinguishing voltages for several common types of neon gas tubes are 65 and 20 volts, dc, respectively.

Circuit Operation. In the following illustration, a simple neon gas-tube sweep-generator circuit is shown. Resistor R1 is a series current-limiting resistor; resistor R2 is a variable resistor which permits the frequency of oscillation to be changed. Capacitor Cl is a charging capacitor and V1 is a neon gas tube.



Neon Gas-Tube Sweep-Generator Circuit

Initially, when voltage is applied to the circuit, capacitor Cl begins to charge through resistors R1 and R2, in series. The R-C time constant establishes the frequency of oscillation for a given value of applied voltage and depends upon the value of the capacitor and the combined resistance of the two resistors, RI and R2. The tube is not ionized during this period of time and represents a high impedance in parallel with the charging capacitor. The voltage across capacitor Cl builds up gradually following the R-C charge curve, shown on the accompanying illustration of the output-voltage waveform, until the terminal voltage of the capacitor reaches the striking voltage of the neon gas tube, V1. When the striking voltage is reached, the tube ionizes and conducts to form a low-impedance path to discharge the capacitor. Capacitor Cl discharges through the tube, and the terminal voltage drops rapidly. As soon as the voltage drops to a value equal to the extinguishing voltage of the gas tube, the tube deionizes and current stops flowing. The tube again represents a bigh impedance in parallel with the charging capacitor, Cl, and the voltage again starts to rise across the capacitor. As shown on the waveform illustration, capacitor Cl charges again until the striking voltage of the gas tube is reached. The tube then ionizes and discharges the capacitor; this operation repeats over and over as long as voltage (E_{bb}) is applied to the circuit.



Output Voltage Waveform

The linear sweep portion of the sawtooth waveform is produced when capacitor Cl is charged, and the retrace or flyback portion of the waveform is produced when the capacitor is discharged by conduction of the tube. The sweep time depends upon the values of resistance and capacitance in the circuit, upon the, applied voltage, and upon the characteristics (striking and extinguishing voltages) of the neon gas tube. The characteristics of the tube are fixed and depend upon the particular type of tube used. Therefore the sweep time and frequency are controlled primarily by any of the first three factors previously mentioned: the resistance, the capacitance, or the applied voltage.

In order to obtain reasonable linearity of the sweep portion of the sawtooth wave, the applied voltage is maintained at a high constant potential so that operation of the neon gas tube and charging capacitor takes place on the lower, straight portion of the charging curve, as shown on the accompanying waveform illustration. Variations in operating frequency are usually accomplished by changing either the circuit resistance or capacitance, or both. In a practical sweep generator, the value of the capacitance (Cl) is fixed, and the resistance (R2) is adjusted to change the R-C time constant of the circuit. The range of operating frequency is sometimes extended beyond that obtainable with a variable resistance alone by incorporating a switch either to select one of several fixed capacitors or to select and parallel a number of fixed capacitors.

The time required for the retrace, or flyback, portion of the sawtooth waveform to occur is determined by the impedance of the neon gas tube when ionized, the difference between the striking and extinguishing voltages of the tube, and the value of the capacitor in the circuit. Normally, however, the impedance of the tube is so low that the retrace, or flyback, time does not become appreciable until the sweep frequency exceeds approximately 10,000 Hz.

Failure Analysis.

No Output. A neon gas tube radiates a characteristic orange-red glow when ionized. An indication of gas-tube operation can therefore be obtained by visual inspection to determine the presence of the characteristic glow from the ionized gas within the tube.

If the gas tube is ionized continuously and no sweep output is obtained, it is likely that capacitor Cl is open or that resistors R1 and R2 have decreased in value. In this case the tube attempts to act as a voltage-regulator tube and it conducts continuously; the voltage developed across the gas tube remains a constant value. Capacitor Cl can be checked by using

a suitable capacitance analyzer to determine whether or not the capacitor is defective. An ohmmeter measurement of resistors RI and R2 can be made to determine whether a decrease in resistance has occured. If the conduction current through the neon gas tube is excessive for any great length of time, the tube may be damaged and its characteristic will be impaired as a result.

Although the gas tube may appear to be glowing in the proper manner, this is not a positive indication that the tube is operating correctly; therefore, the tube itself may be suspected as a source of trouble.

If the gas tube fails to ionize, the voltage across capacitor Cl will rise to the full applied voltage, and no sawtooth output voltage will be developed. If the tube is not ionized, however, this does not necessarily mean that the tube is defective, since the same indication (lack of glow) may occur if either resistor (R1 or R2) is open, if there is no applied dc voltage (E_{bb}), or if the **charging** capacitor (Cl) is shorted. The value of each resistor, RI and R2, can be checked by ohmmeter measurements to determine whether any increase in resistance or an open has occurred. Measurements can also be made across the capacitor terminals to determine whether capacitor Cl is shorted, thus causing the voltage to be either zero or an extremely low value.

Incorrect Frequency. It is reasonable to assume that any change in the values of resistance (Rl, R2) or capacitance (Cl) will affect the R-C time constant of the circuit and, thus, the frequency of operation. When an adjustment is provided, as for example resistor R2 in this circuit, a change in operating frequency can be compensated for by adjustment of the series resistor, R2. " If the R-C time constant is increased, the frequency of operation will decrease; conversely, if the time constant is decreased, the frequency of operation will increase. A change in the value of R1 or R2 can be determined by ohmmeter measurements; the value of capacitor Cl can be measured with a suitable capacitance analyzer.

Assuming that the values of R and C remain constant, a change in the applied voltage (E_{bb}) will affect the operation of the circuit; thus, an increase in applied voltage will increase the frequency of operation, while a decrease in voltage will decrease the frequency.

The characteristics of the neon gas tube may be affected as the tube ages; therefore, the striking and extinguishing voltages of the tube may change causing the circuit to shift its operating range on the R-C charge curve. This condition may cause not only a change in operating frequency, but also changes in sweep amplitude and linearity.

THYRATRON SWEEP GENERATOR

Application.

The thyratron sweep generator is used to produce a linear sawtooth sweep voltage waveform for radar equipments, television sets, electronic displays, and special test equipments employing an electrostatic type of cathode-ray tube.

Characteristics.

Employs a thyratron gas tube in a relaxation oscillator circuit.

The thyratron is used as a switch to control the charge and discharge of a capacitor.

Output is a sawtooth voltage waveform.

Output amplitude is determined by the characteristics of the thyratron.

Output sweep frequency is determined primarily by the time constant of the R-C circuit.

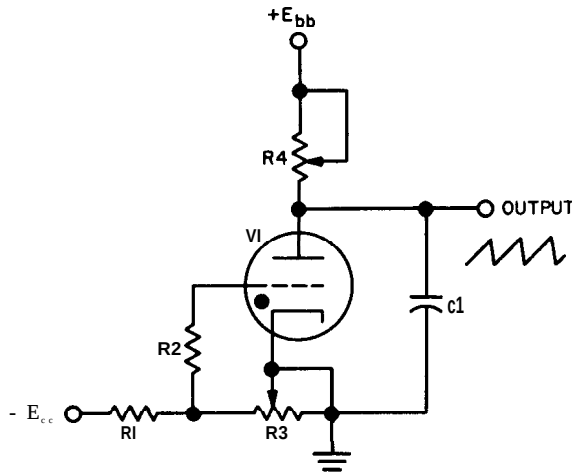
Sweep frequencies up to 75 kHz can be produced.

Circuit Analysis.

General. When a series R-C circuit is connected across a constant-voltage source, the capacitor charges and the voltage measured across its terminals increases at an exponential rate until the voltage becomes equal to the source voltage. Only the initial portion of the capacitor charging curve is sufficiently linear to be used in the generation of a sawtooth wave. To generate the sawtooth wave, it is necessary to restrict the capacitor charge to a small portion of the total source voltage, and then cause it to discharge very quickly. The charging cycle is then repeated. In addition to hard tubes, a thyratron may also be used as a switch to control the charge and discharge of the capacitor, and thus produce the desired sawtooth-wave output.

In a gas-filled tube the ionization potential (firing voltage) determines the plate voltage at which the tube begins to conduct, and the deionization *potential* (extinguishing voltage) determines the voltage below which the tube ceases to conduct. When the plate voltage of a gas tube exceeds the ionization potential, the gas in the tube ionizes and the tube conducts very heavily. It continues to conduct heavily until the plate voltage is lowered below the deionization potential, when the gas in the tube deionizes and the tube ceases to conduct. The thyratron is a special type of gas-filled triode in which a third element, a control grid, is used to control the ionization of the tube. The control grid, however, has no effect on the deionization potential of the thyratron; it can ordy initiate conduction. Once triggered, the thyratron continues to conduct until the plate voltage drops below the deionization potential of the tube.

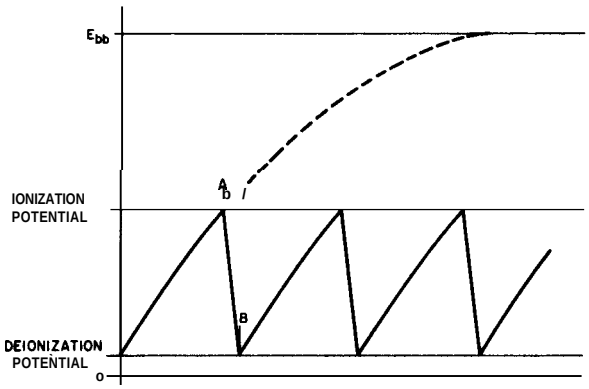
Circuit Oparation. The accompanying circuit schematic illustrates a typical thyratron sweep generator.



Thyratron Sweep Generator

Capacitor Cl and resistor R4 make up the R-C charging circuit, which is used as an integrator to produce the sawtooth output wave. Thyratron VI is connected in parallel with capacitor Cl, and functions as a switch to control the charge and discharge of the capacitor. Resistors RI and R3 forma voltage divider from the negative bias supply to ground, which supplies fixed grid bias voltage to the thyratron through grid-current limiting resistor R2. Since resistor R3 is variable, the brid bias, and thus the trigger potential of the thyratron, can be varied.

When voltage is first applied to the thyratron sweep-generator circuit, capacitor Cl begins to charge through resistor R4. As the capacitor charges, the voltage across it, and across thyratron VI, increases from zero toward the full value of the plate-supply voltage. If the capacitor were allowed to reach full charge, the voltage across it would increase exponentially to the full value of the plate-supply voltage, as shwon by the broken line on the accompanying output-voltage waveform illustration.



Output-Voltaga Waveform

However, when the voltage across capacitor Cl (and across thyratron Vl) exceeds the ionization potential of the thyratron (point A on the waveform illustration), the tube instantly ionizes and begins to conduct very heavily. Since the conducting thyratron has very low (almost zero) impedance, it shunts capacitor Cl and causes the capacitor to discharge very quickly through the tube. Thus, the capacitor charges to the ionization potential of the thyratron, which is determined by the thyratron grid voltage, and then discharges. As the capacitor discharges, the voltage across it drops toward zero. When the voltage across the capacitor drops below the deionization potential of thyratron V1 (point B on the waveform illustration), the tube deionizes and ceases to conduct. Since the non-conducting (cut off) thyratron

has a very high (almost infinite) impedance, it no longer effectively shorts capacitor Cl, and the capacitor again beings to charge toward the full plate-supply voltage value. The capacitor charges until the voltage across it exceeds the ionization potential of the thyratron, at which time the tube conducts and discharges the capacitor. This charge-discharge cycle continues to repeat as long as voltage is applied to the circuit-capacitor Cl charges while thyratron VI is cut off, and discharges when the thyratron conducts. Thus, thyratron VI acts as a switch and causes capacitor Cl to alternately charge and discharge, producing a sawtooth output wave.

The sweep frequency of the thyratron sweep generator is determined by the time it takes for capacitor Cl to charge to the ionization potential of thyratron VI. The charge time of the capacitor is determined by the time constant of the R-C circuit made up of resistor R4 and capacitor Cl, and can be changed by adjusting variable resistor R4. Increasing the value of resistor R4 increases the time constant of the R-C circuit, which increases the charge time of capacitor Cl, and thus decreases the sweep frequency. Decreasing the value of resistor R4 has the opposite effect, and increases the sweep frequency.

The amplitude of the sawtooth output wave is determined by the difference between the ionization (firing) potential and the deionization (extinguishing) potential of the thyratron. The ionization potential is controlled by varying the grid bias. Consequently, resistor R3. is used to adjust the thyratron grid bias for the desired output amplitude. Increasing the value of resistor R3 increases the negative voltage on the grid of the thyratron and raises the ionization potential. The consequent larger difference between the ionization and deionization potentials thus increases the amplitude of the sawtooth-wave output. Decreasing the value of resistor R3 has the opposite effect, and decreases the output amplitude. Adjusting resistor R3 also affects the output sweep frequency slightly, but this frequency can be corrected by readjusting resistor R4.

Failure Analysis.

No Output. A no-output condition maybe caused by lack of plate-supply voltage, an open plate resistor (R4), a faulty sweep capacitor (Cl), or a defective thyratron (V1). Since the thyratron emits a characteristic glow when conducting, observation of the tube will show whether or not it is conducting. If the thyratron is glowing (conducting), lack of plate-supply voltage and an open plate resistor (R4) can be eliminated as possible troubles, since the tube must have plate voltage applied to it through resistor R4 in order to conduct. If the thyratron is not glowing, first measure the plate-supply voltage with a high-resistance voltmeter to eliminate the possibility of a faulty power supply, and then check resistor R4 for continuity with an ohmmeter. If it is determined that neither the power supply nor resistor R4 is at fault (either because they have been checked or because they have been eliminated as possible troubles), further checks must be made to locate the trouble. Use an in-circuit capacitor checker to check capacitor Cl for a shorted, open, or leaky condition. If capacitor Cl is not defective, thyratron V1 is probably at fault.

Incorrect Output Frequency. Any fault which changes the charge time of capacitor Cl will cause the output frequency to be incorrect. Therefore, check for changes in the value of capacitor Cl and in the setting of resistor R4, and for incorrect plate-supply voltage. It is good practice to first measure the plate-supply voltage with a high-resistance voltmeter to eliminate the possibility of a defective power supply. If the supply voltage is correct, use an ohmmeter to check resistor R4 for the correct resistance value, and a capacitance analyzer to check capacitor Cl for the correct capacitance value.

Incorrect Output Amplitude. Since the amplitude of the sawtooth output wave is determined by the difference between the ionization and deionization potentials of thyratron V1, improper grid bias or a defective thyratron may cause the output amplitude to be incorrect. Measure the voltage on the grid of thyratron VI with a high-resistance voltmeter. If the grid voltage is correct, the thyratron is probably defective and should be replaced. If the grid voltage is either high or low, the bias circuit is probably defective. Use an ohmmeter to check resistors RI, R2, and R3 for the proper resistance values.

UNIJUNCTION (DOUBLE-BASE DIODE) SAWTOOTH GENERATOR

Application.

The unijunction transistor is used as a switch or as an oscillator to produce pulses, amplify pulses, and

produce a sawtooth or triangular waveform for sweep generators. It is used mostly in computers, memory circuits, and electronic clocks, but it may be used wherever the solid state equivalent of the thyratron tube is needed.

Characteristics

Is the equivalent of two normal junction transistors in power handling ability (one unijunction transistor effectively replaces two standard transistors).

Uses the stable N-type open-circuit negative-resistance characteristics inherent in its construction to provide astable, bistable, or monostable operation.

Any of its three terminals maybe used as an input trigger connection or output load connection.

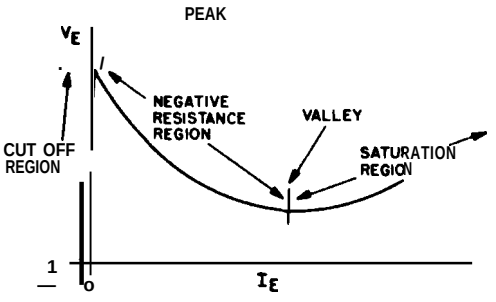
Provides two different output levels for one input signal, and may be similarly or oppositely polarized.

Is temperature-sensitive, with an almost constant linear response (base resistance changes) from –40 to approximately +150 degrees C.

Is photosensitive, and may be made to respond to changes in illumination.

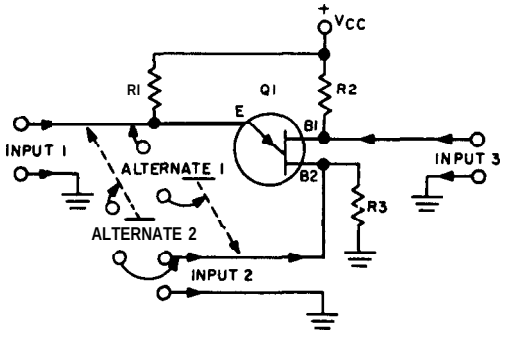
Circuit Analysis.

Generel. By virtue of its construction, the unijunction transistor is basically a negative-resistance device, as indicated by the emitter voltage-current characteristic in the following illustration. By setting the load line so that it touches only one point on the curve (operation in cutoff or saturation-regions only), the unit may be made a one-shot device. By operating only over the negative-resistance portion, on-off operation (oscillation) can be obtained and by operation in all three regions, flip-flop operation may be obtained. These characteristics are inherent in the transistor, and may be obtained if the proper bias and connections are made. In this circuit discussion we shall be concerned only with operation in the *negative-resistance region* with the transistor operating as a relaxation-type oscillator, to produce a sawtooth (sweep) waveform.

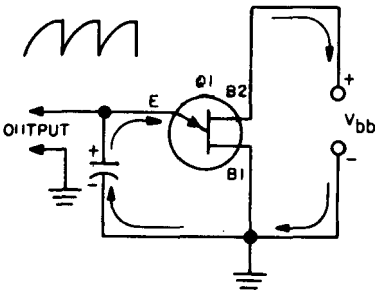


Emitter Characteristics

As constructed, there are three points from which an output may be taken or to which an input may be applied; these are as follows: from emitter to ground or base 1, from base 1 to emitter or ground, and from base 2 to ground, as shown in the accompanying figure. When any of these points are used as an input, the other two points will supply an output. **As** conventionally used, a negative sync trigger is supplied to B2, with a synchronized sawtooth output between emitter and ground, and with a positive pulse available at B1. When synchronization is not employed, the unit will operate as a free-running oscillator at a frequency set by the circuit RC constants, either external, or internal and external.

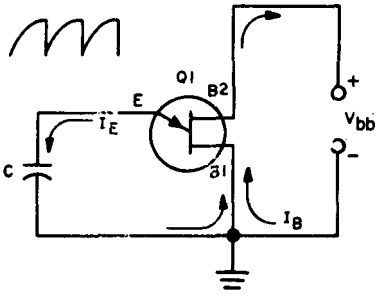


Input and Output Points



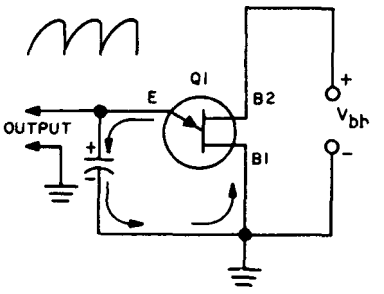
Charge Path

Circuit Operation. A simple sawtooth generator circuit using a unijunction transistor is shown in the following figure. Note that only the unijunction transistor, a capacitor, and a power supply are necessary to produce the sawtooth waveform. With the power supply connected, electron flow is from base 1 to base 2, thus placing an initial reverse bias on the PN junction. With the capacitor connected between emitter and ground, a small amount of reverse current flows through the PN junction because of a flow of hole current from the emitter to base 2. The capacitor charges slowly through the path shown in the following figure.



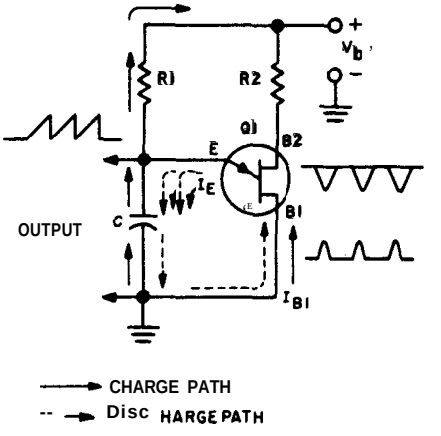
Basic sawtooth Generator

The rate of charge depends on the time constant, which is equal to the product of the capacitance of C and the internal resistance of the reverse-biased junction. As C charges, the positive dc voltage across it rises. When this voltage is greater than the voltage gradient opposite the P-type material, the PN junction becomes forward-biased and the capacitor discharges very rapidly. (This corresponds to the ionization point or voltage of the gaseous thyratron tube.) This action is caused by a heavy electron flow from base 1 to the emitter and a heavy hole flow through the P material of the junction, which causes an electron flow out of the emitter as shown in the following figure. Thus, the capacitor is effectively short-circuited through the PN junction. The time of discharge is determined by the capacitance of C times the forward resistance of the PN junction. Since the forward resistance is very low (on the order of 5 ohms), it is essentially equivalent to a short circuit. After capacitor C discharges, the voltage across C is too small to maintain the forward bias (this corresponds to the deionization point or voltage of the gaseous thyratron tube); the reverse bias again resumes control, charging the capacitor through reverse-leakage current, as previously indicated, and the cycle is repeated. This slow charging and rapid discharging of capacitor C produces the sawtooth output waveform.



Discharge Path

The recurrence rate of the basic circuit just discussed is fixed by the inherent base leakage resistance of the transistor plus the value of capacitance used. To ensure stable operation at the desired sweep rate, and to provide protection against them-ad runaway, an emitter resistor and a base 2 resistor are usually used, as shown in the following schematic. The operation of this circuit is identical to that of the basic sweep generator previously discussed except for the change introduced by the addition of R1 and R2. During the time of heavy conduction (deionization period), the portion of the interbase region between the emitter and base 1 is a very low resistance, whereas the portion between the emitter and base 2 is of high resistivity. Therefore, practically all the power supplied by the interbase power supply is dissipated across the narrow region near base 2. In the absence of R2, a relatively heavy electron current flows through the base 2 region and causes heating of this small semiconductor area. As a result, this thermal effect causes an increased electron flow through the base 2 to emitter portion of the bar. As the heat is built up by current flow, more and more electron current flows through the bar because no external resistance is provided to limit the flow. Thus a" local hot spot is produced. Since this thermal action is accumulative, thermal runaway can occur and destroy the transistor. The use of R2 in the position shown provides sufficient current limiting to prevent the formation of the hot spot and any possibility of thermal runaway. While the circuit is sensitive otherwise to thermal variations, any thermally produced current flow can never be as great as that produced at the location of the hot spot when no limiting resistance is employed. No other form of protection is needed to prevent thermal failures.



Stabilized Sawtooth Genarator

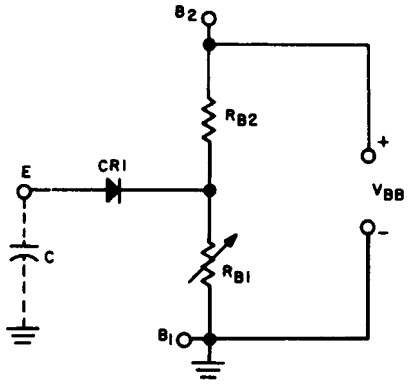
By adjusting the value of RI, the emitter voltage can be controlled and the operating point (where the emitter changes from reverse bias to forward bias) fixed for the desired operating voltage. By proper design, if the resistance of RI is less than that of the internal reverse leakage resistance of the base bar, the charging of sweep capacitor C is determined mainly by the value of R1. Thus, variances produced by production tolerances in unijunction transistors can be minimized, and the sweep time controlled independently of the transistor. If required, R1 can be made variable to provide an adjustable sweep. Regardless of the arrangement used, however, the value of RI together with that of C determine the frequency of the sweep oscillations.

In this improved circuit, then, operation occurs through the charging of capacitor C through R1. When the voltage across C reaches the breakdown voltage, the initially reverse-biased junction breaks down temporarily, becomes forward-biased, and discharges the capacitor through the low base 1 emitter resistance. (This action is similar to that of the gaseous thyratron tube at the point where the voltage reaches the ionization level.) When the capacitor discharges to the point where the voltage across the emitter junction can no longer sustain a forward bias, the transistor stops conducting, and the original reverse-bias condition again exists. (This action is

similar to that of the gaseous thyratron tube, which stops conduction automatically when the voltage across the tube reaches the deionization point or level and is insufficient to sustain ionization of the gas.)

Detailed Analysis. Before proceeding with the following discussion, be certain to read the explanation of the construction and operation of the unijunction transistor given in the Special Circuits Section of this Handbook.

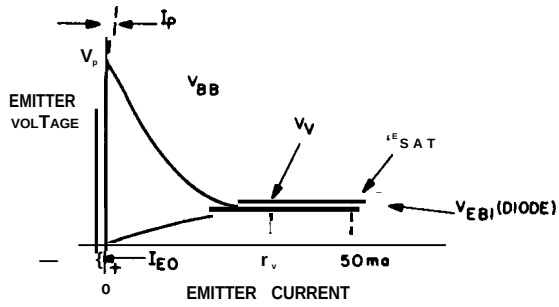
A simplified equivalent circuit for the unijunction transistor may be developed as shown in the accompanying figure.



Simplified Equivalent Circuit

Diode CR 1 can be considered to be a conventional junction diode, with R_{B2} representing the resistance of base 2, and R_{B1} the resistance of base 1; R_{B1} is shown as variable since it does vary as a function of the emitter base 1 current (the greater the current, the lower the resistance, and vice versa).

Assuming that the capacitor is not connected to the emitter and that both R_{B1} and R_{B2} are of a high value, it is clear that the resistors form a voltage divider across the base supply, V_{bb}. Thus, a positive potential exists at the cathode of the diode, and the diode is reverse-biased. The current flow through base 1 and base 2 will be that permitted by the conductivity of the base bar (the resistance of R_{B1} plus R_{B2}), and the emitter current will be zero (cutoff). When the capacitor is connected between emitter and ground, it charges exponentially through the reverse leakage current of the diode. The charge path is from ground through the capacitor, diode CR_1, and R_{B2}. At this time the value of R_{B1} is high. As the capacitor charges, the emitter voltage increases and the reverse bias across the junction diode is reduced. Examine the emitter characteristic curve which follows.



Static Emitter Characteristics

With the emitter biased off, the current due to reverse leakage (I_{eo}) can be considered negative as shown in the figure. As the capacitor voltage builds up it reaches the peak value of emitter voltage at zero emitter current. At this peak point the reverse bias is no longer sufficient to prevent conduction, and emitter (positive) current flows. As soon as emitter current flows capacitor Cl starts to discharge, and the forward resistance of the junction is decreased; this action becomes regenerative, multiplying the discharge current in a somewhat exponential fashion. Once started, this action cannot be reversed or stopped until the lower voltage level (deionization point) is reached. As this current increases, the diode forward resistance decreases and the emitter voltage decreases. The region of decreased emitter voltage with increased emitter current is due to negative resistance, which is the phenomenon upon which the operation of this unit is based. The negative resistance is caused by the injection of holes into the base bar with forward bias change causing increased conductivity between the emitter and base 1 portion of the bar, with base 2 current remaining essentially constant. The sequence of action is such that each enhances the other. That is, as the forward resistance is decreased, so is the amount of reverse bias decreased, and the emitter current increases similarly. This cumulative action continues until the valley point is reached and the base enters the saturation

region. At this point any increase in emitter current merely causes an increased drop in the emitter base 2 portion of the bar. If operation is allowed to enter this saturation region, the unit will merely rest in a stable conducting condition with a fairly low base 1 resistance.

The turn-off action of the unijunction transistor is initiated by the dropping emitter potential as capacitor C discharges through base 1. When the valley point on the curve is reached, the emitter voltage (which is produced by the remaining charge in the capacitor) is insufficient to continue conduction. More emitter voltage would be needed to produce more current, or the emitter voltage would have to remain constant at the valley point to keep the same value of current. Since the capacitor continues to discharge below this point, the initial condition of reverse-biased diode then exists. This action is also regenerative, since a reduction of conductivity of the bar (an increase in resistivity) reduced the amount of current it will carry, and the forward resistance is effectively increased. The increased forward resistance further reduces the conductivity of the bar; thus, the path between emitter and base 1 is quickly reduced to zero current or cut-off, whereupon the reverse bias resumes control, holding until the capacitor is again charged to the forward breakdown voltage. In this respect the unijunction diode operates differently from the normal PN junction. The typical response of a normal diode is shown at the bottom of the static emitter characteristic for comparison. In this case, once current flow is initiated, current flow continues in a relatively steady manner as long as the voltage is applied. The ability of the unijunction transistor to revert from a reverse-biased condition to a forward-biased condition and back again under control of the voltage levels applied to its elements is inherent in its construction. While the previous simplified diode representation was used to help explain its operation, it should be understood that a conventional diode connected schematically with two resistors, as illustrated previously, will *not* operated as a unijunction transistor.

Failure Analysis.

No Output. An open-circuited capacitor will cause the emitter circuit to be open and produce a no-output condition. The few components involved may be quickly checked by a resistance or continuity test with a high-resistance volt-ohmmeter. If the components appear to be normal, the trouble can only be in the power source or in the transistor itself. Substitution of a known good transistor would be necessary to determine whether it is defective, since there is no other simple check possible. A short-circuited capacitor would also prevent the circuit from operating, but this is not necessarily true of any of the other components, as the circuit usually will operated with the capacitor alone. Where the components and transistor appear to be normal, a poorly soldered joint or broken wiring might be suspected.

Low **Output.** Poorly soldered joints or defective resistors can cause low output, as can a defective power supply or transistor. Resistance and voltage checks will determine whether the components are defective. Use of an oscilloscope to examine the waveforms on the emitter, base 1, and base 2 elements should help isolate the defective portion of the circuit. With a sawtooth output, there should be a negative pulse on base 2, with a similarly shaped but smaller-amplitude current pulse in the base 1 circuit. (Place a 100-ohm resistor in series with base 1 and observe the voltage waveform produced by the base current.) Capacitor leakage may prevent the circuit from operating properly, or may reduce the amplitude of the output waveform. Leakage may be suspected if the recurrence rate is different from the original rate. (A change in emitter resistor RI can also produce a similar condition.)

Distorted Output. The shape of the sawtooth sweep will depend upon the capacitor to a great extent. If only a small portion of the capacitor charge is used, it will be linear, otherwise, the waveform will curve at the top because of the exponential discharge of the capacitor. The values of the components and voltages applied will also determine the linearity of the output waveform. Operation at too high a frequency for the transistor used will produce a rounding off of the waveform and, if excessive, produce a sine wave. Check the waveform with an oscilloscope. The recovery time is determined by the base 1 current pulse width and the sweep capacitor value. If the recovery time is excessive, a triangular wave may result.

FOUR-LAYER DIODE SAWTOOTH GENERATOR

Application,

The four-layer diode is used to generate a sawtooth (sweep) voltage waveform for applications where the output waveshape is not critical, and where an extremely simple circuit is desired.

Characteristics

Acts as a switch to control the charge and discharge of a series **R-C** circuit.

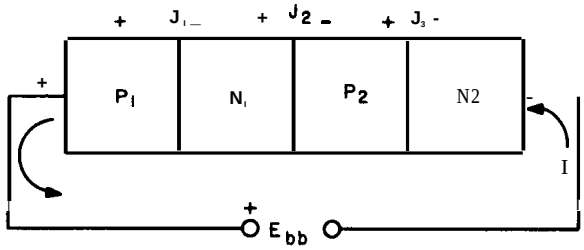
Output is a sawtooth voltage waveform.

Output frequency is determined by the values of resistance and capacitance in the R-C circuit.

Output amplitude is determined by the characteristics of the four-layer diode.

Cirouit Analysis.

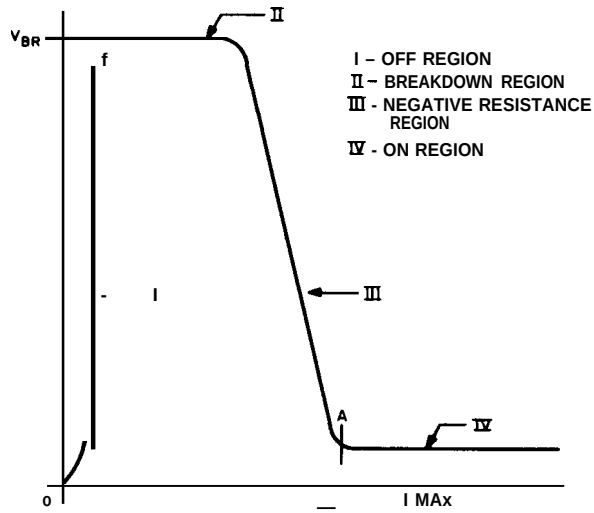
General. The four-layer diode is a two-terminal semiconductor device consisting of four alternate layers of P-type and N-type silicon. The accompanying pictorial diagram shows the construction and biasing of the diode.



Four-Layer Diode

For convenience in discussing the four-layer diode, its three PN junctions are labeled J_1, J_2, **and** J_3. To bias the diode correctly, the positive battery termiml is connected to the P-type diode terminal, and the negative battery terminal is connected to the N-type diode terminal. With the bias voltage applied in this manner (layer P_1 positive with respect to layer N_2), a voltage gradient is set up along the diode as shown by the polarities placed above the junctions on the four-layer diode illustration. The voltage gradient forward-biases junctions J_1, and J_3, and reverse-biases internal-junction J_2. Since a forward biased junction exhibits very low resistance and a reverse-biased junction exhibits very high resistance, junction J_2 (the reverse-biased junction) primarily determines the current flow through the diode. Therefore, the action of junction J_2 determines, to a great extent, the operation of the four-layer diode.

Over the **first** portion (region I) of the accompanying dynamic transfer characteristic curve, which covers from zero level to breakdown voltage V_{BR}, maximum current flow through the diode is limited to the value of the minority carrier current flowing through reverse-biased junction J_2.



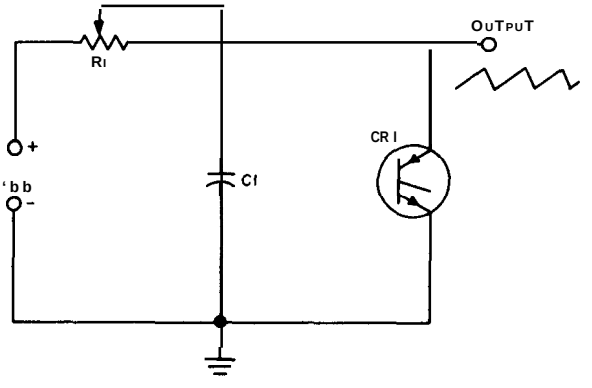
Dynamic Transfer Characteristic Curve

Therefore, over region I of the characteristic curve (also known as the *off* region), diode current flow remains at a relatively constant but low value while the applied input voltage increases. When the voltage applied to the diode exceeds voltage V_{BR}, an action similar to the avalanche breakdown in a Zener diode occurs in junction J_2. That is, the applied voltage temporarily is relatively constant while the current increases (region H on the characteristic curve). Although the breakdown action is not completely understood at the present state of the art, once breakdown occurs and current increases, the characteristic curve passes through another region, known as the negative resistance region (region III), where the voltage across the diode rapidly decreases as the current through it increases. (This corresponds to the action

in a gas-filled electron tube which breaks down at the ionization point and passes a heavy current at a low voltage.) At point A on the curve, the end of the negative resistance region is reached, and the voltage across the diode remains relatively constant throughout the *on* region (region IV). (This corresponds to the action in a gas-filled electron tube which, one broken dew, operates at a level slightly above the deionization point until the applied voltage drops below this point.)

Although the four-layer diode has many applications, it is most widely used as a switch with two stable states. To use the diode as such a switch, it is operated in regions I and IV of the characteristic curve. The diode remains in the high resistance or *off* state (region I) until the bias voltage exceeds the diode breakdown voltage, V_{BR}. The diode then switches to the low resistance or *on* state (region IV) and remains in this state until the bias voltage drops below the diode turnoff voltage level. It then switches back to the *off* state. The four-layer diode is operated in this manner to control the charge and discharge of an R-C circuit to produce a sawtooth-wave sweep voltage output.

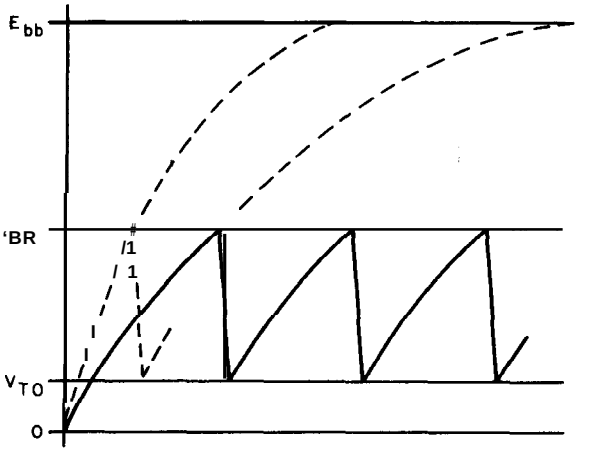
Circuit Operation. The accompanying circuit schematic illustrates a sawtooth-wave generator using a four-layer diode and only two other components.



Four-Layer Diode Sweep Generator

The power supply (E_{bb}) is comected directly across the series R-C circuit made up of capacitor Cl and resistor R1. The four-layer diode, CR1, is connected in parallel with capacitor Cl, and controls the charge and discharge of the capacitor, The sawtooth waveform is taken from across the parallel combination of capacitor Cl and diode CR1.

When voltage is initially applied to the circuit, diode CRI is in the high resistance *off* state, (because of the reverse bias applied to internal junction, J_2), and capacitor Cl begins to charge through resistor R1 toward the supply voltage value. If the capacitor were allowed to charge fully, the voltage across it would increase to the supply voltage value at an exponential rate, as shown by the dashed curve in the accompanying output voltage waveform illustration.



Theoretical Output Voltage Waveform

However, when capacitor Cl charges to the breakdown voltage of diode CR1 (voltage V_{BR} on the waveform illustration), the diode breaks down (effectively forward biasing internal junction J_2) and switches to the low resistance on state. Since diode CR1 is connected in parallel with capacitor Cl, the diode effectively shunts capacitor Cl and causes it to discharge very quickly. As capacitor Cl discharges through the conducting diode, the voltage across the capacitor decreases until it drops below the turnoff voltage of the diode (voltage V_{TO}). At this time, the internal junction is again reverse-biased and the diode switches back to the *off* state, and the capacitor again begins to charge through resistor RI. Thus, capacitor Cl alternately charges relatively slowly through resistor RI and discharges quickly through diode CRI.

Since capacitor Cl charges only during the initial portion of the capacitor charging curve (about 10% of the total time available), the resulting output voltage across the capacitor is a fairly linear sawtooth waveform.

The amplitude of the sawtooth output waveform is determined by the characteristics of the four-layer diode. Since the sawtooth amplitude is equal to the difference between the breakdown voltage (V_{BR}) and the turnoff voltage (V_{TO}), and since these voltages are constant for any particular diode, the output amplitude is fixed. The only way that the output amplitude may be changed is by using a four-layer diode with different breakdown and turnoff voltage characteristics.

The frequency of the sawtooth output waveform is determined by the charge time of capacitor Cl, and therefore by the time constant of the R-C circuit made up of the capacitor and resistor RI. Resistor R1 is usually made variable so that the output sweep frequency may be varied. Decreasing the value of resistor RI decreases the time constant of the R-C circuit, which decreases the time required for capacitor Cl to charge to the breakdown voltage of diode CR1. The resulting waveform (shown by the dotted curve on the waveform illustration) is a sawtooth wave of shorter time duration than the original sawtooth wave, and therefore one of higher frequency. Increasing the value of resistor RI has the opposite effect, and decreases the output sweep frequency.

Failure Analysis.

General. When making voltage checks, use a vacuum-tube voltmeter to avoid the low values of multiplier resistance employed on the low-voltage ranges of the standard 20,000 ohms-per-volt meter. Be careful also to observe proper polarity when checking continuity with an ohmmeter, since the diode may be forward-biased and break down, causing a false low-resistance reading.

No **Output.** A defect in any circuit component, or a lack of supply voltage may cause a no-output condition. Because of the simplicity of the circuit, the trouble can easily be located by making several quick voltage and resistance checks. First, use a vacuum-tube voltmeter to measure the supply voltage. If the correct voltage is measured, use an ohmmeter to check resistor R1 for an open or short circuited condition. Next, use an in-circuit capacitor checker to check capacitor Cl for defects. If these checks fail to locate a defective component, diode CR1 is probably at fault.

Distorted Output. A distorted sawtooth output waveform may be caused by low supply voltage, by changes in value of the components in the R-C circuit (Cl, Rl), or by a defective diode (CR1). First, use a vacuum-tube voltmeter to measure the supply voltage to determine that the power supply is not at fault. Next, use an ohmmeter to check the value of resistor R1, and use a capacitance analyzer to check the value of capacitor Cl. If no defective component is found, diode CR1 is probably at fault.

BASIC TRIODE SAWTOOTH SWEEP GENERATOR (ELECTRON TUBE)

Application.

The basic triode sawtooth sweep generator produces symmetrical, synchronized sawtooth waveforms for sweep voltage use in radar equipments, display indicators, synchroscopes and other types of special-purpose test equipment which use an electrostatic deflection cathode-ray tube.

Characteristics.

Employs a high-vacuum triode.

Requires a negative operating gate.

Output is a symmetrical sawtooth voltage waveform with equal intervals between sweeps.

Sweep time is determined by the duration or the negative operating gate.

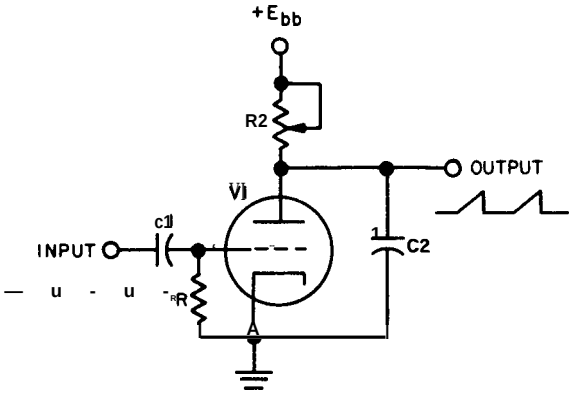
Sweep-repetition period is the same as the repetition period of the operating gate.

Circuit Analysis.

General. Recall from the elementary discussion of time constants in Section 2, paragraph 2.5.1, of this Handbook that when a series R-C circuit is connected across a constant voltage source, the capacitor charges at an exponential rate until the voltage measured across its terminals equals the source-voltage value. Since the initial portion of the capacitor charging curve is nearly linear. This portion of the curve may be used in the generation of a sawtooth wave. In the basic triode sawtooth sweep generator, the electron tube is used as a switch to control the charge and discharge of a capacitor over the initially linear portion of the charging curve, and to produce a sawtooth output wave with good linearity.

491-044 0-73- 53

Circuit Operation. The accompanying circuit schematic illustrates the basic triode sawtooth sweep generator.

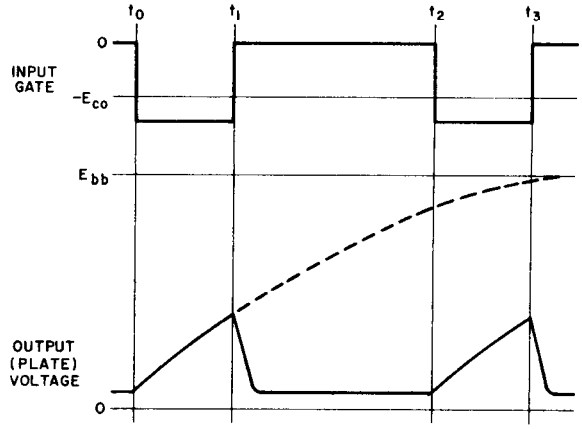


Basic Triode Savvtooth Sweep Generator

Capacitor C2 and resistor R2 form the R-C circuit which produces the sawtooth output waveform. Triode V1 is connected in parallel with capacitor C2, and acts as a switch to control the charge and discharge of the capacitor. Capacitor Cl and resistor RI form a conventional R-C input coupling circuit, which applies the input gate to the grid of triode V1. The sawtooth output is developed across the parallel combination of triode VI and capacitor C2.

In the quiescent state, with no negative input gate applied, there is practically no bias on the grid of triode V1. Consequently, the tube conducts very heavily and the plate voltage drops to a very low value. Since capacitor C2 is connected in parallel with triode V1, the capacitor charges to the low value of plate voltage existing across the tube, and remains charged to this voltage until an input gate is applied.

When a negative input gate is applied to the basic triode sawtooth sweep generator, it drives the grid of triode V1 below plate current cutoff and the tube ceases to conduct. When the triode cuts off, the plate voltage tends to rise instantaneously to the full value of plate-supply voltage, Ebb. However, capacitor C2 is connected in parallel with the triode and thus prevents the plate voltage from rising instantaneously. Instead, the plate voltage rises exponentially toward the plate-supply value at a rate determined by the time constant of the R-C circuit consisting of capacitor C2 and resistor R2. As the capacitor charges, the voltage across it (and therefore on the plate triode VI) rises at an exponential rate as shown, beginning at time t. on the following output (plate) voltage waveform illustration.



Theoretical Input and Output Waveforms

If triode V1 remained cut off indefinitely the voltage across capacitor C2 (and on the plate of Vl) would rise exponentially to the plate-supply value, as shown by the broken line in the illustration. However, at time t_1 the negative input gate ends and the grid bias on triode VI returns to zero. Therefore, triode V1 again conducts heavily and the plate voltage tends to fall instantaneously to a very low value (the initial quiescent value). Since capacitor C2 is connected in parallel. with triode Vl, the plate voltage cannot change instantaneously, but rather falls at a rate determined by the discharge time of the capacitor. Since the conducting triode has a very low impedance, it effectively shunts (shorts) capacitor C2, and the capacitor discharges very quickly through the low impedance offered by the tube. As the capacitor discharges, the plate voltage measured between the plate of triode V1 and ground decreases exponentially to the original quiescent value, and remains there until the next negative input gate is applied. Thus, the basic triode sawtooth sweep generator produces one sawtooth wave each time a negative input gate is applied, and remains in the quiescent (off) state between input gates.

It can be seen from the preceding discussion that the output waveform characteristics of the basic triode sawtooth sweep generator are determined in part by the duration of the negative input gate. If the duration of the input gate is increased, capacitor C2 charges for a longer period of time, and this charges to a higher potential. Since a larger portion of the capacitor charging curve is used when the duration of the input gate is increased, the linearity of the sawtooth output wave is decreased. Thus, increasing the input gate duration (for example, by decreasing the input frequency) affects the sawtooth wave in three ways: the sweep time (duration) increases, the sweep amplitude increases, and the sweep linearity decreases.

Changing the charge time of capacitor C2 also affects the characteristics of the sawtooth output wave. Since capacitor C2 charges through resistor R2, the charge time of the capacitor is changed by varying the resistance of R2. Adjusting resistor R2 for a higher resistance value increases the charge time of capacitor C2; thus, for a given input gate duration, a smaller portion of the capacitor charging curve is used, and the capacitor charges to a lower potential. Consequently, the sweep amplitude decreases and the sweep linearity increases, since only the relatively small straight-line portion of the sweep is used.

Both the duration of the input gate and the setting of resistor R2 affect the sweep amplitude and linearity; therefore, resistor R2 is used to compensate for changes in sweep characteristics caused by changes in the input gate duration. Thus, resistor R2 can be adjusted to cause the circuit to produce a sawtooth output waveform of constant amplitude and linearity, even though the input gate duration changes.

Failure Analysis.

No Output A no-output condition maybe caused by either lack of an input gate, lack of plate supply voltage, or a defective tube or circuit component. It is good practice to first check the input gate with an oscilloscope, and the plate-supply voltage with a high-resistance voltmeter, to determine that the trouble is definitely in the sweep generator circuit. If the correct input gate is observed and the proper plate-supply voltage is measured, use the oscilloscope to observe the waveform on the grid of triode VI. If no grid waveform is observed, either capacitor Cl is open or grid resistor R1 is shorted. Use an in-circuit capacitor checker to check the capacitor, and an ohmmeter to check the resistor. The correct waveform on the grid of triode V1 indicates that the trouble is in the plate circuit (C2, R2, Vl) of the sweep generator. Check capacitor C2 for a short circuit with an in-circuit capacitor checker, and resistor R2 for the proper resistance value with an ohmmeter. If no defective component is found, triode V1 is probably at fault.

Distorted Output. Any defect in the circuit which causes capacitor C2 to charge for a greater than normal portion of the capacitor charging curve will cause a distorted sawtooth output wave. Possible causes of distortion are: A distorted input gate, incorrect plate-supply voltage, changes in the values of capacitor C2 and resistor R2 (including wrong adjustment of resistor R2), and low emission in triode V1. First, observe the input gate with an oscilloscope to be certain that no distortion is present, and then measure the plate-supply voltage with a high-resistance voltmeter to be certain that the supply voltage is correct. If the input gate and the plate-supply voltage are normal, further checks must be made to isolate the trouble. Use a capacitance analyzer to check capacitor C2 for the proper value. Use an ohmmeter to check resistor R2 for the correct value and setting. If these checks fail to locate a faulty component, triode V1 is probably at fault.

BOOTSTRAP SWEEP GENERATOR (ELECTRON TUBE)

Application.

The bootstrap sweep generator is used to produce an extremely linear sawtooth waveform for use in navigation equipment, radar test sets, and in other types of electronic equipment where an extremely linear sweep voltage is required.

Characteristics

Employs one triode as a switch tube, and another as a constant-current generator.

Uses positive feedback to produce the linear sawtooth sweep.

Requires a negative input gate.

Output is a symmetrical sawtooth voltage waveform with equal intervals between sweeps.

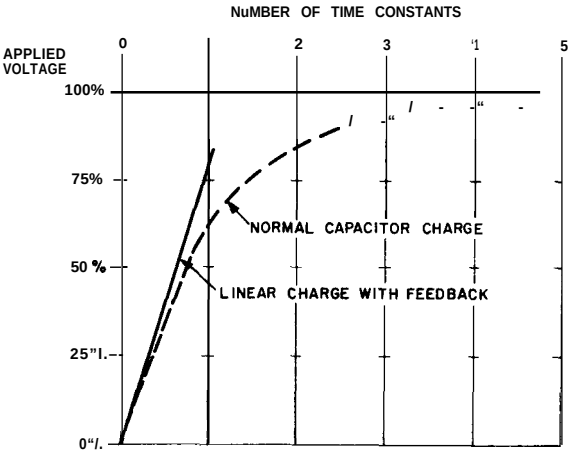
Sweep time is determined by the duration of the input gate.

Sweep-repetition period is determined by the repetition period of the input gate.

Circuit Analysis.

General. Most sawtooth sweep generator circuits use the charging action of a capacitor to produce a sawtooth waveform. By using only the initial portion of the exponential capacitor charging curve, a fairly linear sawtooth output waveform is produced. However, some nonlinearity (curvature) is present in the output waveform because even the initial portion of the capacitor charging curve is not perfectly linear. The bootstrap sweep generator uses a feedback loop to straighten out the curvature in the initial portion of the capacitor charging curve, and thus, to produce an extremely linear sawtooth waveform.

Before discussing the operation of the bootstrap sweep generator, it is necessary to review the charging action of an R-C circuit. The charge time of the capacitor in the R-C circuit is determined by the time constant of the circuit. At the first instant that a series R-C circuit is comected across a constant voltage source, the entire supply voltage appears across the resistor. As the capacitor charges, the voltage drop across it increases, and at the end of one time constant interval, 63 percent of applied voltage appears across the capacitor, and the remaining voltage (377.) appears across the resistor. During the next time constant, the capacitor further charges to 63 percent of the voltage remaining across the resistor, that is, to 86 percent of the total applied voltage. During each successive time constant, the capacitor charges to 63 percent of the voltage remaining across the resistor. Thus, as shown by the dashed line in the following illustration, the voltage across the capacitor rises exponentially toward the supply voltage as the capacitor charges.



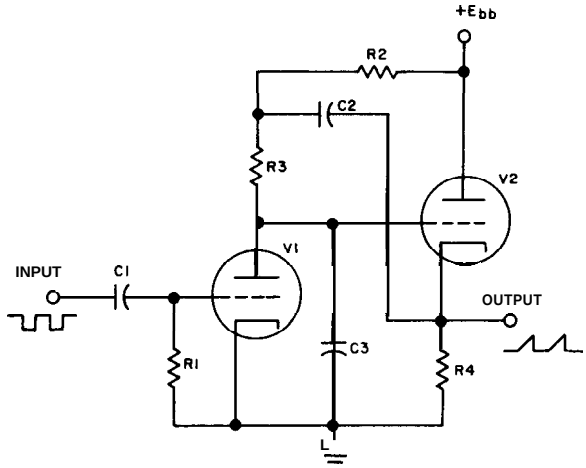
Generation of a Linear Sweep

Although the capacitor theoretically never fully charges, after five time constants it is charged to over 99 percent of the supply voltage and is considered to be fully charged.

The voltage across the capacitor of a series R-C circuit increases at an exponential rate because the capacitor charges to 63 percent of the voltage across the resistor each time constant. Since the voltage across the resistor decreases as the capacitor charges, the capacitor charges a smaller amount each time constant, resulting in an exponential increase in the voltage across the capacitor. If the applied voltage were increased as the capacitor charged, so that the voltage across the resistor remained constant, the capacitor would charge the same amount each time constant. This is, the voltage across the capacitor would increase at a linear (constant) rate. The bootstrap sweep

generator uses a feedback circuit to cause the effective supply voltage for the R-C circuit to increase as the capacitor charges. Thus, the circuit produces an extremely linear sweep, as shown in the sweep generation illustration.

Circuit Operation. The following circuit schematic illustrates one type of bootstrap sweep generator.

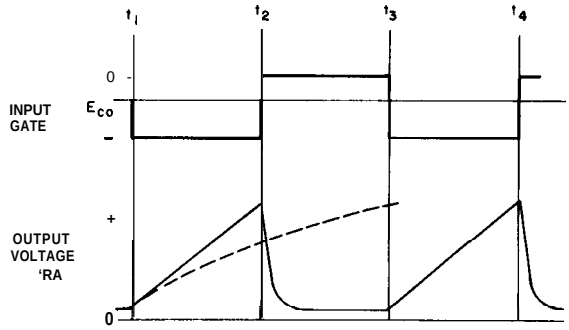


Bootstrap Sweep Generator

The portion of the circuit made up of coupling capacitor Cl, grid resistor R1, switch tube V1, charging capacitor C3, and plate resistor R3 is a conventional basic triode sawtooth sweep generator. Triode V2 is a cathode follower which provides feedback to charging capacitor C3 through dc blocking capacitor C2. The input gate is applied through capacitor Cl to the grid of triode V1, and the output sawtooth waveform is taken from the cathode of triode V2 across cathode resistor R4.

In the quiescent state, no negative input gate is applied to the bootstrap sweep generator, and therefore, no bias is applied to triode V1. Consequently, the tube conducts very heavily, and the plate voltage is very low. Since capacitor C3 is in parallel with triode V1, it charges to the low value of plate voltage existing across the tube. The voltage across capacitor C3 also appears on the grid of triode V2 (because of the direct coupling from the plate of V1 to the grid of V2), and causes V2 to conduct. The plate current of triode V2 flows through cathode resistor R4 and causes a small, but constant, voltage drop across the resistor. So long as no input gate is applied the circuit remains in this quiescent state, and the output voltage across resistor R4 remains at the low quiescent value.

When a negative input gate is applied to the bootstrap sweep generator, it is applied through coupling capacitor Cl to the grid of triode V1. When the input gate is of sufficient amplitude to drive the grid of triode VI below plate-current cutoff, plate current ceases to flow, and the plate voltage tries to rise instantaneously to the plate-supply valve. However, capacitor C3 is connected in parallel with triode VI, and prevents the plate voltage from changing instantaneously. Instead, the plate voltage rises relatively slowly as the capacitor charges. Normally, capacitor C3 would charge exponentially at a rate determined by the values of resistance and capacitance in the circuit, as shown by the dashed line on the following theoretical waveform illustration.



Theoretical Input end Output Voltage Waveforms

In the bootstrap circuit, however, the voltage across capacitor C3 is also applied to the grid of triode V2, which is connected as a cathode follower with almost unity gain. The changing voltage on the cathode of triode V2 (which is nearly equal to the voltage on the grid) is fed back through dc blocking capacitor C2 to the junction of plate resistors R2 and R3. This feedback loop operates in the following manner. As capacitor C3 charges positive with respect to ground, the voltage impressed on the grid of triode V2 also rises and becomes more positive. The increasing plate current flow through cathode resistor

R4 causes the cathode voltage on triode V2 to increase, also in a positive direction. This increasing positive voltage is fed back through capacitor C2 to the junction of resistors R2 and R3, aiding the voltage across resistor R3, and effectively increasing the voltage applied to the R-C circuit. Thus, as capacitor C3 charges, the applied voltage is effectively increased so that the voltage appearing across resistor R3 remains constant, instead of dropping as the charge increases. Since the capacitor always charges to 63 percent of the voltage across the resistor in each time constant, and the resistor voltage remains constant, the capacitor charges the same amount each time constant, or in other words, at a linear rate.

When the negative input gate ends, the grid bias on triode VI returns to zero and the tube again begins to conduct heavily. The low impedance of the conducting tube effectively shunts (shorts) capacitor C3, and the capacitor discharges very quickly through the tube. As capacitor C3 discharges, the voltage on the grid of triode V2 decreases, causing the voltage on the cathode to decrease accordingly. The cathode voltage drops to the quiescent value, and the circuit remains in the quiescent state until the beginning of the next input gate.

Thus, the output voltage of the bootstrap sweep generator rises at a linear rate during the input gate, and returns quickly to the quiescent value at the end of the input gate. It remains at the quiescent level until the next gate is applied.

Failure Analysis.

No Output. A defect in nearly any component in the bootstrap sweep generator may cause a no-output condition. Therefore, it is good practice to use an oscilloscope to locate the defective portion of the circuit. First, use the oscilloscope to observe the input gate to make certain that the proper input is applied. If the correct input gate is observed, use the oscilloscope to observe the signal on the grid of triode VI. No negative gate at this point indicates either an open in capacitor Cl or a short in resistor R1. Use an ohmmeter to check these components. If the normal waveform is observed on the grid of triode V1, observe the waveform on the plate of the tube. No signal on the plate of triode V1 indicates a defect in capacitor C3, resistor R2 or R3, or in the tube itself. If checking capacitor C3 with an in-circuit capacitor checker, and resistors R2 and R3 with an ohmmeter, does not reveal a defective component, triode V1 is probably at fault. If the sawtooth waveform is observed on the plate of triode VI, the trouble is either a defective cathode resistor, R4, or a faulty cathode-follower tube, V2. Check resistor R4 with ohmmeter for the correct resistance value. If no defect is found, triode V2 is probably at fault.

Low Output. A sawtooth output of incorrect amplitude may be caused by low plate-supply voltage, or by a circuit defect which affects the charge time of capacitor C3. First, use a high-resistance voltmeter to measure the plate-supply voltage to be certain that the power supply is not at fault. If the correct plate-supply voltage is observed, use a capacitance analyzer to check capacitor C3 for the proper value and an ohmmeter to check resistor R2 and R3 for the proper values. If no defective component is found, triode V1 is probably at fault.

Poor Linearity. If the linearity of the sawtooth output is poor, probably either capacitor C2 or resistor R4 is at fault. Use an in-circuit capacitor checker to check the capacitor for a shorted or open-circuited condition, and an ohmmeter to check the resistor for the correct value. If neither of these components is defective, triode V2 is probably at fault.

TRIODE TRAPEZOIDAL-WAVE SWEEP GENERATOR (ELECTRON TUBE)

Application.

The triode trapezoidal-wave sweep generator produces a trapezoidal waveform for use as the sweep voltage in television sets, radar equipment, test and other electronic equipment using electromagnetic cathode-ray tube displays.

Characteristics

Employs a triode as a switch to control the charge and discharge of a series R42 circuit to produce the output.

Requires a negative input gate.

Output is a series of trapezoidal waves.

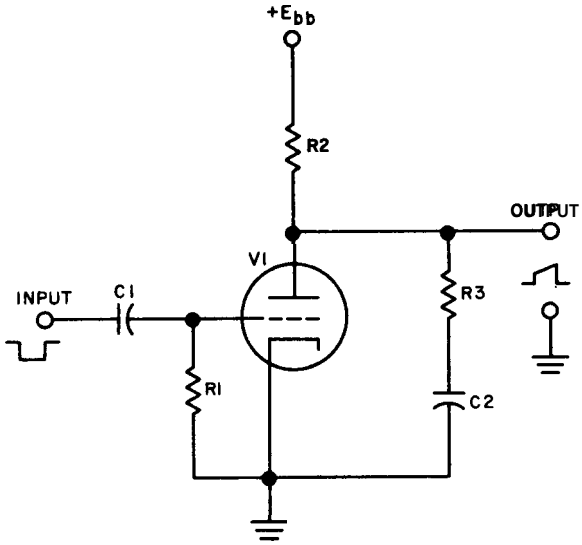
Sweep duration and sweep-repetition period are determined by the characteristics of the input gate.

Circuit Analysis.

General. The deflection coils of an electromagnetic cathode-ray tube require a sawtooth wave of current

to produce a linear sweep across the face of the tube. Because of the inductance and resistance characteristics of the deflection coils, a trapezoidal voltage waveform must be applied across the coils to produce the desired linear sawtooth wave of current through them. The triode trapezoidal-wave sweep generator discussed below produces such a voltage waveform. Since the trapezoidal wave is essentially a sawtooth wave superimposed on a rectangular wave, the triode trapezoidal-wave sweep generator is similar to the triode sawtooth-wave sweep generators discussed previously in this section of the Handbook.

Circuit Operation. The accompanying circuit schematic illustrates one type of triode trapezoidal-wave sweep generator.

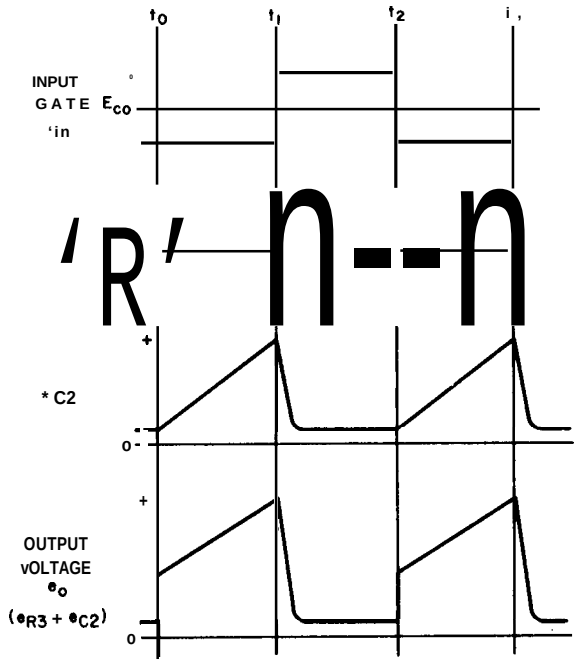


Triode Trapezoidal-Wava Sweep Ganaretor

Capacitor Cl and resistor R1 forma conventional R-C input coupling network used to couple the input gate to the grid of triode VI. Triode V1 acts as a switch to control the charge and discharge of capacitor C2. The charge time of the capacitor is determined by the time constant of the R-C circuit made up of resistors R2 and R3 connected in series with capacitor C2. The trapezoidal output waveform is taken from the plate of triode V1 (across the series combination of capacitor C2 and resistor R3).

In the quiescent state (with no input gate applied to the circuit), contact bias is applied to the grid of triode VI; consequently, the tube conducts very heavily. Since triode V1 conducts nearly at plate-current saturation, the voltage drop across plate resistor R2 is very large and the effective plate voltage is wry low. Capacitor C2 charges through resistor R3 to the low value of voltage existing across the tube, and the circuit remains in this quiescent state so long as no input gate is applied. The quiescent output is the small constant voltage across capacitor C2.

A negative input gate, such as that shown in the following illustration of theoretical waveforms, must be applied to the circuit to produce a trapezoidal output waveform.



Theoretical Waveforms

The negative gate is applied through coupling capacitor Cl to the grid of triode V1, and is of sufficient amplitude to drive the tube below plate-current cutoff. Consequently, plate current ceases to flow, and the plate voltage attempts to rise instantaneously to the plate-supply value. However, since the series combination of capacitor C2 and resistor R3 is connected across the tube, the plate voltage

rises in accordance with the charging action of the R-C circuit made up of resistors R2 and R3 and capacitor C2. When triode VI first cuts off (time t. on the waveform illustration), only the small quiescent charge is present on capacitor C2, and the remain de r of the s u pply voltage appears instantaneously across the series combination of resistors R2 and R3. Thus, at time to, the voltage across resistor R3 (e_R 3) rises instantaneously from nearly zero to a high positive value determined by the total resistance in series with capacitor C2 and the power supply. The voltage drop across resistor R3 produced by the initial flow of charging current to capacitor C2 determines the amplitude of the voltage step shown as $e_{R\,3}$ at time t. in the waveform illustration. At the same time, capacitor C2 charges from the quiescent value to the effective plate voltage value, and the voltage across it (e_{c2}) increases toward the plate-supply value. Though the capacitor charges at an exponential rate, only the initial (relatively straight) portion of the capacitor charging curve is used; therefore, the capacitor charge (from time t_0 to time t_1) is nearly linear. The output from the circuit is taken across the series combination of resistor R3 and capacitor C2, and is the sum of the voltages across these components. The output voltage, therefore, rises instantaneously from the quiescent value to a more positive value at the beginning of the input gate (time to), and then increases at a nearly linear rate until the end of the input gate (time t_1).

When the negative input gate ends (time t_1), the grid bias on triode V1 returns to zero, and the tube again conducts heavily. The low impedance of the conducting tube effectively shunts (shorts) the series combination of resistor R3 and capacitor C2, and the capacitor discharges very quickly through the resistor and the conducting tube. As capacitor C2 discharges, the voltage across it decreases from maximum to the quiescent value. The voltage remains at this value until the beginning of the next input gate.

Failure Analysis.

No Output. An incorrect input gate, a defective input coupling network (Cl, RI), an open plate resistor (R2), a defective tube (V1) or a lack of plate-supply voltage may cause a no-output condition. First, use an oscilloscope to observe the input gate waveform to be certain that the correct input sigml is applied. If the normal input gate is present, observe the waveform on the grid of triode V1. No input gate at this point indicates either an open coupling capacitor (Cl) or a shorted grid resistor (Rl). Use an ohmmeter to check these components for defects. If the correct input gate is observed on the grid of triode V1, use a high-resistance voltmeter to measure the voltage on the plate of the tube. If no plate voltage is present, the trouble may be either a lack of plate-supply voltage or an open plate resistor (R2). Measure the plate-supply voltage with the high-resistance voltmeter, and check resistor R2 with an ohmmeter. If the correct voltage is measured on the plate of triode V1, the tube is probably at fault. 4

Distortad Output. An output waveform with poor linearity or low amplitude may be caused either by a defective tube or by a change in value of resistor R2, R3, or capacitor C2. Use an ohmmeter to check the values of resistors R2 and R3, and a capacitance analyzer to check the value of capacitor C2. If no defective component is found, triode V1 is probably at fault.

Incorrect Output Waveshapa. An output waveform of sawtooth shape (with no initial step) will result if resistor R3 is shorted, while an initial step of incorrect amplitude indicates a change in value of resistor R3.

An output waveform of square-wave shape maybe caused either by an open or short-circuited condition - in capacitor C2 or by an open in resistor R3. Use an ohmmeter to check resistor R3, and an in-circuit capacitor tester to check capacitor C2.

SECTION 9
CRT CIRCUITS

PART 9-1. ELECTROSTATIC

ELECTROSTATIC CATHODE-RAY TUBE CIRCUITS

General.

The circuits used for the electrostatic type of cathode-ray tube are functionally similar to those used for the electromagnetic type of tube, but they differ in the manner of accomplishing their function. Only the electrostatic type will be discussed in this paragraph. Basically, the cathode-ray tube provides a fast moving, easily and quickly deflected electron beam for use in waveform viewing and analysis, and for special display purposes. Generally speaking, the display types of CRT are mostly magnetically controlled, while the types universally used in test oscilloscopes and synchroscopes, for waveform checking, are electrostatically controlled. Therefore, the discussion in this paragraph will be restricted to oscilloscopes. Later paragraphs in this section will describe deflection-modulated display circuits such as used in type A and J scans, and intensity-modulated circuits such as the B and C types, which can employ an electrostatic CRT. All cathode-ray tubes have basic control circuits which are necessary if the tube is to be used at all. These circuits control intensity (brilliance), focus, and beam positioning (centering, both horizontal and vertical). Other circuits with which the CRT is concerned are horizontal and vertical amplifiers, sweep circuits, and synchronizing circuits. All of the latter circuits are standard circuits, with special attention paid to the design for bandwidth, response, and linearity. In some special cases there are peculiar circuits which are mainly combinations of standard circuits used for packaging the components into a convenient size, and for economy. For example, while a console unit may have high and low voltage supplies, they are usually separate and use separate transformers, whereas the conventional oscilloscope uses one transformer to supply both high and low voltage, bias, and filament power.

BASIC ELECTROSTATIC OSCILLOSCOPE CIRCUITS

Application.

The basic circuits described below are used to adapt an electrostatic CRT for use as an oscilloscope which can be utilized for waveform analysis.

Characteristics.

Vertical input (Y-axis)
- High input impedance (approximately 2 megohms shunted by 40 picofarads)
- Step attenuator
- Good frequency response (10 Hz to 1 MHz)

Horizontal input (X axis)
- High input impedance (approximately 2 megohms shunted by 40 picofarads)
- Step attenuator
- Internal sweep or external signal

Sweep
- Selectable sync (polarity and input)
- Sweep frequency 2 Hz to 100 kHz
- Retrace blanking

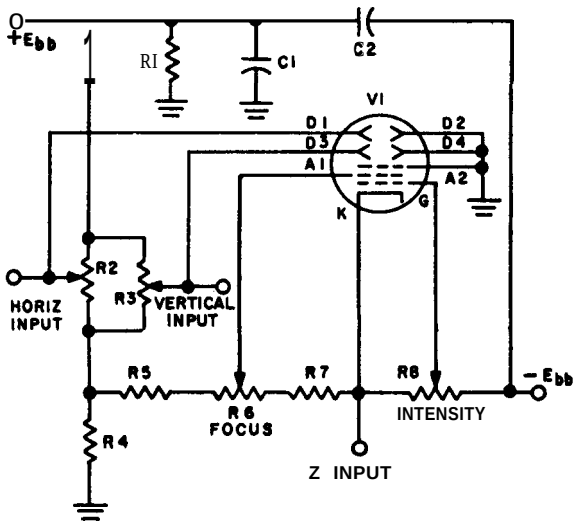
Intensity input (Z axis)

Circuit analysis.

General. The following circuits were chosen as basic examples of the circuits generally used in oscilloscopes. Each was selected to bring out the basic principles and requirements necessary for circuits used in waveform analysis, even though a similar circuit may be found elsewhere in this manual. The discussion is limited to the essentials needed for use with cathode-ray tubes.

Beam-Positioning Circuits. A simple oscilloscope using basic beam-positioning circuits is shown in the following illustration. For a complete schematic of an elementary oscilloscope, see Basic Electronics, NAVPERS IO087A. Note that the voltages are taken from a common voltage divider between B+ and B–. The divider is grounded at a convenient point, usually at the positive voltage required for the accelerating anode (No. 2), and both ends are above' ground. Thus,

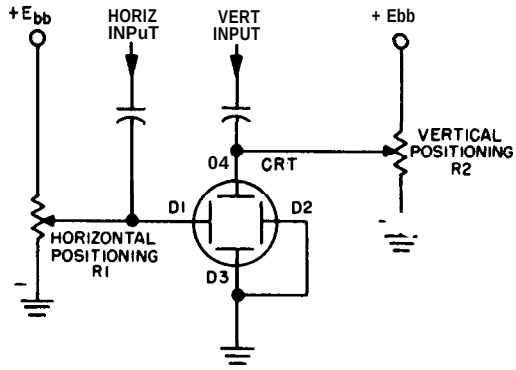
with the positive low voltage and negative high voltage at above-ground potential, the case and chassis can be grounded for protection of the operator. It also permits the anode and one of each pair of deflection plates to be grounded, to form a simple unbalanced deflection or positioning circuit. This connection also keeps the deflection plates and accelerating anode at the same potential, and avoids defocusing effects from differences in potential between them.



Simplified Oscilloscope, Showing Controls

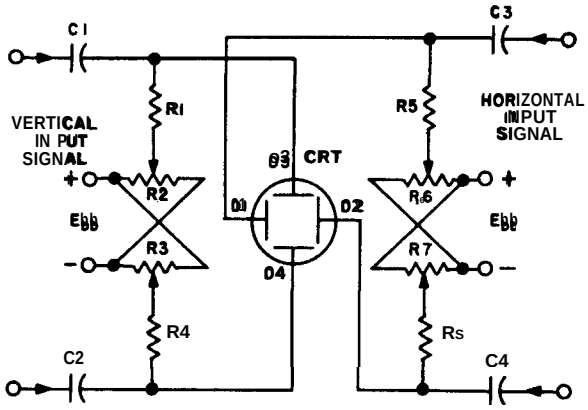
It is evident from the schematic that resistors R4, RS, R6, R7, and R8 form a voltage divider from B minus to ground, and at the junction of R4 and R5 some positive voltage exists. Since the cathode of the CRT is connected at a less negative point on the divider than the grid, the grid is negative with respect to the cathode, and is adjustable by means of potentiometer R8. As in the conventional circuits, variation of this grid bias permits the tube to conduct more or less heavily, as desired. Anode No. 1 is connected to a much lower point on the divider; thus it is effectively much more positive than the cathode and grid, and attracts the electrons from the cathode. By varying the dc potential on this focusing anode, the electron beam from the cathode is directed so that it converges at a point on the face of the CRT. Anode No. 2 of the CRT is grounded; thus, since it is at a more positive voltage than the focusing anode, it attracts the electron beam and accelerates it. The accelerating anode is a concentric ring similar to the focusing anode and the focused beam passes through the center, losing only stray unfocused electrons. The No. 2 anode current, therefore, is minute, and does not detract from the beam. As the beam passes from the accelerating anode to the face of the tube, it passes between two sets of deflecting plates. The plates of the set nearest the No. 2 anode are positioned horizontally above and below the tube centerline, and deflect the beam vertically. (The vertical deflection plates are physically located nearest the No. 2 anode, for maximum control of the electron beam.) The plates of the second set are nearest the face of the tube; they are positioned vertically to the left and right of the centerline of the tube, and deflect the beam horizontally.

Positioning controls R2 and R3 are parallel-connected, and are connected between B+ and ground through R1 and R4. Since one of each pair of deflecting plates is connected to ground, a dc positioning voltage exists between the plates and ground. Thus, by adjusting the positive voltage on R2 and R3, the electron beam is attracted (deflected) toward them and can be centered on the tube face. A simplified version of the positioning circuits is shown in the following figure; since one of each set of deflecting



Unbalanced Positioning Circuit

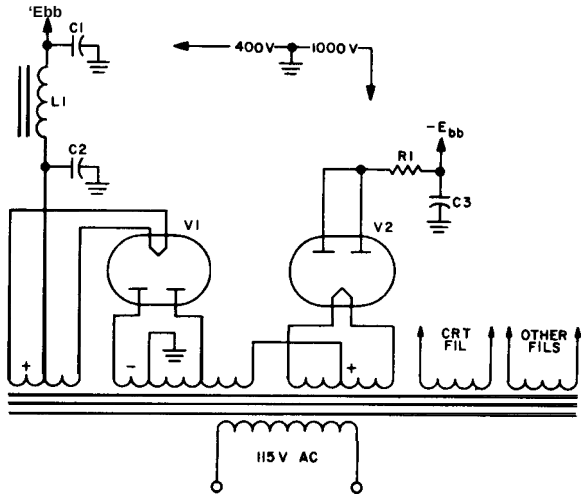
plates is connected to ground, the circuit is unbalanced. Controls RI and R2 are represented simply as variable potentiometers between B+ and ground. A simplified positioning circuit of the balanced type is shown in the accompanying illustration, and is discussed below.



Balanced Positioning Circuit

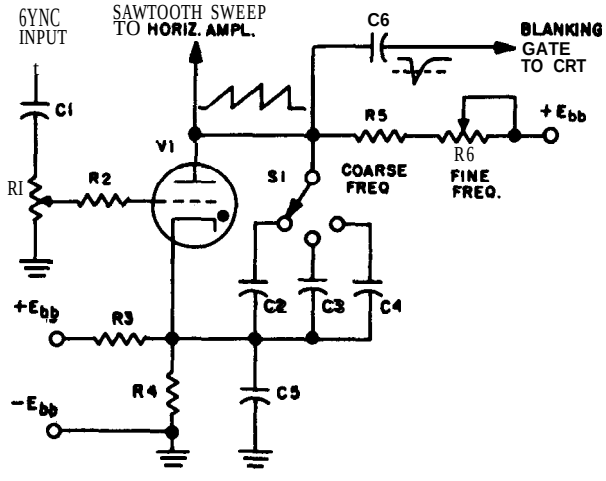
In the balanced circuit, each deflecting plate (D1 through D4) is controlled by a separate potentiometer (R2, R3, R6, and R7), and the plates are isolated and balanced equally by being connected to the positioning controls through equal resistors RI, R4, RS, and R8. Each plate is also connected to the deflection amplifiers, through a coupling capacitor, in a push-pull arrangement. Thus the CRT is balanced for dc, for ac, and for any stray capacitance to ground. Since the isolating resistors (RI, R4, R5, and R8) are always of a very large value, the deflecting plates may be connected into any circuit without danger to the operator (it takes a current of only a few microampere to drop the positioning voltage to zero).

Power Supply. A typical power supply for an elementary oscilloscope is shown in the illustration. Two fullwave rectifier tubes are used with a single transformer to supply a positive low voltage for circuits other than the CRT and a negative high voltage for the CRT. The low-voltage supply is a conventional full-wave rectifier circuit with the center tap grounded, and B+ is taken from the cathode and applied to a single pi-type C-L falter (Cl, Ll, and C2). The negative high-voltage supply uses the other full-wave rectifier tube (V2), with the plates parallel-connected as a half-wave rectifier, and the low-voltage center tap used as a common ground. Because of the small amount of current taken by the CRT, the simple R-C filter offered by the bleeder and C3 is sufficient for hum elimination. The low-voltage output is on the order of 400 volts, and the high-voltage output is about 1000 volts. The filament windings for the CRT, as well as the other tubes, are also included on the same transformer, providing a compact and economical power supply.



Typical Power Supply

Sweep Circuit. To provide a time base for the waveform, the CRT beam must be deflected horizontally across the face of the tube from left to right, then caused to return quickly from right to left, ready to resume another cycle of operation. A sweep voltage obtained by the charge and discharge of a capacitor is employed for this purpose. During the charging period the sweep is developed and the beam moves from left to right; during the discharging period the capacitor reverses polarity of deflection and the beam moves back to the start (retrace time). Some oscilloscopes provide blanking for the retrace period so that the return sweep camot be seen. A typical thyratron type sweep generator for general oscilloscope use is shown in the following illustration. Other types of relaxation oscillators, such as a neon tube, a vacuum tube R-C oscillator with discharge tube, or a multivibrator, could be used, provided that a reasonably linear sawtooth sweep waveform is produced.



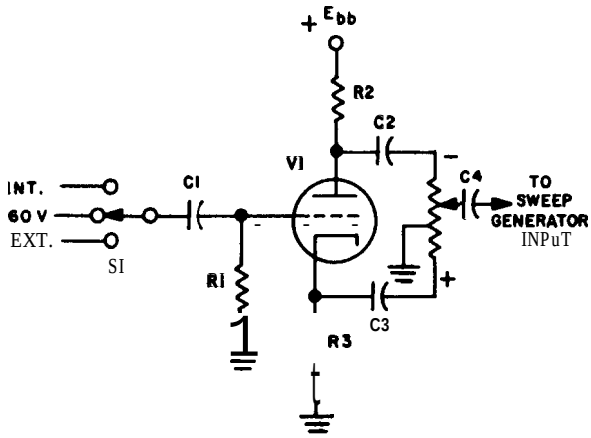
Typical Sewtooth Generator (Thyratron)

Thyratron tube VI operates as a relaxation-type oscillator at frequencies from 5 to 100,000 Hz. The frequency of operation is selected roughly by S1, which connects various values of capacitance between the cathode and plate of the tube. The frequency of operation is adjusted finely by variable resistor R6, which, together with R5 and the capacitor selected by S1, provide a specific frequency fixed by the time constant of the R-C circuit. R5 primarily determines the amplitude over the range adjustable by R6 for a specific supply voltage. Normally, the circuit starts in an inoperative condition with the cathode fixed-biased by voltage divider R3 and R4, and capacitors C2, C3, or C4 (as selected by S1) charge slowly at a rate determined by the setting of R6. When the voltage between the cathode and plate reaches the ionization voltage (value depends upon type of gas used), the tube fires. Heavy current flows from the cathode to the plate and effectively produces a short-circuited condition across the capacitor selected by S1. Thus, the capacitor quickly discharges until the deionization voltage is reached and the tube stops conducting, resting in a biased-off condition, and the cycle of operation resumes again. During the charging period, blanking capacitor C6 is also charging slowly and reduces the CRT bias, allowing operation. When V1 conducts, C6 discharges through a grid-cathode resistor in the CRT circuit, and the common bleeder, biasing the CRT off and blanking off the retrace interval.

Capacitor Cl is a coupling capacitor which applies the sync signal between R1 and ground; the amount of synchronizing signal fed to the grid of VI is adjusted by the position of RI. Resistor R2 is a protective resistor which limits grid current flow to a safe value; it also acts as a decoupling resistor. Capacitor C5 bypasses cathode resistor R4 to prevent degenerative feedback during sweep operation, and effectively shunts R4 so that it is not a part of the R-C time constant circuit.

Synchronizing Methods. To keep the waveform stationary on the face of the CRT tube, the sweep frequency must be an exact multiple or submultiple of the waveform under observation. To avoid the need for constant resetting of the sweep frequency control because of drift, power-supply voltage changes, etc, a sweep-locking or synchronizing circuit is provided. In the basic unit, a three-position switch is generally provided to permit selection of either an external signal, a 60-Hz signal, or the internal sweep (or input signal) taken from the verticrd deflection amplifier plate. Since some circuits do not have an output of the proper polarity for synchronization, an adjustable synchronizing circuit is sometimes included to permit selection of sync signal and choice of sync polarity. The following illustration shows a typical sync-input circuit of this type. Switch S1 selects one of three inputs: an external synchronizing signal, a 60-Hz signal (usually taken from a filament winding), or the output from the vertical amplifier (this is the signal under observation, but it is called interrrul sync); it then applies the input through coupling capacitor Cl to the grid of V1. Tube V1 is a paraphase amplifier, with the grid returned to ground — through R1. The tube is cathode-biased and unbypassed; the plate and cathode resistor, R2 and R3, are of the same value, so that for the same current identical signals are developed in the plate and cathode circuits (except that the polarity of one is opposite the polarity of the other). For a positive input signal, a negative plate-output signal is developed, and the cathode-output signal is positive. For a negative input signal, a positive plate-output signal is developed, and the cathode is negative. Both plate and cathode outputs are coupled through capacitors C2 and C3 to a common load resistor, grounded at its center tap and also variable. At the ground position both signals are

equal and opposite, and of zero amplitude; therefore, no output is obtained. As R4 is rotated in either direction, the signal amplitude is increased. Since the synchronizing signal to the sweep generator must be of positive polarity, for a negative input to VI a positive signal is available on the plate side, and for a positive input to V1 a positive signal is available on the cathode side. Thus a signal similar to the input signal but of positive polarity is obtained and coupled through C4 to the thyratron sweep generator discussed above. When this paraphase input is supplied, the sweep generator has a fixed grid resistor instead of the variable one shown in the illustration of the thyratron sweep generator.



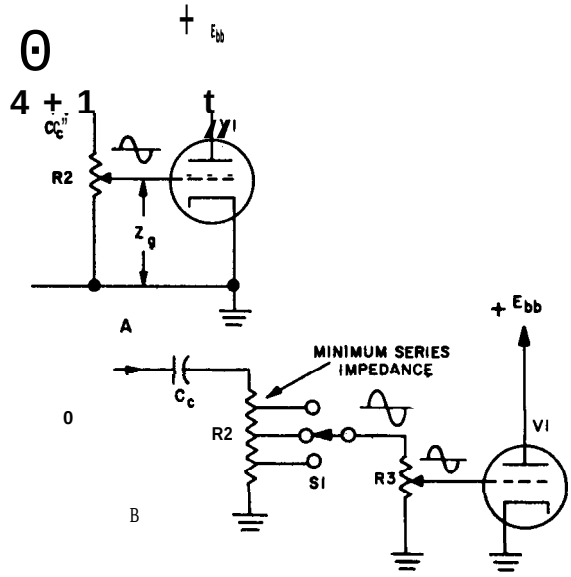
Typical Sync Input Circuit

When the sweep generator is adjusted to a slightly lower frequency than that desired, a positive-going sync signal applied to the grid of the thyratron will cause ionization to occur earlier in the operating cycle. Since this has the effect of changing the ionization potential, the frequency of operation is increased and the sweep generator locks-in and operates at the same frequency as the sync signal. Thus the CRT waveform remains stationary, rather than drifting across the screen, because it is synchronized so that the sweep occurs at the same place at the same time each sweep.

Deflection Amplifiers. To produce satisfactory deflection with small signals, it is necessary to employ both vertical and horizontal deflection ampli13ers. These stages may be single-ended or push-pull (unbalanced or balanced); they are conventional video amplifiers designed for the desired frequency response and linearity. A simple equipment usually provides only one stage of amplification and an output stage, whereas a laboratory-type equipment provides two or three stages of amplification with output stages.

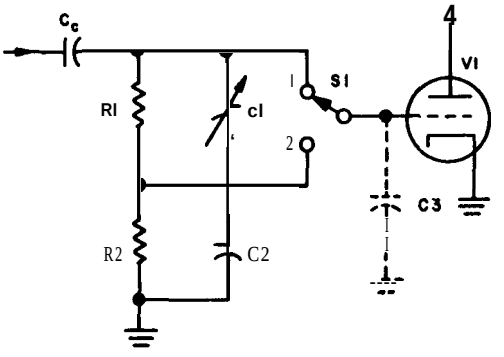
The horizontal amplifier in a good scope is identical to the vertical amplifier, permitting the same signal to be applied to the X axis and the Y axis. In the majority of oscilloscopes, however, only the horizontal sweep is amplified; thus less gain is needed since the sweep output voltage is large. Because the sweep is usually a submultiple in frequency of the observed signal, less frequency response is needed. Thus the horizontal deflection amplifier need not be described, since the vertical amplifier has more stringent requirements.

Since the vertical amplifier must be able to amplify very weak signals with sharp rising waveforms, it must have good frequency response and large amplification. To cover the range of signal amplitudes encountered, the vertical input is usually provided with an attenuator. Simple potentiometer-type attenuators are shown in the accompanying figure. The simple circuit shown in part A of the illustration uses the potentiometer as the output load resistor of an R-C coupling network. Thus, since the grid-to-ground impedance (Z_g) of the input tube is in shunt



Potentiometer Attenuators

across it, as the potentiometer arm is moved upward the impedance presented to the circuit under test is decreased (less loading and less attenuation). The simple step-attenuator circuit shown in part B of the illustration is a better type of input circuit, allowing coarse selection of the attenuation ratio with switch Sl, and fine adjustment with potentiometer R3. It is evident that even for the smallest input step resistance, the full range of R3 is available for control. With the available settings of S1, the input impedance will never decrease to a value less than the series section of R2 (that portion above the upper tap) plus the parallel combination of the remainder of R2, R3, and the grid-to-ground impedance of the input tube. The most desirable input is in the range of megohms, with little or no shunting capacitance to ground. To achieve this result sometimes a cathode follower input stage is combined with a step attenuator to isolate the oscilloscope input from the stage being tested. The usual input capacitance is on the order of 30 picofarads, which can be appreciable (1000 ohms at 5 MHz). Therefore, frequency-compensated attenuators are used in the better type of oscilloscopes to minimize the effect of input capacitance (as shown in the figure), by presenting identical impedance-response curves to the circuit under test for the various attenuator settings.

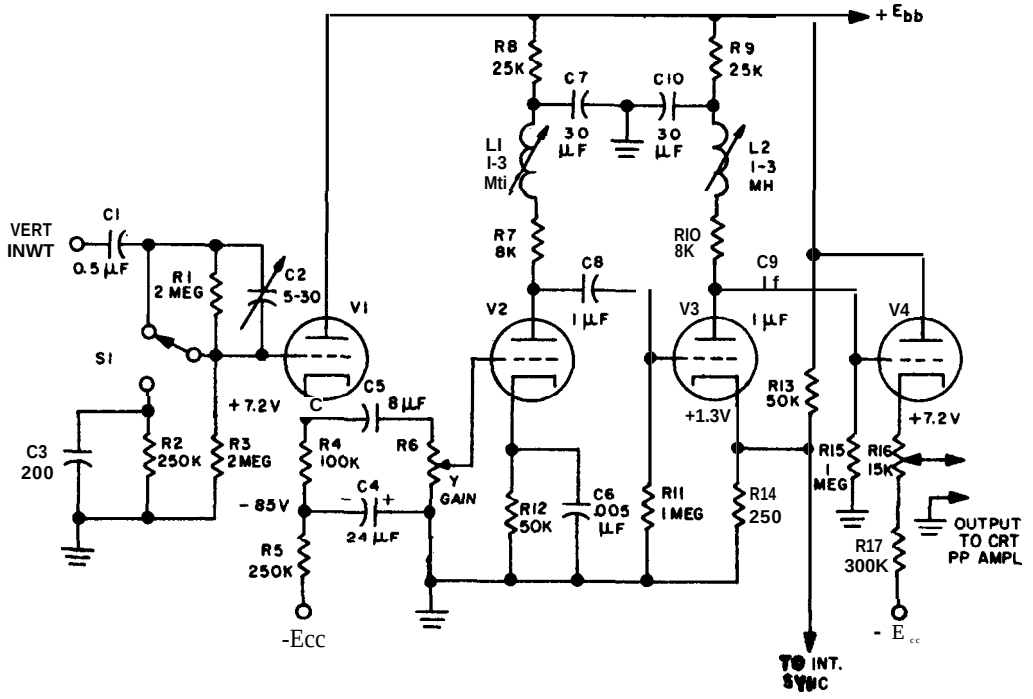


Frequency-Compensated Step Attenuator

Frequency-compensated attenuators further provide the same voltage division ratio (resistive to reactive) of the input signal, so that the drop-off in signal level at the higher frequencies can be compensated for in the following video amplifiers. Attenuator compensation is usually effective over the entire useful frequency range of the oscilloscope. The attenuator potentiometer is frequency-sensitive because of the distributed and stray capacitance from the moving arm of the potentiometer, the wiring and circuit elements, and the electron tube input capacitance to ground. While the resistance of the potentiometer must be as high as possible to maintain maximum input impedance, the greater the resistance, the greater the effect of the stray capacitance. Since there is only one setting of the attenuator arm where the resistance division and the capacitance division are of the same ratio, shunt capacitors Cl and C2 are added to the attenuator, as shown in the illustration, to provide frequency compensation. When the attenuator (S1) is set to position 2, the input to the amplifier is reduced to one-tenth of the total signal across the voltage divider. R2 is then one-tenth of R1 plus R2. The ratio of the capacitive reactance is then chosen to be of the same order. That is, the reactance of C2 and the stray capacitive reactance of C3 is made to be one-tenth of the total reactance of Cl in series. with the parallel combination of C2 and C3. Normally, because of the difficulty in measuring the stray capacitance indicated by C3, Cl is made variable and is adjusted during operation to produce the best compensation effects, using a square-wave input (this is made initially and once calibrated requires only an occasional check).

Since most attenuators and amplifiers have reduced high-frequency response because of the shunting effect of stray capacitance, a parallel R-C circuit in series with the input lead is usually inserted to boost the relative response of the attenuator at high frequencies. Another device is an input probe located at the end of a special connecting cable which applies the input to the vertical amplifier. The probe houses a frequency-compensated voltage divider, and is constructed to reduce to a minimum the amount of shunt capacitance existing at its input terminals. This is usually called a “DC probe”, or simply “input probe”, as distinguished from an “r-f probe”, which contains a diode rectifier to remove the modulation.

A typical three-stage vertical amplifier is shown schematically in the accompanying illustration; it



Vertical Deflection Amplifier

drives a conventional push-pull paraphase deflection output amplifier (see the Amplifier Section of this Handbook for a discussion of deflection output amplifier stages). The vertical input signal is applied through blocking and coupling capacitor Cl to a cathode follower attenuator stage incorporating triode V1. The attenuator is a two-step, frequency-compensated type. For signals under 25 volts, S1 connects the input directly to the grid of V1. For signals over 25 volts, C2 is adjusted so that the time constant of the circuit consisting of C2 and RI is the same as the time constant of the circuit consisting of C3 and the parallel combination of R2 and R3, including the stray grid-to-ground capacitance of VI. Thus the attenuation in this position of S1 is practically constant for all frequencies. The constants are so proportioned that the input impedance is approximately 2 megohms for either position of the attenuator, with an effective shunt input capacitance of about 40 picofarads. Although V1 has its cathode connected to the -280-volt supply, the plate current flow through R4 and R5 is sufficient to bias the cathode positive with respect to ground. The output of cathode follower V1 is taken from the cathode through C5, which is a large capacitor (on the order of 8 microfarads), and applied to the input gain potentiometer, R6. Capacitor C4 is a conventional filter capacitor to bypass the negative supply. Y-gain (vertical) control R6 controls the amplitude of the input signal to the two-stage, high-gain compensated video amplifier consisting of V2 and V3. Both high-frequency and low-frequency compensation are employed in each stage. The cathode of V2 is bypassed by a small capacitor, which makes it degenerative for low frequencies, thus reducing the response and flattening out the low-frequency response. Low-pass R-C falters R8, C7 and R9, C1O offer a high impedance to the low frequencies and a shunt path to the high frequencies in the plate circuits of the amplifiers. Thus the effective load impedance at low frequencies is increased, which

compensates for the normal drop off at about 30 Hz, and extends the response down to 2 Hz. The high-frequency response is increased by peaking coils L1 and L2, which compensate for the shunting effect of tube and wiring capacitance, providing a reactance which increases with frequency. The use of the peaking coils extends the response up to about 1 MHz. To help improve the high-frequency response, plate load resistors R7 and RIO are made low in value to reduce the shunting effect of stray capacitance. To improve the low-frequency response, the time constants of R-C coupling networks C8, R11 and C9, R15 are long (on the order of 1 second). Amplifier V3 is fixed-biased by connecting the cathode to the junction of R13 and R14, which are connected in series between the plate supply and ground. Cathode resistor R14 is also unbypassed so that the circuit is completely degenerative for high and low frequencies, further improving the over-all frequency response. The use of the fixed cathode bias sets the operating point of V3 and helps stabilize the stage. An output from the cathode of V3 is taken for application to the sync circuit for internal synchronization. The output of V3 is fed to cathode follower output stage V4, which is biased positive with respect to ground by plate current flow, even though the cathode is returned to the minus supply. Variable potentiometer R16 serves as an output and positioning control for the following paraphase amplifier. The paraphase amplifier is similar to those described in the Amplifier Section of this Handbook; therefore, it is not further discussed here.

Failure Analysis.

Beam-Positioning Circuits. Usually, a control circuit failure is indicated by loss of a specific control function, and can be quickly verified by a resktance or voltage check. It must be understood that all controls affect the electron beam in some manner, and that the controls are interacting. For example, increasing the intensity of the beam will also thicken the beam and require a readjustment of the focus control for the thinnest line at that intensity. Likewise, a change in accelerating anode potential will cause a change in spot diameter and the maximum intensity available. Where high humidity and excessive moisture prevail, control failures from insulation breakdown, are usually more prevalent because of the high potential involved, which causes a short circuit to ground.

Power Supply Circuits. Because of the high negative potentials used for operation of the CRT electron gun, the oscilloscope power supply is particularly susceptible to flash-over, particularly in damp and humid locations. A voltage check is usually sufficient to reveal the location of the trouble.

Sweep Circuit. Failure of the sweep circuit is evident by a lack of horizontal deflection, assuming that the beam positioning and adjusting circuits operate. A nonlinear sweep produced by changes in value or failure of components will show itself as a crowding together (or an expansion) of the waveform at the ends (or in the middle), particularly when a known linear waveform is observed. Distortion which results from the application of an excessive amplitude of sync pulse to the synchronizing circuit should not be confused with sweep nonlinearity. Most sweep troubles can be corrected by replacement of defective electron tubes, although there may be an occasional component failure. Where thyratron or other gas tubes are used, it may be necessary to try two or three tubes before obtaining one that will operate properly. Even with vacuum-tube sweep circuits, tube selection may be necessary.

Synchronizing Circuits. When the sync pulse amplitude is insufficient, or is of the wrong frequency or polarity, synchronization will not be obtained. With internal synchronization, lack of signal to the synchronizing circuit can occur from poor switching contacts or by failure of any component in the sync circuit. Wrong polarity can occur with external sync, but not with internal sync. Incorrect sync amplitude is compensated for by adjusting the input control. In the case of the controllable sync amplifier, only a shorted or open component or a bad tube can cause difficulty. A resistance check should quickly reveal the trouble. False synchronization is possible with unstable operation due to improper setting of the sync and fine tuning controls. Over synchronization results from too large a synchronizing pulse, and causes distortion of the waveform under view. Reduction of the sync input will return the circuit to normal. The effects of poor voltage regulation may also result in apparent instability, but this is the fault of primary transients rather than sync circuit action. This type of instability is usually recognized easily as it is usually

coupled with constant fluctuations of the CRT presentation up or down and to the right or left, or by a constant jittering of the pattern.

Deflection Amplifiers. Lack of output can be caused by failure of components or an electron tube, and can quickly be isolated by using another oscilloscope to check the signal from grid to plate through the amplifier for the point of signal disappearance. In most oscilloscope amplifiers, it is possible to have the circuit operating, but producing false indications because of failure of the compensating circuits. Use of a square-wave input will quickly determine whether the circuit is rounding off the peaks because of the lack of highs, or drooping at the top because of bad low-frequency response. Comparison of the same waveform on another scope which is in good condition is the best method of determining performance.

SYNC HROSCOPE

Application.

A synchroscope is a waveform measuring device very similar to an oscilloscope, only it is used primarily for observing pulse waveforms of short duration.

Characteristics.

Vertical Input.

Variable input impedance - may be matched with the output impedance of the signal source.

Vertical input delayed before being applied to vertical plates.

Sync Input.

Variable input impedance

Sweep only generated when a sync signal is present.

Sync signal may be internally or externally originated.

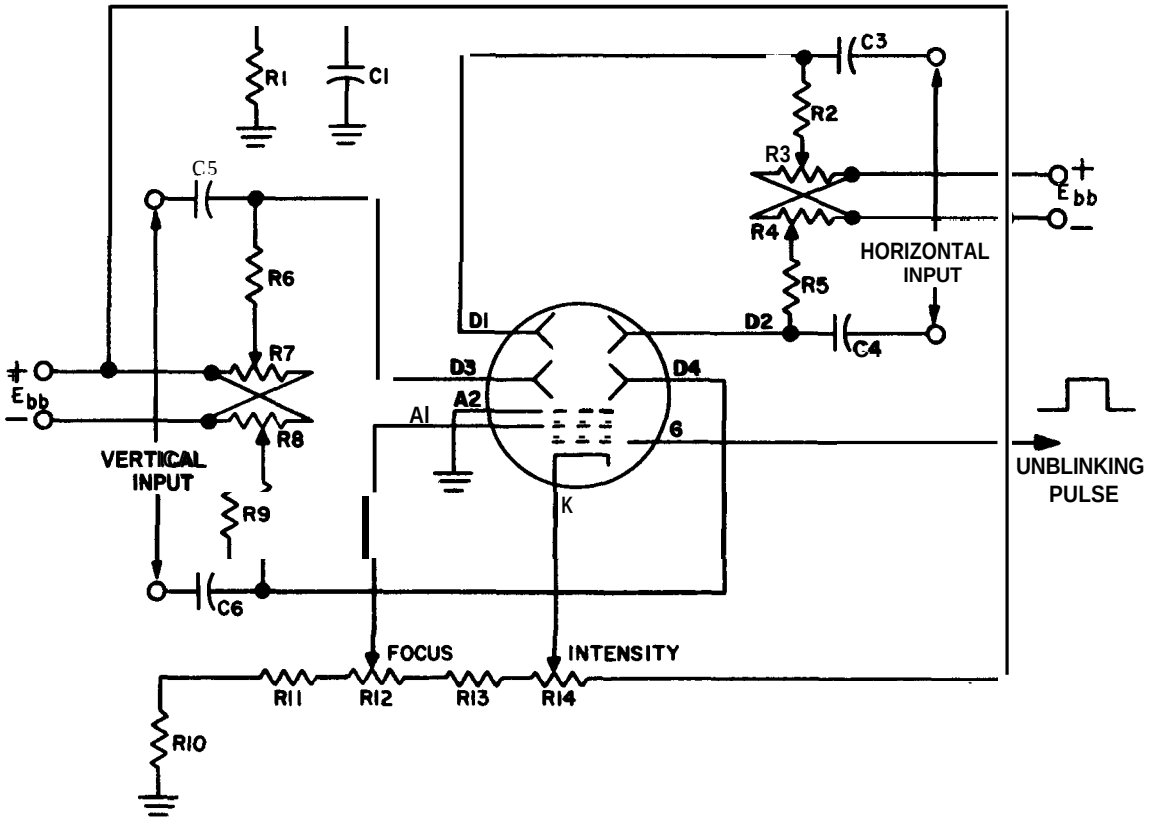
Cathode Ray Tube

Electrostatic - uses medium persistence phosphor.

Circuit Analysis.

General. The following circuits were chosen as basic examples of circuits commonly used in synchroscopes. Each circuit was selected to bring out the basic principles and requirements necessary for circuits used in non-repetitive waveform analysis, even though similar circuits may be used in other sections of the manual. The circuit discussion is limited to essentials needed for cathode tube displays.

Beam-Positioning Circuits. A basic beam-positioning system used in a synchroscope, using a balanced deflection network, is shown in the following illustration.



Simplified Synchroscope CRT Control Circuits

The voltages for the CRT electrodes are taken from a common voltage divider between the negative voltage supply and ground. The voltage divider is grounded at the positive voltage required for the accelerating anode, while the cathode is operated at a high negative potential with respect to ground, the low voltage is operated above ground. Thus, with the positive low voltage and negative high voltage at above ground potential, the case and chassis can be grounded for the protection of the operator.

It is evident from the schematic that resistors R1O, R11, R12, R13, and R14 form a voltage divider from the junction of the negative supply to ground, and at the junction of R1O and R11 some positive voltage exists. The control grid is supplied with a positive unblinking pulse, produced by the start-stop sweep generator, which enables the CRT to conduct. As in conventional circuits variation of the voltage on the grid permits the CRT to conduct more or less heavily. Anode no. 1 is connected to a much lower point on the divider; thus it is effectively much more positive than the grid and cathode, and attracts the electrons from the cathode. By varying the dc potential on this focusing anode, the electron beam from the cathode is directed so that it converges at a point on the face of the CRT. Anode no. 2 of the CRT is grounded; thus, since it is at a more positive voltage than the focusing anode, it attracts the electron beam and accelerates it. The accelerating anode is a concentric ring similar to the focusing anode, and the focused beam passes through the center, losing only stray unfocused electrons. The second anode current, therefore, is minute and does not detract from the beam. As the beam passes from the accelerating anode to

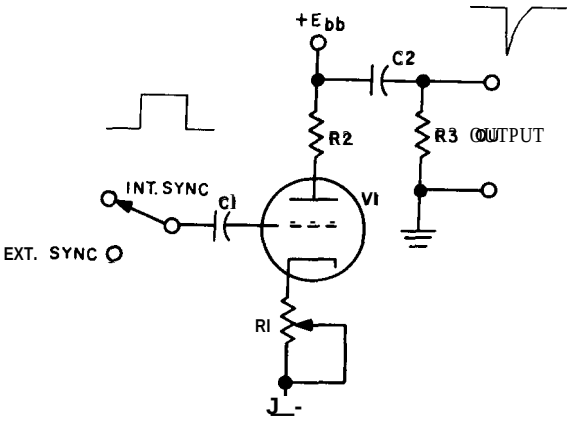
the face of the tube, it passes between two sets of deflection plates. The plates of the set nearest the second anode are positioned horizontally above and below the tube centerline, and deflect the beam vertically. The plates of the second set are nearest the face of the tube, and deflect the beam horizontally.

Each deflecting plate (Dl through D4) is controlled by a separate potentiometer (R3, R4, R7, R8), and the plates are isolated and balanced equally being connected to the positioning controls through equal resistors R2, R5, R6, and R9. Each plate is also connected to the deflection amplifiers, through a coupling capacitor, in a push-pulf arrangement. Thus the CRT is balanced for dc, for ac, and for any stray capacitance to ground. Since the isolating resistors (R2, R5, R6 and R9) are always of a very large value, the deflecting plates may be connected into any circuit without danger to the operator (it takes a current of only a few microampere to drop the positioning voltage to zero).

Power Supply. Refer to the discussion of a typical power supply circuit in the previous discussion of Basic Oscilloscope Circuits in this section of the Handbook.

Horizontal (Sweep) Channel. There are two types of sync signal input available at the input of the horizontal channel. A positive pulse derived from the signal input may be taken from the coupling amplifier, or some external sync may be applied from an external source.

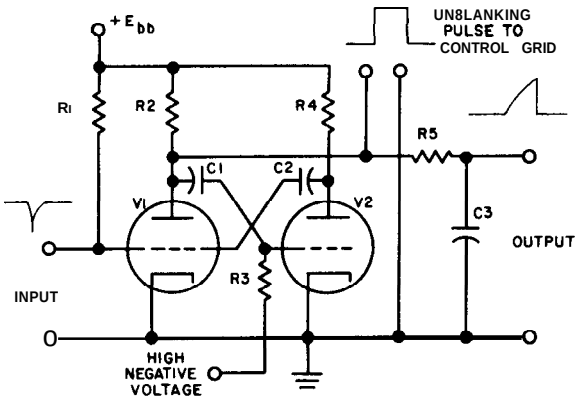
With the sync switch in the int. sync position, a positive pulse (taken from the coupling amplifier) is applied to the sync pulse amplifier, where it is inverted, amplified, and formed into a sharp spike. The circuit used to develop this spike is shown in the following illustration. The positive pulse is applied through capacitor Cl to triode V1, where it is inverted and amplified at the plate. The variable potentiometer RI determines the amount of amplification of the signal. The sync pulse is coupled through capacitor C2 and resistor R3, which develops a differentiated form of the negative rectangular pulse. The output is taken from across R3 in the form of a negative spike occurring at the pulse input frequency.



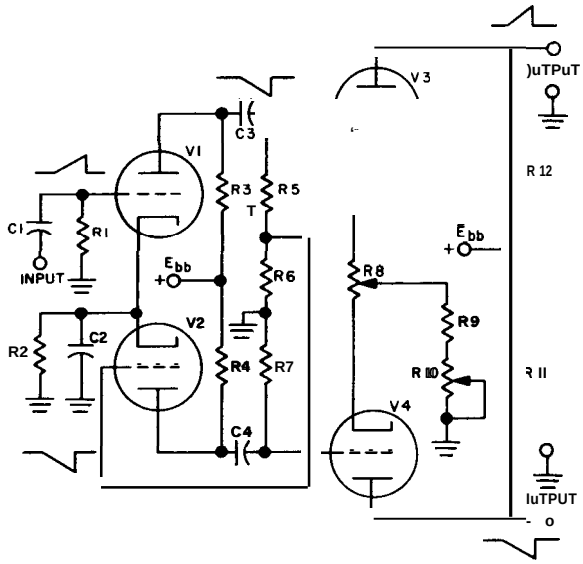
Sync Pulse Amplifier

The typical sweep generator is a start-stop multivibrator, shown in the following illustration. This circuit is a cathode coupled type of start-stop multivibrator, with the grid of VI at a high positive potential and the grid of V2 at a high negative bias value, so that V1 is normally conducting heavily and V2 is normally cutoff. With the application of the negative input pulse, V1 is cut off and V2 is brought to maximum conduction for a period of time determined by the time constant of the circuit. This time constant is dependent on the values of R2, Cl and R4, C2. The resulting output, taken from the plate of VI, is a positive rectangular pulse obtained during the time that V1 is not conducting. Besides using the rectangular output for unblinking the CRT during the period that the input signal is to be viewed, the rectangular output pulse is applied to an RC circuit (R5 and C3) where it is integrated. A sawtooth output is then obtained from C3, which has the same duration as the unblinking pulse. This sawtooth is applied to drive the output sweep amplifier shown in the following illustration. The output sweep amplifier is a paraphase push-pull type of amplifier which produces a

sawtooth waveform from each output, equal in amplitude but of opposite polarity. The single input (driving) sawtooth is applied through Cl to the grid of VI where it is amplified and inverted. The output of V1 is applied to the grid of V3 and across voltage divider R5 and R6, connected from output to ground. The voltage dropped across R5 is applied to the grid of V2. Since the input of V2 is 180" out of phase with the input of Vl, the outputs of VI and V2 are likewise 180° out of phase. The outputs of V1 and V2 are applied to V3 and V4, respectively, where these outputs are amplified and supplied to opposite horizontaldeflection plates in the CRT to produce a balanced deflection of the electron beam (detailed description of the operation of paraphase amplifiers can be found in the Amplifier Section of this Handbook).

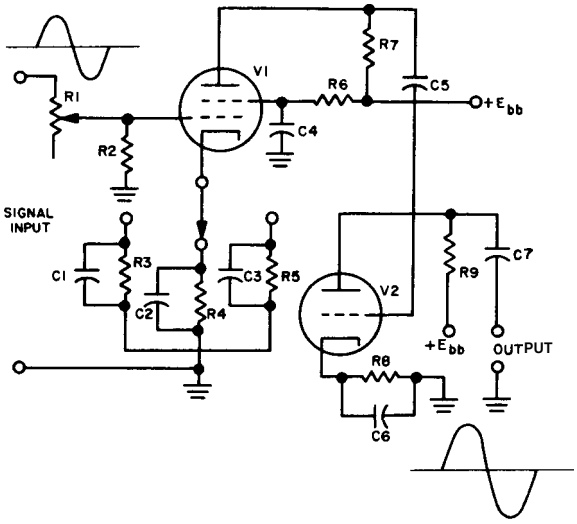


Start Stop Sweep Generator

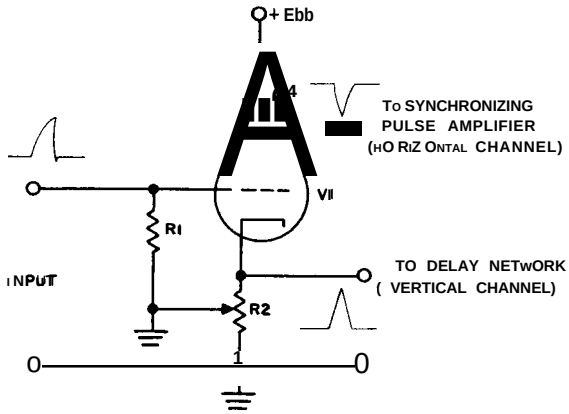


Paraphase Push-Pull Amplifier

Vertical Channel. The signal input is applied to the vertical charnel through an input impedance selector circuit, which is used to match the output impedance of the signal source to the input impedance of the coupling amplifier. A typical, simplified, input impedance selector circuit is shown in the accompanying illustration.



Input Impedance Selector Circuit



Coupling Amplifier

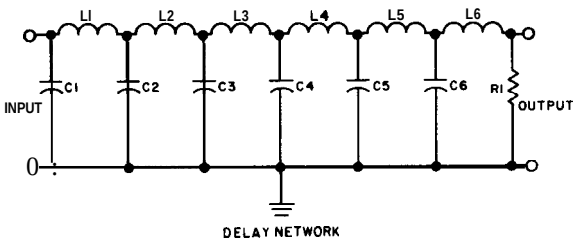
This circuit uses a typical tetrode input amplifier, with the input signal being coupled to the control grid of V1 across an input voltage divider consisting of variable resistor R1 and fixed resistor R2. The variable resistor provides both a means of attenuating the input signal, and a method of supplying a variable input impedance for the synchroscope; while fixed resistor R2 determines the minimum input impedance to VI. Together this resistive input arrangement facilitates matching the input impedance of VI, to the impedance of the signal source. Resistors R3, R4, and R5 are different values of cathode bias resistors. These different values are selected by a switch to provide a large range of attenuation for the input signal by changing the input bias. Capacitors Cl, C2, and C3 are conventional cathode bypass capacitors associated with these cathode resistors. Besides providing a variable input impedance, and a large attenuation range, the input selector circuit provides high amplification with undesired inversion of the input signal at the plate of VI. Therefore, another amplifier stage (V2) is provided to supply an additional 180° phase shift, so that the output of stage V2 is in phase with vertical input signal. The output of the input impedance selector circuit is applied to a coupling amplifier.

The coupling amplifier, shown in the accompanying illustration, has two functions.

One function is to supply a pulse to the synchronizing pulse amplifier when internal sync is used. This sync pulse, which is the inverted and amplified input to the coupling amplifier, is obtained at the plate of Vl, and is coupled through an Int–Ext. sync switch to the sync (pulse) amplifier. The pulse then serves as a trigger for the start-stop sweep generator.

The second function of the coupling amplifier is to act as a cathode follower, providing an impedance match for the low-impedance input of the delay network. This input is the uninvested signal pulse obtained at the cathode of V1 without amplification. A potentiometer is used for R2 instead of a fixed cathode resistor. The potentiometer setting determines the amplitude of the pulse obtained at the cathode of V1. This potentiometer functions as a vertical image size control.

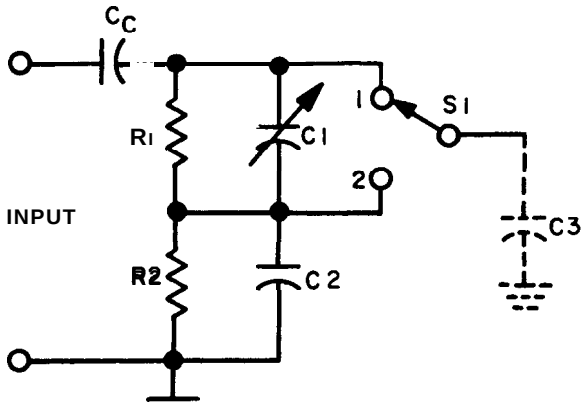
The pulse obtained at the cathode of the coupling amplifier is applied to a delay network, which prevents the pulse from causing a vertical deflection of the electron beam until shortly after the sweep has started. (A typical delay time is 1/2 μ sec.). An accompanying illustration shows a delay network which



Delay Network

may be used. It is composed of series inductors and shunt capacitances terminating in a resistor having an ohmmic value equal to the total impedance value of the foregoing inductors and capacitors. The delay effect is due to the fact that each capacitor retards the voltage from appearing across it, and each inductor retards the current from flowing through it. The terminating resistor minimizes reflections of standing waves. (Standing waves upset the normal function of the delay line and introduce error).

The delayed signrd is coupled through a signal attenuator, which is a tapped voltage divider, to the vertical amplifier. A typical attenuator is shown in the following illustration.

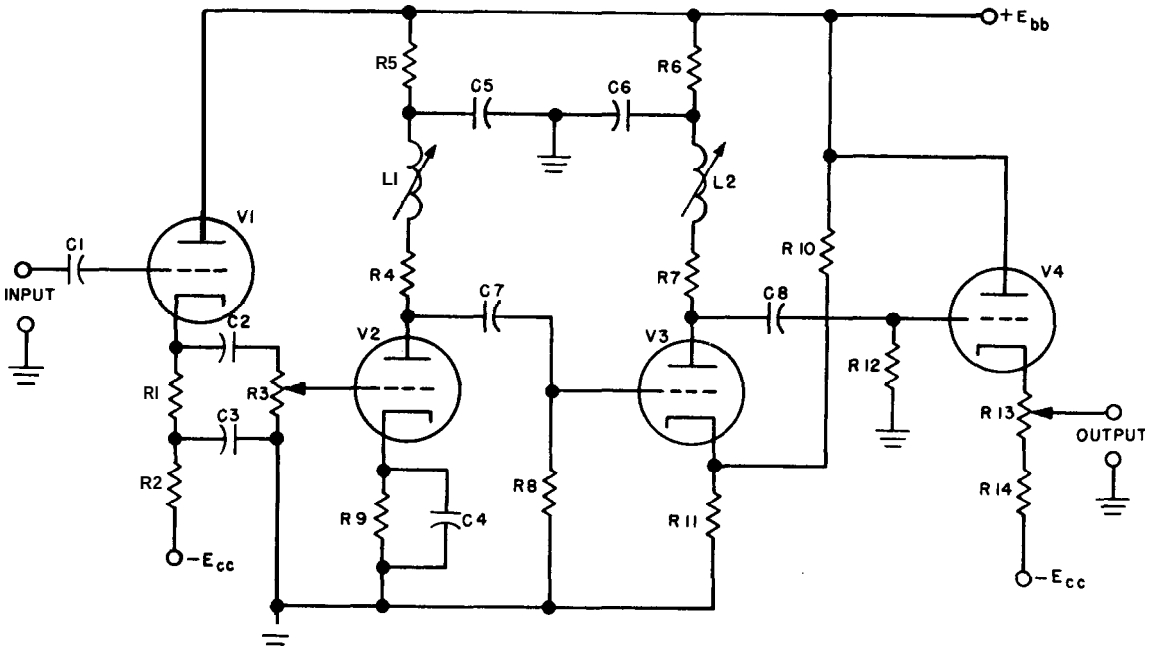


Signal Attenuator

This attenuator is frequency compensated to reduce the distributed and stray capacitance of this circuit and the following circuit. Frequency-compensated attenuators further provide the voltage division ratio (resistive and reactive) of the input signal, so that the loss in signal level at the higher frequencies can be compensated for in the following amplifiers. Attenuator compensation is usually effective over the entire useful frequency range of the scope. When a potentiometer type of attenuator is used, the attenuator potentiometer is frequency-sensitive because of the distributed and stray capacitance from the moving arm of the potentiometer, the wiring and circuit elements, and the electron tube input capacitance to ground. While the resistance of the potentiometer must be as high as possible to maintain maximum input impedance, the greater the resistance, the greater the effect of the stray capacitance. Since there is only one setting of the attenuator arm where the resistance division and the capacitance division are the same ratio, shunt capacitors Cl and C2 are added to the attenuator, as shown in the illustration to provide frequency compensation. When the attenuator (S1) is in position 2, the input to the amplifier is reduced to one-tenth of the total sigml across the voltage divider. R2 is then one-tenth of RI plus R2. The ratio of the capacitive reactance is then chosen to be of the same order. That is, the reactance of C2 and the stray capacitive reactance of C3 is made to be one-tenth of the total reactance of Cl in series with the parallel combination of C2 and C3. Normally, because of the difficulty in measuring the stray capacitance indicated by C3, Cl is made variable and is adjusted during operation to produce the best compensation effects, using a square-wave input (this is made initially and once calibrated requires only an occasional check).

Since most attenuators and amplifiers have reduced high-frequency response because of the shunting effect of stray capacitance, a parallel R-C circuit in series with the input lead is usually inserted to boost the relative response of the attenuator at high frequencies.

A typical three-stage vertical amplifier is shown in the following illustration; it drives a push-pull paraphase deflection output amplifier, similar to the one used as the horizontal sweep amplifier.



vertical Amplifier

Although VI has its cathode connected to a negative high voltage supply, the plate current flow through R1 and R2 is sufficient to bias the cathode positive with respect to ground. The output of cathode follower V1 is taken from the cathode through C2, which is a large value capacitor, and applied to an input gain potentiometer R3. Capacitor C3 is a conventional filter capacitor used to bypass the negative supply. Vertical gain control R3 controls the amplitude of the input signal to the two-stage, high-gain compensated video amplifier consisting of V2 and V3. Both high- and low-frequency compensation are employed in each stage. The cathode of V2 is bypassed by a small capacitor, which makes it degenerative for low frequencies, thus reducing the response and flattening out the low-frequency response. Low-pass R-C falters R5, C5, and R6, C6 offer a high impedance to the low frequencies and a shunt path to the high frequencies in the plate circuits of the amplifier. Thus the effective load impedance at low frequencies is increased, which compensates for the normal drop off, and extends the low frequency response. The high-frequency response is increased by peaking coils L1 and L2, which compensate for the shunting effect of tube and wiring capacitance, providing a reactance which increases with frequency. To help improve the high-frequency response, plate load resistors R4 and R7 are made low in value to reduce the shunting effect of stray capacitance. To improve the low-frequency response, the time constants of R-C coupling networks C7, R8 and C8, R12 are long. Amplifier V3 is fixed-biased by connecting the cathode to the junction of R1O and R11, which are connected as a voltage divider in series between the plate supply and ground. Cathode resistor R11 is also unbypassed so that the circuit is completely degenerative for high and low frequencies, further improving the over-all frequency response. The use of a fixed cathode bias sets the operating point of V3 and helps stabilize the stage. The output of V3 is fed to cathode follower output stage V4, which is biased positive with respect to ground by plate current flow, even though the cathode is returned to the minus supply. Variable potentiometer R13 serves as an output and positioning control for the following paraphase amplifier.

Failure Analysis.

Beam-Positioning Circuits. Usually, a control circuit failure is indicated by loss of a specific control function, and can be quickly verified by a resistance or voltage check. It must be understood that all controls affect the electron beam in some manner, and that the controls are interacting. For example, increasing the intensity of the beam will also thicken the beam and require a readjustment of the focus control for the thinnest line at that intensity. Likewise, a change in accelerating anode potential will cause a change in spot diameter and the maximum intensity available. Where high humidity and excessive moisture prevail, control failures from insulation breakdown are usually more prevalent because of the high potential involved, which causes a short circuit to ground.

Power Supply Circuits. Because of the high negative potential used for operation of the CRT electron gun, the synchroscope power supply is particularly susceptible to flash over, particularly in damp humid locations. A voltage check is usually sufficient to reveal the location of the trouble.

Horizontal (Sweep) Channel. A failure in the horizontal channel can be due to a failure of any of the individual circuits comprising the channel as well as two circuits within the vertical channel. If the input impedance selector and the coupling amplifier, the two circuits within the vertical channel, are the cause of the sweep faihrre; the vertical deflection will also be defective as well as the sweep. If this is the case, voltage and waveform checks, made by a voltmeter and an oscilloscope will reveal the location of the faulty component within the two circuits. If, however, there is no trouble with the vertical deflection and faulty sweep exists, the trouble exists within the three horizontal channel circuits. Beginning with the sweep amplifier, the inputs should be checked with a voltmeter and an oscilloscope. If the proper input exists the trouble is within this circuit. If an improper input exists check the input of the start-stop sweep generator with an oscilloscope. If the input is proper the trouble must exist in the start-stop sweep generator. Voltage and waveform checks with a voltmeter and an oscilloscope will reveal the location of the faulty component. If the input to this circuit is proper, check the input to the sync (pulse) amplifier. If the coupling amplifier is working properly and the sync selector switch is functioning properly, the trouble should be within the sync (pulse) amplifier. Voltage and waveform checks with a voltmeter and oscilloscope will reveal the faulty component.

Vertical Channel. A failure in the vertical channel is characterized by improper amplitude of the presentation of the pulse on the synchroscope screen. There are six circuits which could result in the vertical charnel failure. Two of these, the input impedance selector, and the coupling amplifier, produce sweep failure. The trouble shooting of these circuits has already been mentioned. The other four circuits of the vertical channel, the push-pull paraphase amplifier, the vertical amplifier, the signal attenuator, and the delay network, affect only the vertical display of the scope. If the failure exists in the delay network, the vertieal deflection will not occur at the proper time interval with respect to the sweep. If this effect is apparent on the display, check the delay network with an oscilloscope to determine where the improper waveforms or voltages exist. If the failure exists in the push-pull paraphase amplifier the vertical position of the display on the CRT screen is improper. If this is apparent on the display check the voltages and waveforms of the push-pull paraphase amplifier with an oscilloscope to determine where the faulty component is located. If these circuits of the vertical channel have been checked and found to be operating properly, and trouble still exists in the vertical display, the troubIe must exist in the signaI attenuator or the vertical amplifier. To determine where the trouble exists check the appropriate voltages and waveforms with an oscilloscope.

CRT DISPLAY CIRCUITS

~~How~~ Show All Scans

The CRT display supplies a visual indication of any signals which are applied to the CRT. One of the most important uses to which cathode-ray-tube displays and their associated circuitry are applied is the location of objects or targets in space. This is the prime purpose of radar. Generally speaking, there are two types of radar systems; the pulsed radar system, and the continuous wave radar system. Since continuous wave radar systems are very rarely used, the discussion in this section is limited to displays associated with pulsed radar systems.

The display units used in pulsed radar are either deflection modulated or intensity modulated. These terms describe the method by which the echo signal

affects the trace on CRT. In deflection modulated displays, the input signal, after being detected and amplified, is applied to the deflection system of the CRT, and shows up as a pulse or pip on a circular or single horizontal sweep line. Typical radar displays of this type are the A-scope and the J-scope. In intensity-modulated systems, the echo is fed to an intensifying circuit, which changes the bias on the control grid of the CRT. The control grid is normally biased at cut-off. When the signal is received, it causes the bias on the control grid of the CRT to become less negative, thereby increasing the density of the electron beam and the intensity of the trace. Typical radar displays of this type are the B-scope and the C-scope.

Application.

The A, B, C, and J-scope type CRT presentations are relatively simple radar displays used for the purpose of locating the position (range and bearing) of a target with respect to the position of the radar.

Characteristics.

A-Scope and J-Scope presentations use deflection modulated displays.

A-Scope and J-Scope presentations use single line displays.

A-Scope and J-Scope presentations show only one component of location (usually direction).

B-Scope and C-Scope presentations use intensity modulated displays.

B-Scope and C-Scope presentations form rectangular field displays.

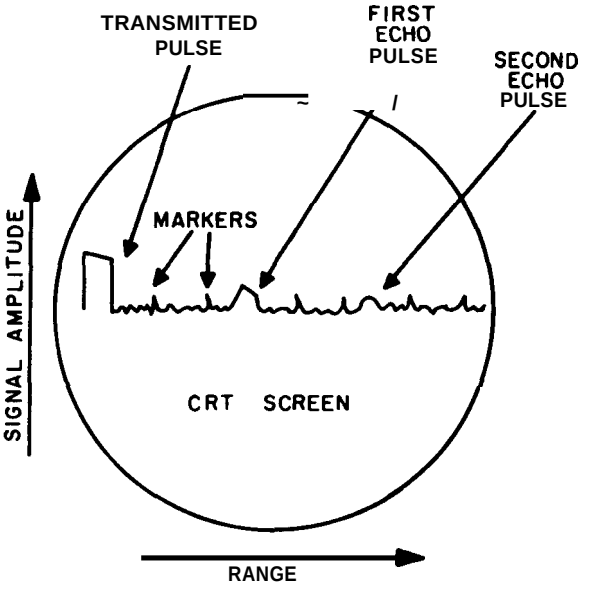
B-Scope and C-Scope displays show two components of location (usually direction and range)

A-scope, J-scope, C-scope and D-scope displays are usually designed to use electrostatic deflection systems.

Circuit Analysis.

Generel. The A-, B-, C-, and J-Scope displays constitute the most commonly encountered types of radar displays employing electrostatic type cathode ray tubes. They respond to the reception of echoes of signal pulses striking specific targets, and present these echoes as pips or illuminated targets on the trace of the display, indicating location of targets through the time relationship of the echo signals compared with the sweep signals.

The typical A-scan is shown in the following illustration. It consists of a single horizontal line with a transmitted pulse identication, representing the beginning of the sweep, and echo pulse indications, representing targets. The transmitted pulse indication has an amplitude greater than any of the other echo pulse indications.



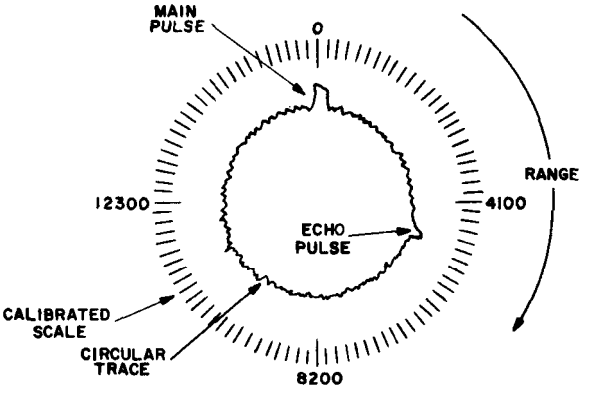
A-Scope Display

The A-Scope is primarily used in conjunction with other radar indicators, since the A-Scope can only locate the range of a target. The A-Scope is particularly used in artillery fue control because of the accuracy of its range determination. The A-Scope is also used as a test instrument to observe video input signals during the testing and alinement of radar receivers.

A typical J-Scan is shown in the following illustration. It consists of a single circular trace line, which remains at a relatively constant distance from the center of the CRT face. A main pulse indication on the circular trace indicates the beginning of the sweep, and the echo pulses are located somewhere along the circumference of this circle. The distance between the echo pulse and the main-pulse along the circumference of the circle, indicates the range of the

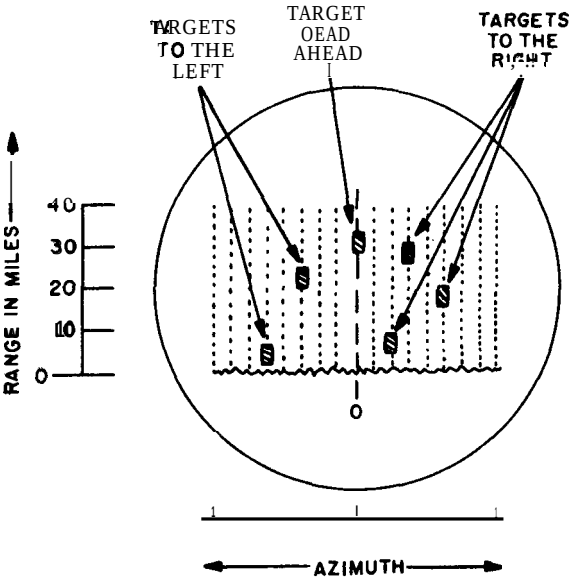
target. A calibrated range ring is used to measure the distance along the circular trace.

The J-Scope is used in radar for extremely accurate range determination of a particular target. In the laboratory, the J-Scope is applied to the measurement of very short time intervals.



J-Scope Display

A typical B-Scan is shown in the following illustration. It consists of a rectangularly scanned field made up of parallel vertical trace lines, with the center line of the field representing zero azimuth (dead ahead) position. The radar location is at zero azimuth position on the horizontal base line. Any targets which appear to the right or left of this center line are actually located to the right or left of the ship or radar center line, at the vertical distance shown.

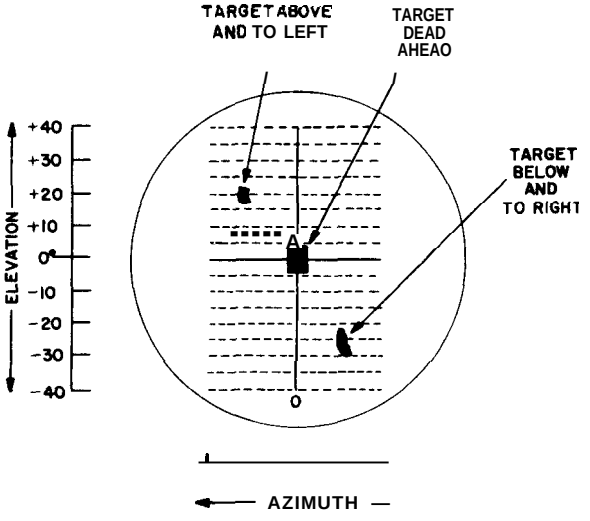


B-Scope Display

The B-Scope is used in radar systems for continuous scan of an assigned area, chiefly for ground (or sea) targets in a limited sector.

A typical C-Scan is shown in the following illustration. It consists of a rectangularly scanned field made up of a number of parallel horizontal lines; the center vertical line which bisects the horizontal length of the field represents zero azimuth position, while the center horizontal line which bisects the

vertical length of the field represents zero elevation position. All vertical positions above the zero elevation position represent a positive elevation, and all vertical positions below the zero elevation represent a negative elevation.

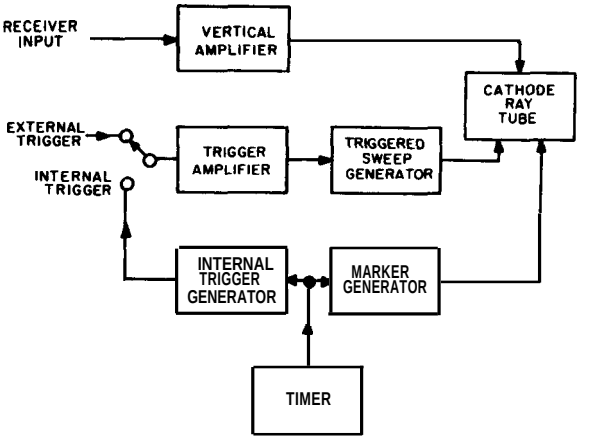


C-Scopa Display

The C-Scope is used in radar systems for continuous scan of an assigned area, chiefly for aircraft interception and beam landing.

Circuit Oparation. The A-and J-Scopes are similar in that the signal is obtained from the radar receiver and applied through vertical amplifiers to the vertical deflection elements of the CRT. The manner in which each type of scan accomplishes the sweep, however, is different.

A typical A-Scope arrangement is shown in the following block diagram.

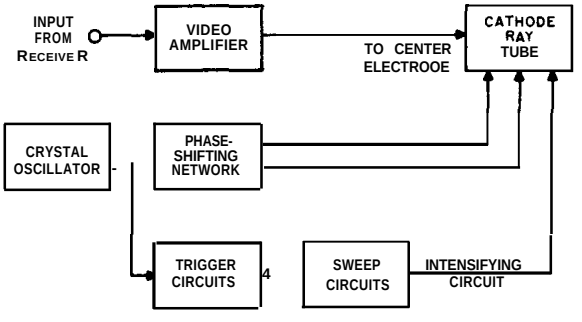


A-Scopa Circuit

In the A-Scope arrangement a trigger signal is fed to the trigger amplifier stage, simultaneously, the received echo signal is applied from the radar receiver through the vertical (video) amplifier to the CRT. The trigger for starting the sweep may come from either the timer within the indicator or from the transmitter. The trigger amplifier both amplifies and sharpens the trigger pulse, which is then applied to the triggered sweep generator where a sawtooth voltage is produced and applied to the horizontal deflection plates. The resultant sweep produces a straight horizontal trace line on the CRT. With the application of the received echo signal, a vertical deflection in the form of a pip appears located somewhere along the horizontal trace. The distance between the radar antenna and the target is indicated by the linear position of the pip on the trace. Some of the pulse voltage of the transmitter is impressed directly upon the

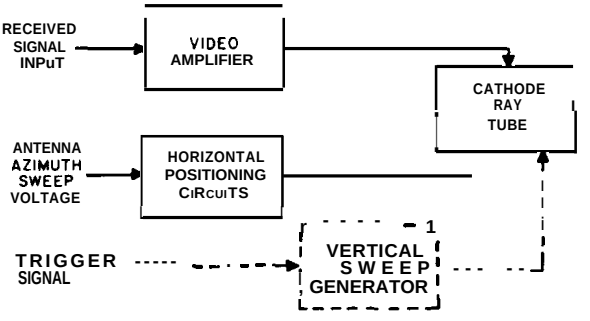
receiver, and produces a large pulse on the extreme left of the CRT trace. All distances are measured relative to this pulse. To facilitate the measurement of the distance of the echo pip from the zero reference point (transmitter pulse), calibrated markers generated by the marker generator stage are also applied to the CRT. Thus by counting the number of markers between the transmitted signal and the received echo, target distance is quickly determined.

A typical J-Scope is shown in the following block diagram. A crystal oscillator and a phase-shifting network furnishes two sine-wave voltages, 90° out of phase, to both sets of CRT deflection plates to produce a circular trace. The trigger and sweep circuits blank out the tube, intensifying the electron beam only during the active sweep time. The J-Scope display is the same as the A-Scope display, except that the J-Scope uses a circular sweep rather than a linear sweep. Time and range measurements on the J-Scope are more accurate than those of the A-Scope since the J-Scope scan is longer. The target echoes are indicated as radial pips or pulses pointing away from the center of the CRT. To produce these pips another CRT electrode is introduced. This electrode is a thin metallic rod inserted through the face of the tube, almost reaching the deflection plates. The echo signals then are applied to this center electrode from the vertical amplifier.



J-Scopa Circuit

The B-Scope and the C-Scope, like the A- and J-Scopes are mostly similar in their mode of operation. The B-Scope and the C-Scope both use intensity modulated displays, that is the echo signals appear as bright patches against a dark background. Intensity modulation is produced by applying the amplified echo signals to either the control grid or the cathode of the CRT. In both the B-Scope and the C-Scope, the sweep scans a rectangular area on the screen of the CRT. Also, in both the B-Scope and C-Scope, the horizontal axis always represents azimuth. On the other hand, the vertical axis on the B-Scope represents range while the vertical axis on the C-Scope represents elevation. The block diagram of a typical B-Scope and a typical C-Scope arrangement is shown in the following block diagram. The only difference in the circuitry between them is the omission of the vertical sweep generator in the C-Scope. The vertical deflection circuits of the B-Scope are driven by a linear timebase signal from a sweep generator. This sweep is initiated by a sync signal from the central timing circuits of the radar. The vertical deflection circuits of the C-Scope are driven by a sweep voltage from a variable potentiometer connected the radar antenna.



B-Scope and C-Scope Circuits

The horizontal-deflection circuits of the B-Scope and C-Scope are the same type of circuits as those used for the vertical-deflection system of the C-Scope. The horizontal motion of the antenm is translated into a regularly varying (sweep) voltage which produces the horizontal sweep for the cathode-ray tubes.

The electrostatically deflected CRT common to the A-, B-, C-, and J-Scopes is shown in the following illustration with its accompanying control circuitry. The rod shaped dotted lines, extending from the face of CRT almost to the deflection plates represents the

electrode used only in the J-Scope to which negative video (echo) signals are coupled. This electrode causes the electron beam to be deflected radially outward in accordance with the incoming signals.

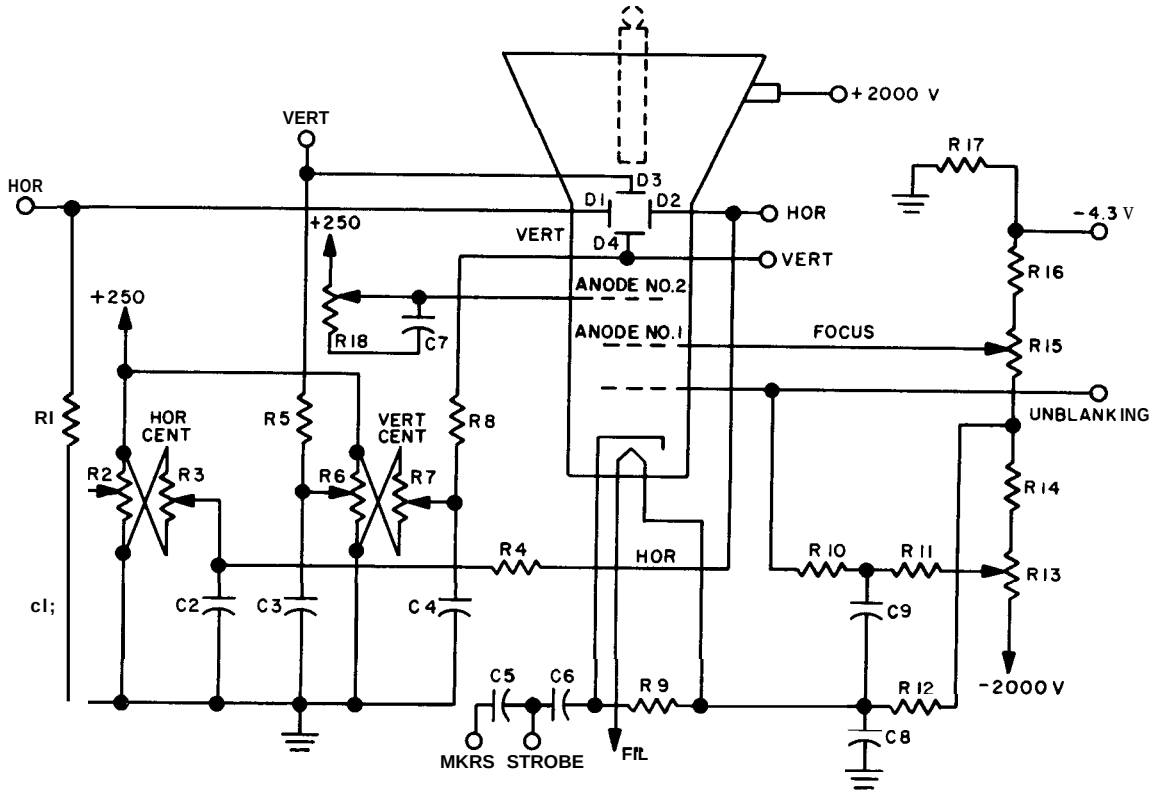


Figure A-675
Electrostatic CRT Used in A-, B-, C-, and J-Scopes

It is evident from the schematic that resistors R9, R1O, RI 1, R12, R13, R14, R15, R16, R17 form a voltage divider network. The cathode of the CRT is connected at a less negative point on the divider than the grid, the grid is negative with respect to the cathode, and is adjustable by means of potentiometer R13. R13 then, as in conventional circuits, permits the tube to conduct more or less heavily. This is the intensity control. Anode no. 1 is connected to a much lower point on the divider through potentiometer R15; thus it is effectively less negative than the cathode and grid, and attracts electrons from the cathode. This is the focus control. By varying the d-c potential on this control, the electron beam from the cathode is directed so that it converges at a point on the face of the CRT. Anode no. 2 is at a positive potential and as anode no. 1 attracts electrons from the cathode. It provides the function of acting as an auxiliary focus control and an accelerating anode. As the beam passes from the accelerating anode to the face of the tube, it passes between two sets of deflecting plates. The horizontally positioned plates deflect the beam vertically and the vertically positioned plates deflect the beam horizontally.

A balanced deflection system is used for this cathode-ray tube. Each deflecting plate (Dl, D2, D3, and D4) is controlled by separate dual potentiometers (R2, R3, R6 and R7, respectively), and the plates are isolated and balanced equally by being connected to the positioning controls through equal resistors Rl, R4, R5, and R8. A-C balance is provided by capacitors Cl, C2, C3, and C4. Since the isolating resistors

Rl, R4, R5 and R8 are always a very large value, the deflecting plates may be connected into any circuit without danger to the operator.

Failure Analysis.

Cathode-Ray Tube. Usually, a control circuit failure in the CRT is indicated by loss of a specific control function, and can be quickly verified by a resistance or voltage check. It must be understood that all controls affect the electron beam in the same manner, and that the controls are interacting. For example, increasing the intensity of the beam will also thicken the beam, and require readjustment of the focus control for the thimest line at that intensity. Likewise, a change in the accelerating anode potential will cause a change in spot diameter and the maximum intensity available. Where high humidity and excess moisture prevail, control failures from insulation breakdown are usually more prevelent because of the high potential involved, which causes a short circuit to ground.

If it is found that all of the voltages on the CRT electrodes are proper the CRT must be the defective component. If, however, the voltages on the CRT electrodes are not proper, and the associated control circuitry is checked and found to be proper and the power supply is functioning properly, the fault must exist in some stage preceding the electrode with the improper voltage on it. It is also possible to determine the area of the fault by the CRT indications.

In the A-Scope, if the improper voltage or waveform exists on the horizontal deflection plates and the CRT indication shows that there is an improper or no horizontal sweep, check the input of the triggered sweep generator with an oscilloscope. If it is correct the fault lies in this circuit. If the voltage is incorrect, check the input of the trigger amplifier with an oscilloscope. If the trigger amplifier input is correct the faulty component is in this stage. If the input is incorrect and an external trigger is used the fault is in this external source. If, however, the input of the trigger amplifier is incorrect and the trigger is obtained from the internal trigger generator, check the input to the internal trigger generator with an oscilloscope. If the voltage or waveform applied to the internal trigger generator is improper the fault should be in the timer. If the CRT display indicates that only the range markers are missing the trouble must be in the marker generator.

If the improper voltage or waveform is present on the vertical deflection plates the trouble must be in the vertical amplifier or circuitry prior to the A-Scope indicator. Check the input of the vertical amplifier with an oscilloscope. If it is correct the fault is within this circuit.

In the J-Scope, if circular trace is improper and improper voltages or waveforms exist on the vertical and horizontal deflection plates, check the input of the phase shifting network with an oscilloscope. If the input is proper the fault is in this circuit. If, however, the input is improper the fault is the crystal oscillator. If the intensity of the display is improper and the voltage existing on the control grid is improper, check the input of the sweep circuits. If the input is proper the fault is in these circuits. If the input is improper the fault must be in the trigger circuits. If the improper signal exists on the center electrode of the CRT and if the video signal on the display is incorrect, check the input of the video amplifier with an oscilloscope. If the input is proper the fault is within the video amplifier. If the input is improper the fault must be in the radar receiver.

In the B- or C-Scope, if the voltages or waveforms on the horizontal plates are improper, or if the horizontal trace is improper check the input to the horizontal positioning circuits with an oscilloscope. If the input is correct the failure is in the horizontal positioning circuits. If the input is improper, the failure is in the antenna azimuth sweep voltage. If the voltages or waveforms on the vertical plates of the B-Scope are improper, or if the vertical trace is improper check the input of the vertical sweep generator with an oscilloscope. If the input is proper the failure is in the vertical sweep generator. If the input is incorrect the failure is in the trigger source. If the voltages or waveforms on the vertical plates of the C-Scope are improper, or if the vertical trace is improper, the antenna voltage must be incorrect. If the target echo signals are not present on the control grid of the CRT, check the input to the video amplifier stage or stages with an oscilloscope. If the input is proper the fault is within these stages. If the input is improper the failure is in the radar receiver.

PART 9-2. ELECTROMAGNETIC

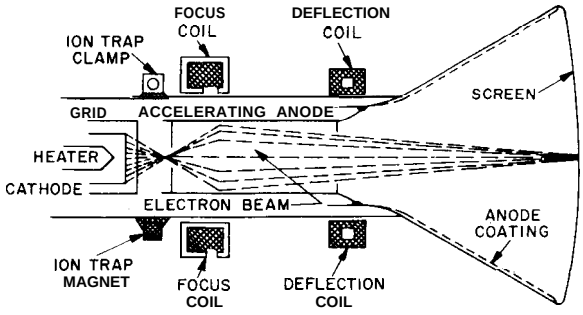
ELECTROMAGNETIC CATHODE-RAY TUBE CIRCUITS

General.

A cathode-ray tube is an electron tube in which the electrons trajecting from the cathode toward an anode are focused into a concentrated beam which eventually strikes the luminescent screen. This beam is varied in position and intensity which produces a visible pattern on the screen. An electromagnetic cathode ray tube utilizes magnetic fields to provide a means of focusing and deflecting the electron beam.

Electromagnetic cathode-ray tube circuits are preferred where the cathode ray tube (commonly) referred to as CRT) is to have a large screen diameter. The electromagnetic CRT has several advantages over the electrostatic tube. Some of these advantages are that: a well focused electron beam of higher current density can be produced; greater accelerating voltages can be used to obtain brighter screen patterns without as great a reduction in the deflection sensitivity of the tube; the structure of the electron gun is simpler and more rugged; and the over-all length of the envelope is shorter.

A pictorial representation of the electromagnetic CRT is shown in the accompanying illustration.



Electromagnetic Cathode Ray Tube

The electromagnetic CRT uses a triode type gun. It consists of an indirectly heated cylindrical cathode closed off at one end by a small plate, which is coated with barium and strontium oxides. The oxides emit a large number of electrons. A twisted heater element is contained within the cylindrical cathode to bring the cathode to the operating temperature. The control grid is also a cylinder, which surrounds the cathode cylinder. It contains a baffle with a tiny aperature of smaller diameter than the emitting surface of the cathode, which is located very close to the aperature. Beyond the control grid is a hollow cylinder which contains several baffles and which has its circumference around the same axis as the control grid. This cylinder is the accelerating anode which is connected to a conductive coating within the tube. This coating acts as an extension of the accelerating anode and as an electrostatic shield. There is no second anode for focusing as there is in the electrostatic CRT. Instead, an external focusing coil encircles the neck of the tube and magnetically focuses the electron beam. The complete focusing system is composed of two lenses, one is produced by the electrostatic field between the control grid and the following electrode. This electrostatic field causes the electron beam to converge at a point some distance before the magnetic field of the focusing coil which acts as the second lens. After the electrons travel beyond the convergent point they again begin spreading until they enter the magnetic field of the focusing coil, where the reaction causes the electrons to later converge at the phosphorescent screen, if the position of and the current through the coil are correct. The position of this external focusing coil is not only capable of being varied along the neck of the tube, but the physical construction of the coil also permits one side of it to come in closer proximity to the tube than the other. This characteristic of the focusing coil provides a means of centering the electron beam as well as focusing it.

The method of accomplishing horizontal and vertical deflection also relies on an external electromagnetic force. This electromagnetic force is provided by a set of coils, which encircles the neck of the CRT and is located after the focus coil. Usually four deflection coils are used. Two of these are wired in series and are mounted in such a way as to produce a magnetic field whose lines of force run vertically through the neck of the tube. This vertical magnetic field causes horizontal deflection of the electron stream. The other pair of coils is wired in series and mounted in such a way as to produce a magnetic field whose lines of force run horizontally through the neck of the tube. This horizontal magnetic field causes a vertical deflection of the electron stream. A current is used to activate the coils and produce the

magnetic fields at right angles to the electron movement. The amount of deflection that may be obtained is dependant upon: accelerating anode voltage, distance between the screen and the deflection coils, length of the magnetic field, and the strength of the magnetic field. These deflection coils are contained in a mounting and called the deflection yoke. The position of the deflection yoke, hke the position of the focus coil, can be shifted along the neck of the tube to vary the amount of deflection. The deflection yoke can also be rotated about the neck of the tube. This property permits the visual pattern or raster to be centered squarely on the screen.

Another element used on an electromagnetic CRT is called the ion trap. It removes a problem that is specifically peculiar to the electromagnetic CRT. Negative ions exist in the CRT as a result of the bombardment of the residual gas or tube electrodes by the emitted electrons. This condition is of no consequence in an electrostatic CRT since electrostatic focusing networks can focus the ions along with the electrons. In the electromagnetic CRT, however, the greater mass of the ion prevents proper focusing and deflection of these ions. The result is a constant bombardment of the screen at one particular spot, causing the gradual deterioration of the phosphorescent material at this point and a dark spot on the screen. There are several types of ion traps that may be used. One type consists of a modified electron gun arrangement and a permanent bar magnetic unit which is slipped around the neck of the tube close to the electron gun. Although it is not shown in the illustration, the gun is made to produce a bent electrostatic field that carries both ions and electrons toward the accelerating anode. The ion-trap magnet affects only the electrons in this combined beam in such a way that they change their direction of motion and return toward the main axis of the tube. In this reamer only the electrons strike the screen, while the ions strike the anode and are removed.

The types of scan and circuits used with the electromagnetic CRT are described in following paragraphs in this section.

PLAN POSITION INDICATOR (PPI)

Application.

The plan position indicator (or PPI) type of radar display is used when it is desired to track objects on a 360° polar map giving range and azimuth. This map can easily be correlated with standard maps, since, not only the target but also physical features of the area are made apparent.

Characteristics.

Uses electromagnetic CRT.

May use rotating or stationary deflection yoke.

PPI CRT uses high persistence phosphor.

PPI utilizes intensity modulation.

Antenna and sweep trace are synchronized.

Center of sweep represents radar location.

Sweep starts at the center and moves radially outward.

Angle of target from heading represents bearing of target.

Distance of target from center of sweep represents range of target.

Circuit Analysis.

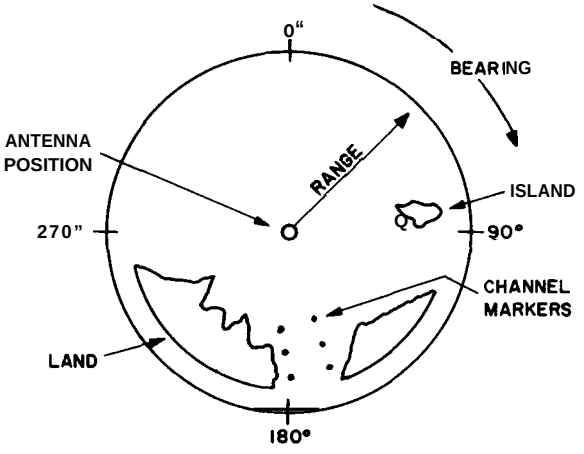
General. The plan position indicator is a type of radar display which utilizes an electromagnetic CRT. A high persistence phosphorescent material is used on the face of the CRT, which permits the glow produced by the electron bombardment to remain for a relatively long period of time. Signals reflected from targets are taken from the radar receiver and applied to the control grid of the CRT, via limiting and amplifying circuits, during the sweep time of the beam. Intensity modulation of the electron beam occurs in accordance with the amplitude of the received echoes, which produce corresponding bright portions on the screen.

The distance that the brightened portion of the trace is from the origin of the sweep, is the range of the target. The angle that is made by the brightened portion of the trace with respect to the zero degree radius of the sweep constitutes the bearing (or azimuth) of the target. This type of display also

permits an operator to locate a target with respect to the position of physical features of an area, which are shown on the display in the form of a polar map.

The rotating sweep which characterizes the polar map display is produced by a magnetic deflection field rotating in synchronization with the radar antenna. This may be accomplished by a mechanical azimuth sweep (rotating deflection yoke) or electrical azimuth sweep (stationary deflection yoke).

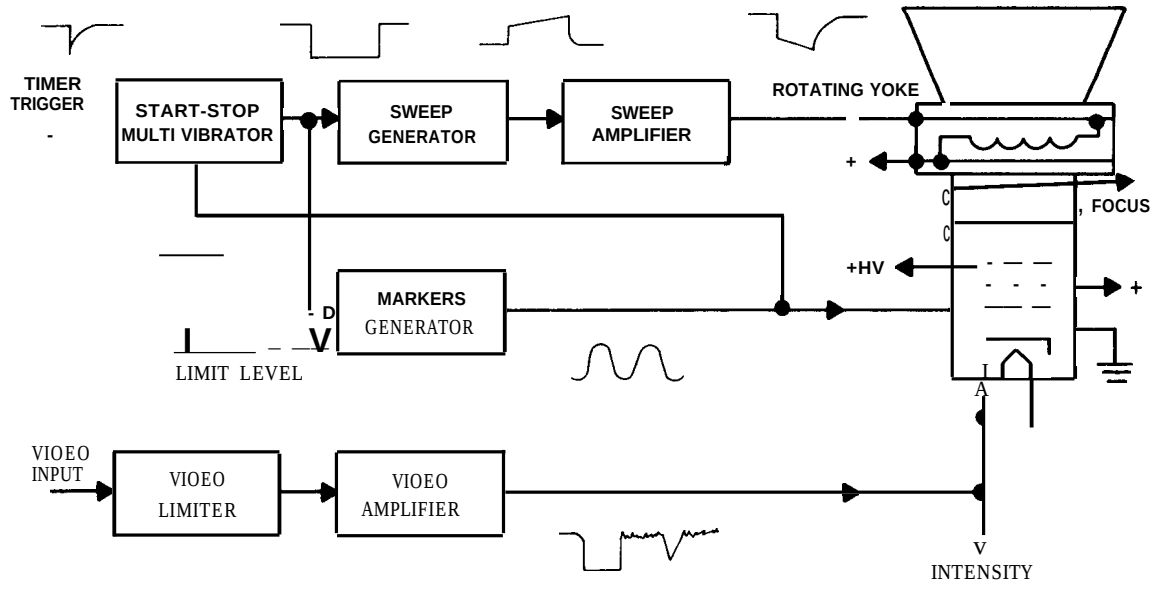
A pictorial representation of a typical PPI display is shown in the following illustration.



Typical PPI Display

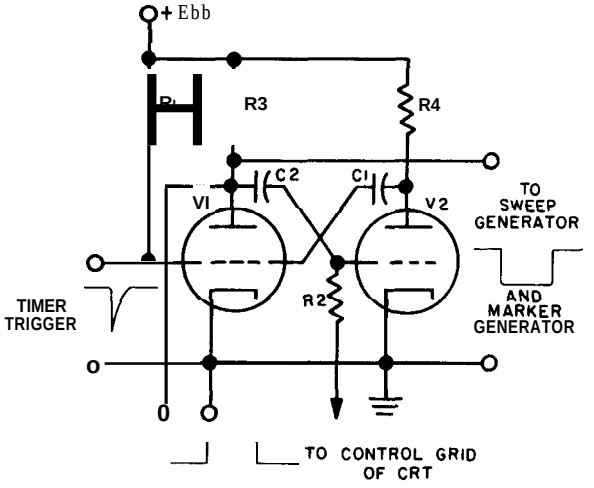
Circuit Oparation. The circuits used in the discussion of circuit operation are typical circuits used, in PPI displays, but do not represent every circuit that could be used in PPI displays. A block diagram of a simple PPI display is shown in the following illustration with corresponding waveforms. An analysis will be made of the operation of each representative circuit corresponding to the block diagram.

491-044 0-73- 55



Simple PP1-Scan Block Diagram

The timer trigger is a negative pulse obtained from the timing circuits, and used to acutate the start-stop multivibrator. The multivibrator produces negative gate signals which are applied to the sweep generator and the marker generator, and a positive gate signal which is applied as an unblinking gate to the control grid of the CRT. A typical start-stop multivibrator is shown in the following illustration. Resistors R1 and R2 are grid bias resistors for triodes VI and V2, respectively. Resistors R3 and R4 are the plate resistors for V1 and V2, respectively. Capacitor Cl couples the grid of VI to the plate of V2. Capacitor C2 couples the grid of V2 to the plate of VI.

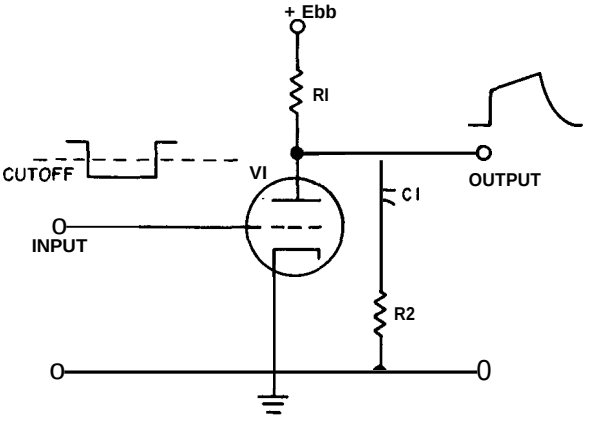


Start-Stop Multivibrator

Normally, triode V1 is conducting due to the positive bias applied on the grid of VI. At the same time, triode V2 is normally cut off due to the fixed negative bias applied to the grid of V2. A negative pulse applied to the grid of VI reduces the conduction of Vl, causing the plate voltage to increase. The positive plate voltage swing of V1 drives the grid of V2 into conduction, thereby decreasing the plate voltage of V2. This decrease (Negative swing) in the plate voltage of V2 is fed back to the grid of V1 and drives V1 into cutoff. The circuit now rests in the opposite condition with V2 conducting heavily and VI cut off. During this period the flat portion of the output pulse is generated. Since capacitor C 1 is connected to the positive supply through R1, it eventurdly develops a positive charge which is sufficient to bring the grid of V1 above cutoff. Once again VI conducts and the negative plate swing is coupled to the grid of V2 through C2, driving V2 towards cutoff and producing the trailing edge of the square wave as its plate voltage rises. Eventually, V1 is brought to the state of maximum conduction and V2 is brought to cutoff, where the circuit stabilizes due to the positive biasing voltage on the grid of V1 and the high negative bias voltage on the grid of V2. Another negative pulse must be applied to the grid of VI in order to change the conduction states of V2 and V2.

From the description of the circuit operation of the start-stop multivibrator it can be seen that with the application of one negative timer pulse to the input, one negative rectangular pulse is obtained at the plate of V2. This negative rectangular puke is used to operate the sweep generator and a marker generator. At the same time, a positive rectangular pulse is taken from the plate of V1 and is applied to the control grid of the cathode ray tube for unblinking use.

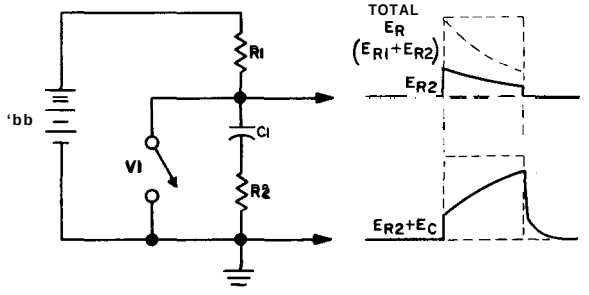
The typical sweep generator, which receives the negative rectangular pulse from the start-stop multivibrator, produces a trapezoidal sweep. The following schematic is that of a typical sweep generator circuit. The negative rectangular pulse is applied to the grid of triode VI, which acts as a high speed switch. Resistor RI is the plate resistor of V1. R1 is also part of an r-c network, which determines the amplitude of the leading edge and the slope of the trapezoidal waveform, when V1 is cutoff. Resistor R2 is also part of the r-c network when V1 is cutoff. Its vrdue also affects the amplitude of the leading edge of the trapezoidrd waveform. Capacitor Cl is the capacitive part of the r-c network. Its value affects the slope of the trapezoidrd waveform.



Sweep Generator

When no rectangular pulse is applied to the input, triode VI is conducting and effectively shunting R2 and Cl. As the negative rectangular input pulse is applied to the grid of V1, conduction of V1 ceases

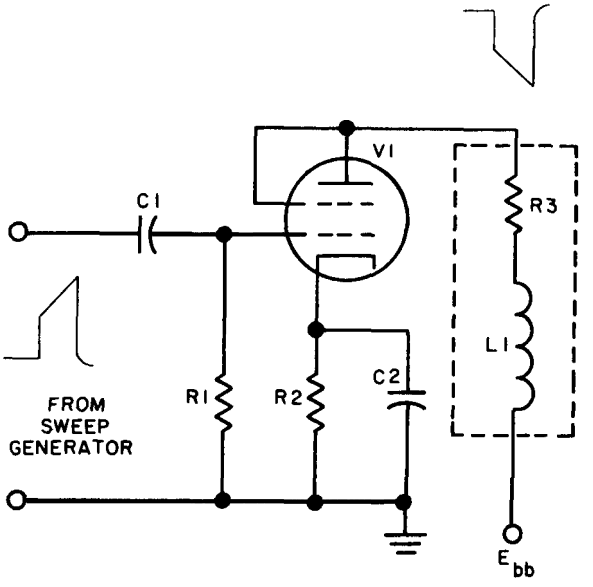
and the plate voltage rises towards the supply value generating the leading edge of the trapezoidal sweep waveform. The cutting off of V1 acts like opening a switch, and causes capacitor Cl and resistor R2 to be brought into circuit action. An equivalent circuit with corresponding waveforms is shown in the following illustration for ease of understanding.



Equivalent Trapezoidal Sweep Generator Circuit

Capacitor Cl charges up to towards the value of the plate supply voltage through resistors RI and R2 at a rate dependent on the product of Cl times the sum of RI and R2. The output is taken across capacitor Cl and resistor R2. Thus, as capacitor Cl charges, the voltage drop across R1 appears at the output. The output voltage increases toward the plate voltage supply at the charging rate of capacitor Cl until the end of the negative rectangular input pulse occurs. At this time, the positive trailing edge drives V1 into conduction, removing capacitor Cl and resistor R2 from the circuit action by effectively closing the triode switch shown in the illustration of the equivalent circuit of the sweep generator. The circuit remains in this state until the next negative rectangular pulse is applied to the input. The resultant output waveform is a trapezoidal pulse for every negative rectangular pulse applied to the input.

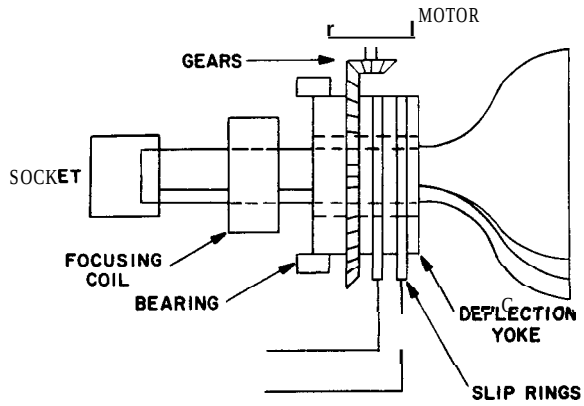
The trapezoidal pulse is applied to a sweep amplifier where it is amplified before being applied to the sweep coil circuit. A typical sweep amplifier is shown in the following illustration. Capacitor Cl is a coupling capacitor and the grid of V1 is returned to ground through grid resistor RI. Cathode bias is provided by resistor R2 and R2 is bypassed by capacitor C2 to prevent any degenerative effect. Vacuum tube V1 is a beam power tube, used because of its high power sensitivity. Power amplification is required to provide sufficient current to the deflection coils. The coils may require from 50 to 100 milliamperes of current for maximum deflection. Inductance L1 and resistance R3 comprise the deflection coil and act as the plate load for the sweep amplifier. The output waveform, at the plate of V], is trapezoidal. As this waveform is applied to the deflection coil, it becomes resolved to a sawtooth waveform across the resistance of the coil, and a square waveform across the inductance. The square wave across the inductance produces a sawtooth sweep current due to current lagging voltage in an inductance. (For detailed information on amplifier circuits refer to the Amplifier Section of this Handbook.)



Sweep Amplifier

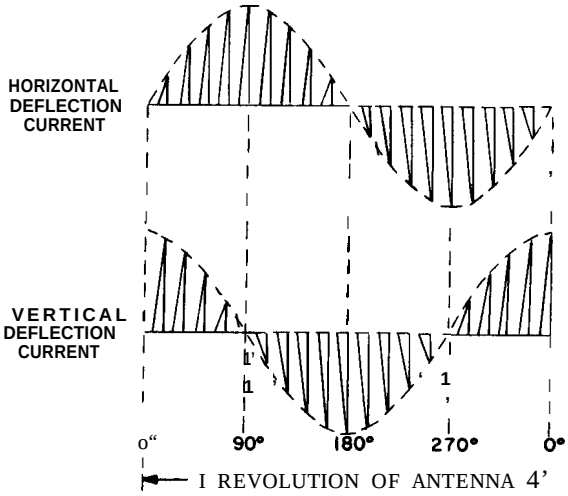
The PPI sweep starts at the center of the CRT, and moves radially outward to the periphery of the CRT. The sweep trace position is made to indicate target bearing (or azimuth) by rotating it in synchronization with antenna rotation. This can be accomplished by any of several methods in two general categories. The first category uses a mechanical azimuth sweep, which provides a means of physically rotating the deflection yoke in synchronization with the antenna. This may be accomplished by using synchronous

motors connected to the same power supply which drives the antenna and the deflection yoke; or it may be accomplished by using electromechanical repeaters to provide proper synchronization. The following figure illustrates how deflection is produced at the cathode ray tube.



Mechanical Azimuth Sweep

The second method is to use an electrical azimuth sweep which uses a stationary deflection yoke. The amplitudes of the sawtooth sweep currents are varied sinusoidally, from zero to maximum, corresponding to the rotation of the antenna. Furthermore, there is a 90° phase difference between the amplitude variations of the horizontal end vertical sawtooth waveforms. The sinusoidal variation is such that at maximum amplitude of the vertical sawtooth signal, the sweep will extend from the center of the CRT to the top of the CRT, or the maximum vertical position, which usually represents north. The amplitude of the horizontal deflection sawtooth waveform is zero, at this time. Thus, the sweep does not extend in the horizontal direction at all. If the sweep were to represent East, or 90° east of the direction of travel, the horizontal deflection sawtooth amplitude would be maximum and the vertical deflection sawtooth amplitude would be minimum, or zero. Once the sweep travels beyond East, or 90° east of the direction of travel, the amplitude of the vertical sawtooth becomes negative; and, once the sweep travels beyond South, or 180° from the direction of travel, the horizontal sawtooth amplitude becomes negative also. The accompanying figure shows the deflection coil currents for electrical azimuth sweep.



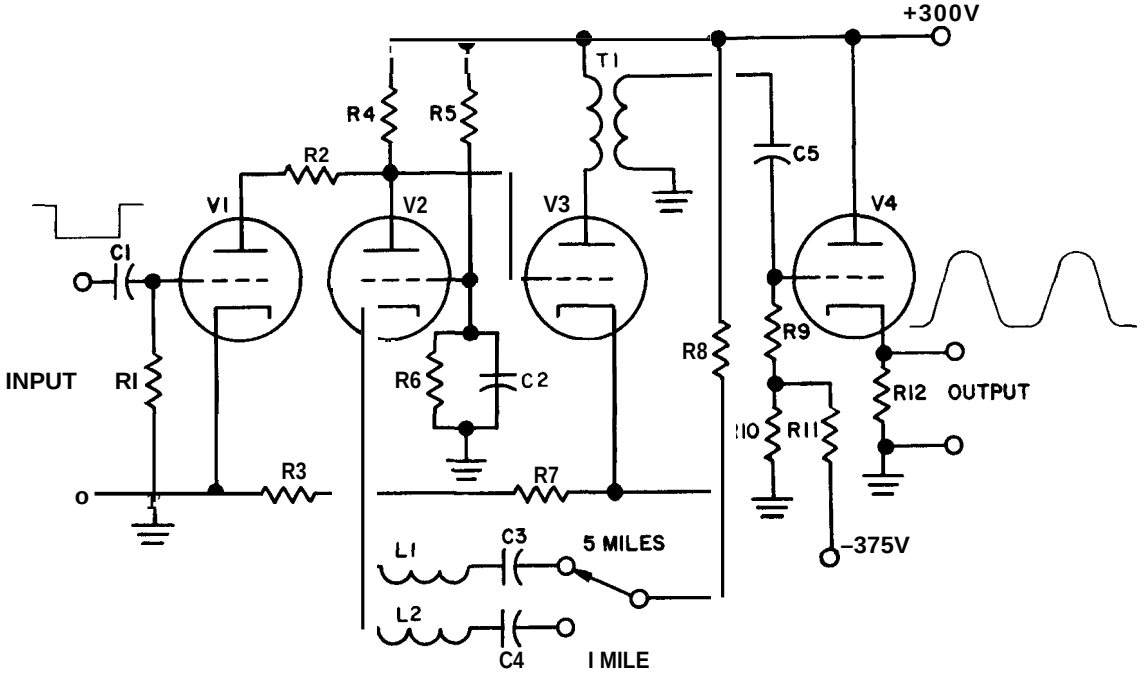
Deflection Coil Currents for Electrical Azimuth Sweep

In order to obtain two sinusoidally varying sawtooth waveforms, having a 90° phase difference, a rotary transformer is used. This transformer resembles a small electric motor and has two secondary windings, which are mounted at right angles to each other in the stator housing. The primary is mounted on the rotor, which is driven by the rotating antenna. A trapezoidal-wave generator is connected to the primary winding by means of slip rings. As the rotor is turned, the voltage obtained from either secondary varies. Maximum voltage is obtained from one secondary when zero voltage is obtained from the other. The transformer is so constructed that the amplitude of the output voltage varies sinusoidally with the rotor angle. The amplitudes of the trapezoidal output voltages, then, vary sinusoidally, and are 90° apart in phase. The trapezoidal output voltages are applied to separate power amplifiers. The required sawtooth sweep currents are obtained at the output of the power amplifiers. Sweep clampers are usually used to keep the reference level constant, and cause every sweep to start at the same point on the CRT.

It was mentioned previously that the start-stop multivibrator has an output applied to the control grid of the CRT and to the marker generator, as well as to the sweep generator. A positive gate produced

by the multivibrator is applied to the CRT control grid. This positive pulse increases the electron flow between the cathode and the face of the CRT, and permits the intensity of the trace to increase during the period that the timing pulse is applied. This is in reality an tmblanking gate which permits the CRT to be operated at the desired time.

The negative rectangular pulse applied to the marker generator from the start-stop multivibrator is used to trigger the production of range marks on the screen of the CRT. These range marks provide a means of determining representative distances of targets from the origin. A typical range marker generator is shown in the following illustration. It is comprised of four triodes, the first of which (VI) acts as a switch for triodes V2 and V3, which can only conduct when V1 is cutoff. Triodes V2 and V3 form a complete path for the series resonant circuit L1 C3, or L2 C4, which determines the frequency of the range mark pulses. Transformer T1 differentiates the output waveform of V3 before being applied to V4, which serves as a cathode follower output stage. Capacitor Cl is an input coupling capacitor, and resistor RI establishes contact bias for V1. Resistor R2 is a plate voltage dropping resistor to provide V1 with a lower potential than the plate voltage value of V2. Resistor R4 is a common plate load resistor for triodes V1 and V2. Resistor R3 places the cathode of VI at a less positive potential than the cathode of V2. Resistor R5 holds the grid of V2 at approximately zero bias. Resistor R6 serves as a return to ground for the grid of V2, and capacitor C2 places the grid of V2 at an a-c ground potential. Resistor R7 places the cathode of V2 at some less positive potential than the cathode of V3. Resistor R8 is part of a cathode bias voltage divider on the cathode of V3. The divider consists of R3, R7 and R8 which places different fixed bias on the cathodes of VI, V2, and V3 respectively. The primary of T1 serves as a plate load for triode V3. Capacitor C5 couples the differentiated waveform to the grid of the cathode follower, V4. Resistors RI 1 and R9 place the grid of V4 at some highly negative potential. Resistor R1O provides a d-c return to ground for triode V4 and together withR11 forms a bias voltage divider between the negative supply and ground. Resistor R12 is the cathode resistor of V4 and serves to match the output of the cathode follower.

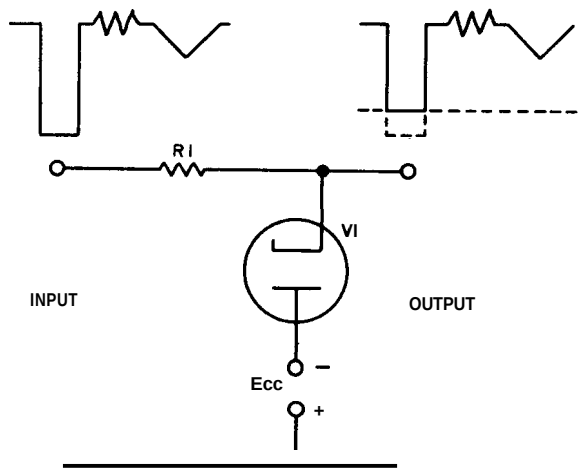


Range Marker Generator

Prior to the application of the sweep starting pulse from the start-stop multivibrator, the triode VI is conducting, which keeps the plate voltage at a low value. This low voltage prevents the plate voltage of V2 from being higher than the grid voltage of V2. This low plate voltage of VI also causes the potential at the grid of V3 to be less positive than the cathode and of sufficient negative value to cutoff the tube. With V3 cutoff no output signal is developed.

When the negative sweep start pulse is applied to capacitor Cl, triode V1 is cutoff, which causes the plate voltage of VI to increase, and the voltage on the plate of V2 to increase, and at the same time causes the grid voltage of V3 to increase. With the increased grid voltage, V3 conducts completing the circuit containing triode V3, the series resonant circuit of L1 C3 or L2 C4, triode V2, and the primary of T1. A pulse type waveform is produced by this circuit with a frequency dependent on the vrdue of the resonant circuit. The waveform is applied to transformer T-1, where it is differentiated by the inductance in conjunction with the resistance of the primary before being coupled to the secondary of T1. From the secondary of T1, the differentiated pulses are applied to the grid of cathode follower (V4) through capacitor C5, which blocks out any d-c component. The output is obtained from cathode resistor R12. This output is not only decreased in amplitude and in phase with the applied pulses, but it is also limited to positive pulses by the high negative bias on the grid of V1. These positive pulses are than applied to the control grid of the CRT to increase the intensity of the trace at the point where the range marker rings are to occur.

The video signal is applied to a biased video limiter, where the signal is made to vary above a specific level, so that the signal will not become so negative as to cause blooming on the screen. A schematic of the video limiter is shown in the following illustration. The limiter consists of only three components; resistor R1, and used to drop the applied voltage when diode V1, the second component, is conducting, and voltage source E_{cc}, the third component, used to establish the limiting level.

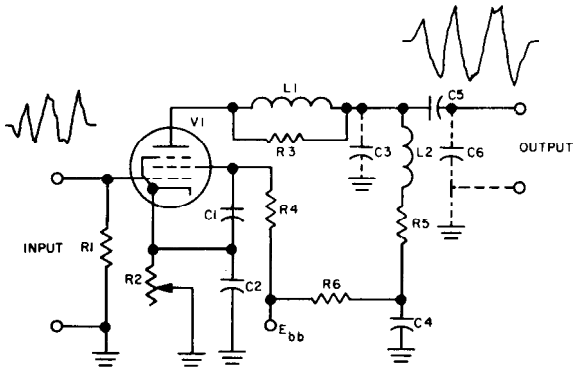


Video Limiter

With no signal applied there will be no signal output. When a positive signal is applied, it will appear at the output unaffected by the limiting diode and the voltage source E_{cc}, since the nonconducting diode acts as an open circuit. Even as the signal begins going negative, the signal will remain unaffected; since the negative voltage on the plate of VI is greater than the applied negative signal, thereby maintaining V1 in the nonconducting state. When the signal becomes as negative as E_{CC}, **V1** begins conducting, and the output is now E_{CC}. Even when the input becomes more negative, the output still remains at the value of the source voltage E_{CC}. The output voltage will vary as the input signal only when the input signal becomes more positive than E_{cc}.

The output voltage of the video limiter is applied to a video **amplifier,** or several video amplifiers, where the voltage is increased in gain before being applied to the cathode of the CRT. A typical video amplifier is shown in the following illustration. Resistor **R1** is the grid leek resistor, and resistor R2 is the cathode bias resistor, which, along with RI, establishes the

total grid bias. R2 is made variable to regulate the gain of the amplifier. Capacitor C2 is the cathode bypass capacitor, which bypasses the a-c signal to ground and prevents degeneration. R4 is the screen grid dropping resistor, and capacitor Cl is the screen grid bypass capacitor. The load consists of resistor R5, and resistor R6; however, at high frequencies the signal bypasses R6 through capacitor C4. Capacitor C5 is the coupling capacitor to the following stage.



Video Amplifier

Up to this point, the components which were discussed could form a common amplifier. The remaining components add to the previously discussed components to form the video amplit3er. Inductance L1 is a series peaking coil, which functions as a series falter for passing required frequencies. It also isolates circuits preceding it from circuits following it. Resistor R3 aids L1 by extending the effects of L1 and broadening the Q characteristics. Inductance L2 is a shunt peaking coil, which forms a parallel resonant circuit with the distributed capacitance (C3) and provides a high impedance for the signal. Capacitance C6 is the inter-electrode and distributed capacities of the following stage. Vacuum tube V1 is a pentode.

The negative signal coming from the video limiter is applied directly to the grid of the tube Vl, decreasing the conduction of V1 and varying it in accordance with the signal variation, and at the same time establishing a bias level through resistors R1 and R2. The variation in conduction rate of V1 produces an oppositely varying plate output voltage, which is developed across resistors R5 and R6. The higher frequencies of the signal, which would normally be lost or distorted by distributed capacitance (C3) and the interelectrode capacity, are passed undistorted by means of the series peaking (Ll) and shunt peaking coils (L2) inserted in the amplifier. These coils form resonant circuits with the effective capacities, permitting the higher frequency signals to be passed easily to the output and preventing these frequencies from being shunted to ground. (For a more detailed discussion of video amplifiers, refer to section 6 of this handbook.) One or several video amplifiers may be used to provide the desired amplitude of output signal.

Failure Analysis.

Start-Stop Multivibrator.

No Output. Since the start-stop multivibrator is responsible for producing synchronized sweep, range markers, and intensified trace during the time that information is to be presented, a defect in this circuit will affect each of these areas. If no output occurs it will be difficult to localize the trouble, since no spot will appear on the CRT. This effect can also be caused by the sweep generator or sweep amplifier having no output.

The no-output condition, in the start-stop multivibrator, may be due to lack of signal or lack of plate supply voltage. Check the signal with an oscilloscope at the input of the multivibrator. Check the plate supply voltage with a voltmeter. If the no-output condition exists and there is plate supply voltage, the condition may be due to a combination of faulty components. If resistors R3 and R4 were both open, or if triodes VI and V2 were both defective, the no-output condition would occur. Measure the resistors on a ohmmeter. If the condition still exists, triodes V1 and V2 are probably defective.

Low or Distorted Output. If a low or distorted output occurs in the start-stop multivibrator, it becomes more apparent that the trouble is in this stage, rather than the sweep generator or the sweep amplifier, since each one of the three applications of the multivibrator will show the effect of the trouble.

The low or distorted output maybe due to any of the following component failures: Shorted or open plate load resistor R3, shorted or open plate load resistor R4, shorted or open bias resistor RI, shorted or open bias resistor R2, shorted or open capacitors Cl or C2, improper plate supply voltage, defective triode Vl, defective triode V2, or improper input signal.

To determine which of these component failures is responsible for the condition, make the following checks: measure the input signal with an oscilloscope; measure the plate supply voltage with a voltmeter, and adjust the supply for the proper voltage; measure the resistors with an ohmmeter to be certain that they are of the proper ohmic value and within tolerance; and measure the capacitors with an in-circuit capacitor checker. If these components have been checked and the condition still exists, triodes VI and V2 are probably at fault.

Trapezoidal Sweep Genarator.

No Output. If no output is obtained at the output terminals of the sweep generator, no sweep is produced and the cathode ray tube will indicate only a single spot at the origin of the sweep.

A no-output condition may be due to any of the following circuit failures: no plate supply voltage, open resistor R1, open capacitor Cl, or open resistor R2. To determine which of these is responsible for the no-output condition, first check the input signal with an oscilloscope. Check the plate supply voltage with a voltmeter, and adjust the supply voltage to the proper voltage value. Check resistors R1 and R2 with an ohmmeter, and check capacitor Cl with an in-circuit capacitor checker.

Low or Distorted Output. If a low or distorted output is obtained at the output terminals of the sweep generator, and the proper input signal is applied, the fault may be due to any of the same component failures that occur in the no-output condition, plus the possibility of a defective triode, V1. The same checks apply in the low or distorted output condition as in the no-out condition. If these checks do not locate the trouble, triode VI is probably defective.

Sweep Amplifiar.

No Output. If no output is obtained at the output terminals of the sweep amplifier, no deflection will be produced and the trace will be in the form of a single dot at the origin of the sweep.

A no-output condition may be due to any of the following circuit failures: open capacitor Cl, no plate supply voltage, no input signal, or a defective triode, **V1.**

To determine which of these failures is responsible for the no-out condition, use the following checks: measure the input signal with an oscilloscope; measure the plate supply voltage with a voltmeter, and adjust the source if it is the cause of the condition; measure capacitor Cl with an in-circuit capacitor checker. If these checks do not locate the trouble, triode V1 is probably defective.

Low or Distorted Output. A low or distorted output may be due to any of the following circuit failures: shorted capacitor C1, shorted or open resistor RI, shorted or open resistor R2, a shorted or open capacitor C2, low plate supply voltage, or a defective triode, V1.

To determine which of the circuit elements is responsible for this condition, make the following checks: measure capacitors Cl and C2 with an in-circuit capacitor checker; measure the values of resistors R1 and R2 on an ohmmeter; measure the plate supply voltage source with a voltmeter, and adjust the source to the proper plate supply voltage. If these checks do not lead to the defective part, triode VI is probably defective.

Range Marker Ganarator.

No Output. A no-output condition in the range marker generator will result in no range markers being produced on the face of the CRT. This condition may be due to any of the following circuit failures; no plate supply voltage, defective triode V2, defective triode V3, open or shorted transformer Tl, open inductors L1 or L2, open capacitors C2 or C4, open capacitor C5, open or shorted resistor R12, or defective triode V4.

To determine which of these components is at fault, make the following checks: measure for possible defective resistors with an ohmmeter; check the applicable capacitors with an in-circuit capacitor checker; check the ohmic values of inductors Ll, L2, and the primary and secondary windings of transformer T1. Check the plate supply voltage with a voltmeter, and adjust the plate supply voltage if it is not the proper voltage. If the no-output condition still exists after all other checks have been made, triodes V2, V3, and V4, and probably defective.

Low or Distorted Output. Low or distorted output may result in improperly situated range marks on the screen of the CRT. This condition may be due to any of the following circuit failures, providing the proper input signal is applied: improper plate supply voltage, shorted capacitor Cl, shorted capacitor C2, shorted capacitors C3 or C4, shorted capacitor C5, shorted inductors L1 or L2, shorted or open transformer T1, shorted or open resistors Rl, R2, R3, R4, R5, R6, R7, R8, R9, RIO, or R11; or defective triodes Vl, V2, V3, or V4.

To determine which of the components is responsible for the condition, make the following checks: check the applicable capacitors with an in-circuit capacitor checker; check applicable resistors with an ohmmeter; check inductors and transformer windings with an ohmmeter; Check the plate supply voltage with a voltmeter, and adjust the supply if the voltage is not the correct value. If the low or distorted output still exists after checking and correcting any of the possible foregoing failures, the tubes are probably at fault.

Video Limiter.

Since the video limiter is composed of three components the failure analysis may be simplified.

No Output. In order to have a no-output condition, an open resistor RI, an open bias supply voltage E_{CC}, or a defective diode V1 would have to exist. This no-output condition would result in no indication of the target as well as no indication of the area being scanned.

To determine which of the three components is responsible for the no-output condition, measure the bias supply voltage with a voltmeter and adjust it if it is not the correct value; measure resistor R1 and check V].

Low or Distorted Output. A low or distorted output would result if any one of the same three components is defective. Use the same checks to determine which of the components is responsible for the low or distorted output condition.

Video Amplifier.

No Output. A no-output condition in the video amplifier would result in no visual representation of the target or scanned area. This condition maybe due to absence of signal, absence of plate supply voltage, open resistor R6, open resistor R5, open inductor L2, shorted capacitor C4, open capacitor C5, or a defective pentode V1.

To determine which of these components is defective make the following checks: measure the input signal with an oscilloscope; check the plate supply voltage source with a voltmeter and adjust the source to the proper value, if it is not the proper voltage, check resistors R5 and R6 with an ohmmeter; check inductor L2 with an ohmmeter, and check capacitors C5 and C4 with an in-circuit capacitor checker. If the no-output condition still exists after these checks and corrections have been made, pentode V1 is probably at fault.

Low or Distorted Output. A low or distorted output may be caused by any one of the actual circuit components being defective, or an improper input signal.

To determine which component is at fault, use the following procedures: check the input signal with an oscilloscope, check the plate voltage supply with a voltmeter and adjust the supply voltage to the correct value, if it is not at the correct value. Check all resistors with an ohmmeter and check the ohmic values of inductors L1 and L2 with an ohmmeter. Check capacitors with an in-circuit capacitor checker. If all of these checks do not locate the defective component, pentode V1 is probably at fault.

OTHER TYPES OF ELECTROMAGNETIC SCANS

Application.

Of the remaining types of electromagnetic scans three general types are probably encountered more often than any others. These scans are the spiral, the RHI, and TV scans. The spiral scan is usually used for range measurements where it provides a much longer time base than is available for circular or linear scans. The RHI scan is used where it is desired to determine the range and target height as a special radar presentation, and the television (TV) scan is used to reproduce scenes or images.

Characteristics.

A long persistence type of CRT is used with the RHI and spiral scans, while a medium persistence CRT is used with the TV scan to prevent blurring of the moving images.

In the RHI scan the horizontal base line always indicates range, while the height is indicated vertically.

The spiral scan may start at the center of the CRT and rotate spirally outward, or start at the periphery of the tube and rotate spirally inward to the center, depending upon design.

The TV scan uses a two field, odd-line interlaced scan operating at 30 frames vertically per second, and 525 lines horizontally, (a sweep frequency at 15750 Hz).

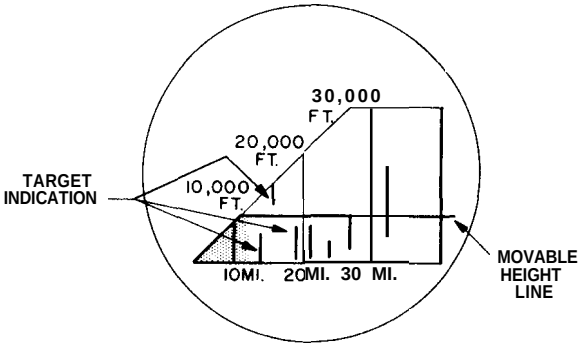
Scanning begins at top left of the CRT and travels to the right and down.

Each frame consists of 525 individual horizontal scanning lines which move from top to bottom.

Circuit Analysis.

General. The spiral scan, the RHI scan, and the TV scan are all produced by means of an electromagnetic deflection system; however, each may be produced by an electrostatic deflection system for special applications. The spiral and the RHI scans are similar in circuitry and in operation to previously mentioned CRT scans. The TV scan is unique in comparison to these scans, since, this type of scan produces a detailed reproduction of a specific scene or image.

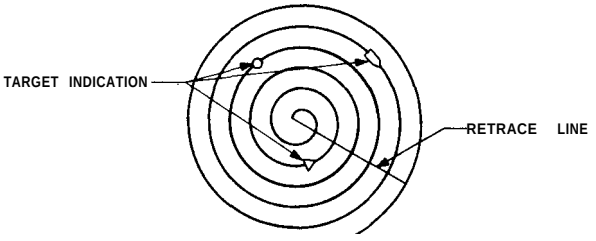
An RHI scan is similar to an off-center PPI scan, but has an elevation or height indication in place of what would normally be the azimuth or bearing indication, as shown in the following illustration.



Range Height Indicator Scan

The actual representation of the trace on the CRT originates at the lower left side of the screen and extends horizontally to the right, and vertically at the same time, resulting in an angular type display. The horizontal distance represents the range and the vertical distance represents the height. The origin of the trace represents the radar location. There are equidistant vertical lines along the angle of the display, which are range markers. A movable horizontal line appearing across the pattern is used to determine the height of the target. Targets appear as intensified portions of the trance on the CRT.

The spiral scan is used when linear and circular traces do not have a sufficiently long time bases to record certain data with the required accuracy. The spiral scan is evolved from the circular scan, as used in PPI and is shown in the accompanying illustration.



SPIRAL SCAN

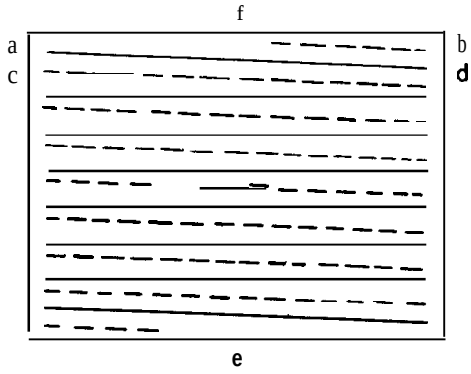
Spiral Scan

The range of the scan can be varied by changing the number of turns in the spiral. The sweep rotates at a constant rate of speed, so that equal divisions along the spiral indicate equal range increments. The spirrd scan may start at the center of the trace, as it does in PPI, but it rotates spirally from the center of the CRT and only reaches the periphery of the tube by the end of the sweep. It is possible, too, that the spiral scan may start at the periphery of the tube and rotate spirally toward the center of the CRT, only reaching the center of the CRT by the end of the trace. The origin of the sweep represents the position of the radar location. Targets are represented by intensified portions of the trace.

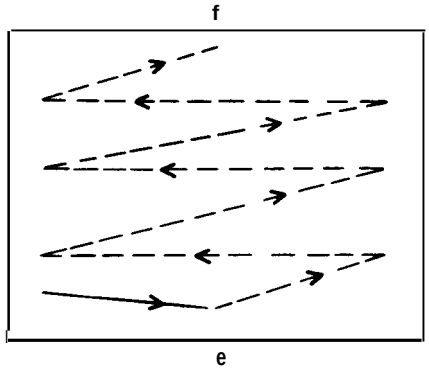
The TV, or uniform linear scan, is based on a beam that moves much as the human eye does in scanning a written page. It moves from the top left to the right and rapidly returns to the left, only slightly further down from the top than the previous line. It moves this way until reaches the bottom of

the sweep on the right side. This, however, only constitutes half of a complete frame. To complete the second half frame the sweep is rapidly returned to the top center of the CRT. The first line in the second half frame descends less than the first line in the first half frame, since the second half frame starts at the top center and has less horizontal distance to cover, and less time for the line to descend than the first half frame. In this way, the second half frame fills in scanning lines between the lines that were scanned during the first half frame.

The TV scanning sequence when looking at the picture tube is shown in the following figure. The scanning spot starts in the upper left hand corner and travels at a uniform rate from left to right along lines that lie at a distance below each other as shown by the solid lines in the figure. When the end of a line such as ab is reached the scanning spot quickly returns to the left (that is from b to c) to start new line cd. During this return interval the spot is blanked out and so is not shown in the figure. As the scanning spot moves back and forth across the tube, the spot also moves downward at a constant rate. Hence the lines in the figure are slightly sloped, and each line begins at a level that is a little below the end of the previous line. When the bottom of the picture is reached (point e in the figure), the spot quickly returns to point f at the top of the picture, while maintaining the back and forth horizontal line motion uninterrupted. Since the time required to travel from e to f corresponds to the passage of a number of lines, the spot traverses a path similar to that shown in the retrace figure as it goes from e to f. This return pattern is not seen by the eye, however, as the spot is blanked out during the return.



HORIZONTAL TV TRACE



VERTICAL TV RETRACE

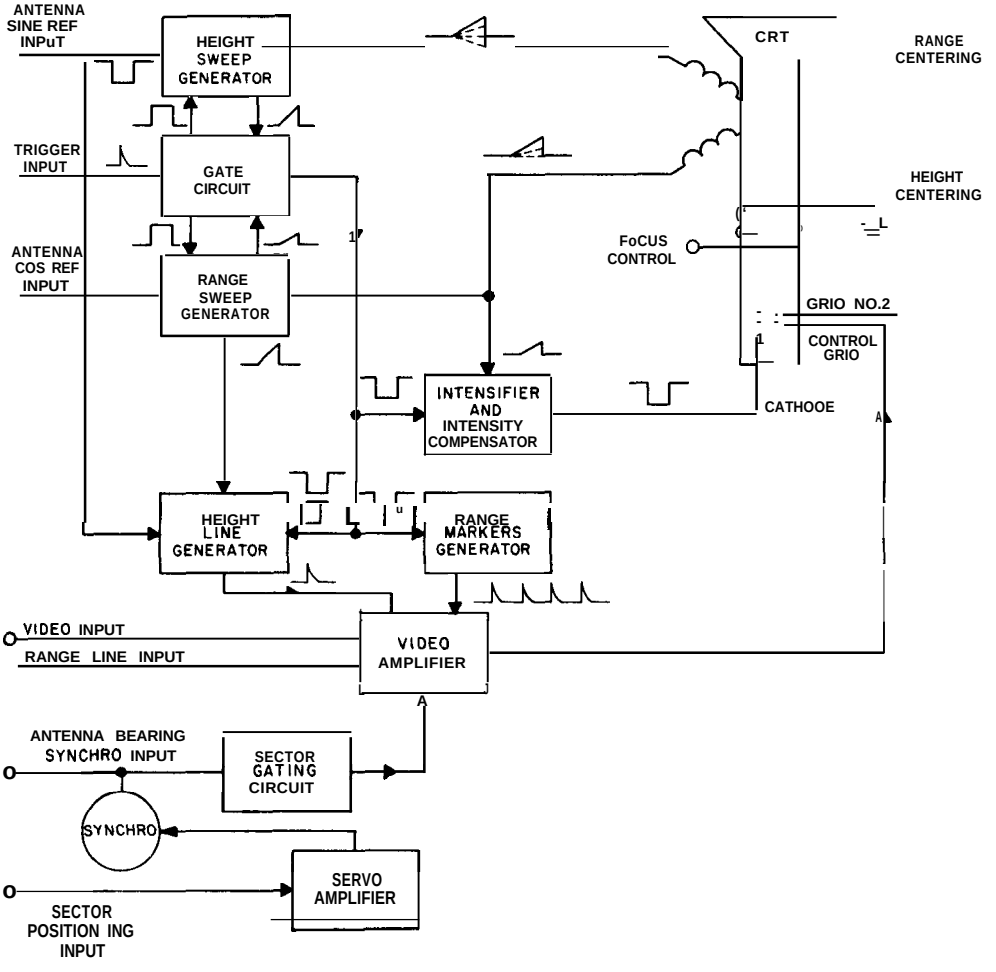
FIRST FIELD

SECOND FIELD

TV Scan

The standard television picture takes 1/60 second to go from the top to the bottom of the picture and return to the top. During this time, which is called one *field* 262.5 lines are transmitted. Because each field contains a half line, the next field lies between the lines of the first field as indicated by the dotted lines in the figure; thus successive fields are interlaced. The complete picture, called a frame, therefore, consists of 525 lines and is transmitted in 1/30 second. The original pattern showing the trace lines is what is observed on a television receiver in the absence of a picture, and is termed the raster. Interlacing makes it possible to avoid flicker while using the lowest repetition frequency for the picture that will satisfactorily portray motion. Thus, while a picture repetition rate of 30 times per second is adequate to give the illusion of continuous motion under nearly all circumstances, large bright areas repeated 30 times per second will have a noticeable flicker. By interlacing, a flicker rate of 60 hertz is achieved which is too high to be perceptible; at the same time the picture is repeated only 30 times a second.

RHI Circuit Oparation. The block diagram of a typical RHI scanning system is shown in the following illustration. Since the operation of each basic circuit is described in detail in other sections of this Handbook, description of circuit operation is limited to the effect of each individual stage on the total scan system.



RHI Bleak Diagram

The first circuit to be considered is the gate circuit stage. It produces positive and negative gates occurring at the trigger input frequency which switches the range sweep circuit, the height sweep circuit, the height line generator, and the intensifier and intensity compensation and, in addition, a specird count-down gate which is used to gate the range marker circuit stage. The range sweep generator is one of two stages required to produce two linearly increasing, mutually perpendicular, magnetic deflection fields. One magnetic field, causing horizontal movement of the beam, is produced by current in the range sweep deflection coil as a result of the voltage produced by the range sweep generator. The rate of increase of the range magnetic field is proportional to the cosine of the elevation angle of the antenna. The range sweep generator transforms a dc reference voltage into the linearly increasing magnetic field in the CRT. The rate of increase of the magnetic field determines the speed at which the beam moves horizontally across the screen and is proportional to the dc reference voltage.

The height sweep generator stage also produces a linearly increasing magnetic deflection field. This magnetic field supplies the verticrd component of the CRT beam deflection. The rate of increase of the magnetic field is dependent on the dc reference voltage, which in turn is proportional to the sine of the angle of the antenna elevation. The rate at which the vertical magnetic field increases determines the speed at which the beam moves vertically on the screen.

The negative gate from the gate circuit stage is applied to operate the intensifier and intensity compensation circuit stage. This stage has two functions. One function is to allow signals to appear on the CRT only during the sweeping periods. During the intervals between sweeps the CRT is blanked off. The other function is to keep the intensity of the CRT signals constant with the changes in range, pulse repetion rate, and the elevation angle. Intensity compensation is produced by automatic variation of the dc voltage on the cathode of the CRT.

The range marker generator circuit produces equally spaced range markers. The range markers are applied to a video amplifier where they are amplified, and then applied to the grid of the CRT. The nodding of the antenna causes the markers to appear as bright lines on the sweep.

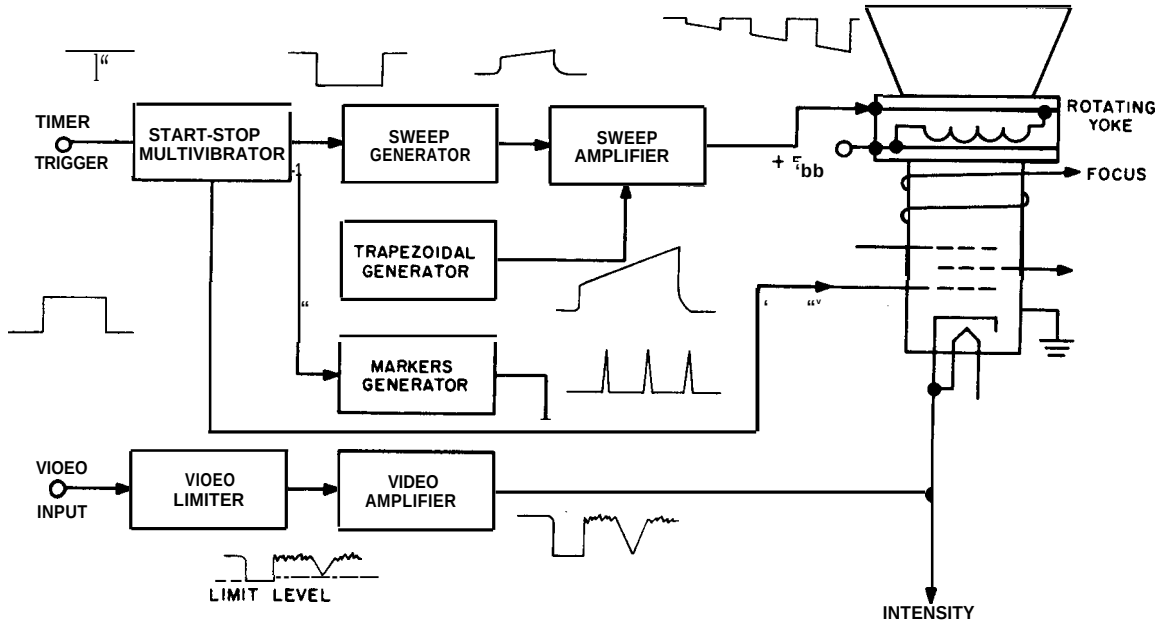
The video amplifier stage amplifies the video target signals received from the radar receiver. It also amplifies the range markers, the height line pulses, and the range line input signals, and mixes them with the video signal. The amplified signals are applied to the CRT control grid.

The sector gating circuit, which has its output connected to the video amplifier stage, allows only those targets present in a selected azimuth sector to appear on the CRT face. It also determines the angular width of the sector to be viewed.

The servo amplifier stage supplies voltage to a motor which drives a sector gating synchro rotor. The position of the synchro rotor determines the bearing of the azimuth sector viewed on the RHI scope. The position of the sector gating synchro rotor always corresponds with the setting of the manual sector control.

The resulting RHI sweep appears on the CRT as a wedge. The vertex of the wedge, corresponding to the origin of the trace, appears at the left lower portion of the screen. The horizontal distance of the trace corresponds to the range, and the vertical distance of the trace corresponds to the height or elevation of the trace. The range indicating marks are vertical lines, of intensified trace with angular compensation, equidistant along a horizontal plane. The height line is a horizontal line of intensified trace. The video information coming from the radar receiver, which represents targets within the selected sector, produces intensified portions of the trace at the range and height positions on the display corresponding to the actual location of the target from the radar location.

Spiral Sean Circuit Oparation. A typical block diagram of the spiral scan producing system is shown in the following illustration. Since the operation of each basic circuit is described in detail in other sections of this Handbook, circuit operation will be limited to the effect of each stage on the total system.



Spiral Searl Systam Block Diagram

The primary controlling state is the start-stop multivibrator. It converts an external negative timing pulse into a number of square wave pulse to the sweep generator stage, results in a trapezoidal sweep pulse output with the same duration as the square wave pulse applied to the input of this circuit, and occurring at the same frequency and time as the input pulse. This trapezoidal sweep output is applied to the sweep amplifier stage.

The application of the negative square wave pulse, from the start-stop multivibrator stage, to the trapezoidal generator stage also results in a trapezoidal output. This trapezoidal output, unlike that of the sweep generator stage, is not of the same duration as the input pulse, but occurs for a longer period of time. This period of time normally is an even multiple of the input pulse. The ratio of the trapezoidal pulse to the negative square input pulse determines the number of turns in **the** spiral sweep on the CRT. The trapezoidal output pulse, like the output of **the sweep** generator stage, is also applied **to** the sweep amplifier **stage.**

The negative square wave pulse output from **the** start-stop multivibrator stage is also applied to the markers generator stage, where short duration marker pulses are produced for application to the CRT **con**trol grid. These pulses produce intensified points on the sweep trace **which** correspond to specific range indications.

The positive square **wave** pulse produced by the start-stop multivibrator **stage is** applied to the control **grid of the** CRT. This pulse provides unblinking of the sweep on the CRT during the period that it is applied.

The trapezoidal sweep pulses produced by **the sweep** generator stage and the varying amplitude trapezoidal pulse from **the** trapezoidal generator **stage are** combined in **the sweep amplifier** stage and amplified. The addition of the increasing trapezoidal pulse to **the sweep** pulses produces a continually increasing sawtooth sweep of current through the deflection coils while the yoke rotates.

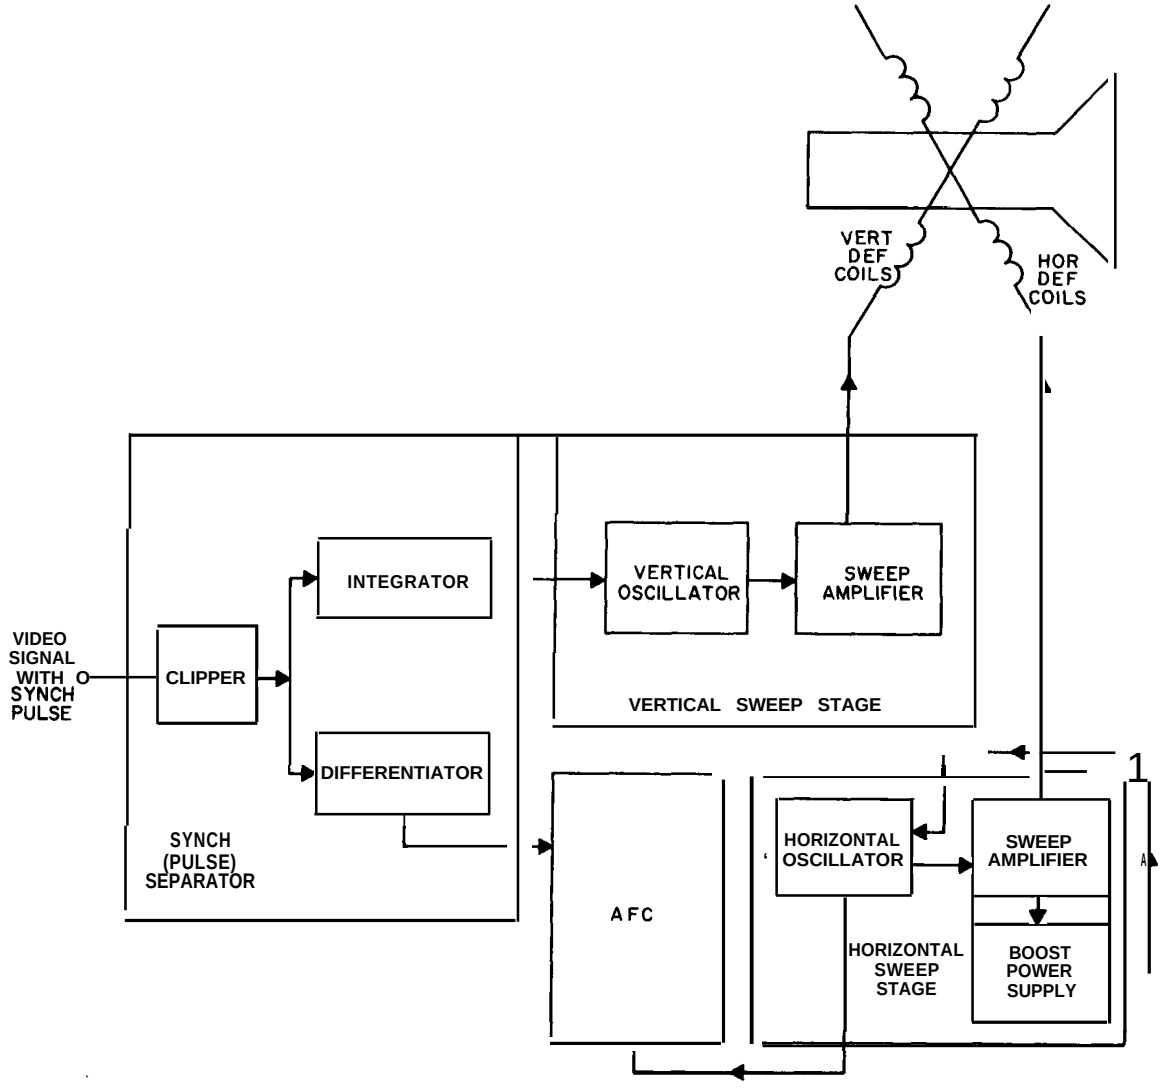
The resulting sweep on the CRT is similar to that of the PPI sweep, with **the** exception that each pulse

produced by the sweep generator stage does not produce a scanning line which extends from the center of the sweep to the periphery of the CRT. Instead, each sweep line extends a distance from the center of the CRT which corresponds to the amount of sawtooth current occurring in the deflection coil, at that time. Since the current in the deflection yoke continually increases in a sawtooth manner, the distance that the sweep trace extends from the center of the sweep increases in a linear manner, while rotating about the sweep origin, until it reaches the periphery of the CRT, forming a spiral sweep.

The video input is applied to a video limiter stage where any portions of the signal extending beyond the limiting voltage level are clipped off. The limited signal is applied to a video amplifier stage. The video amplifier stage amplifies the limited video signal. This amplified and limited video signal is then applied to cathode of the CRT, where it causes the intensity of the electron beam to vary accordingly.

The resultant scan on the CRT appears as a spiral, with the sweep originating at the center of the CRT and gradually reaching the periphery of the CRT by the end of the spiral, which may contain a number of turns. Equidistant intensified points on the spiral sweep correspond to range indication marks. Any other intensified points or sections of the spiral, or extra-intensified range marks correspond to target indications.

Television Scan Circuit Operation. The typical block diagram of a television scanning system is shown in the following illustration, the seaming - system comprises approximately one third of the complete television receiver. The synch (pulse) separate stage, which contains a limiter, an integrator and a differentiator is not actually part of the scanning system of the receiver, but is included in the block diagram to give a more complete description of the development of vertical and horizontal sweep pulses.



TV Scanning Systam

Actually the integrator and differentiator stage consists of only a resistor and capacitor combination. The clipper circuit eliminates all portions of the composite video signal below the synch pulse level. The differentiator network segregates the horizontal pulse information from the combined horizontal and vertical pulse waveform, and applies the integrated waveform to the vertical sweep stage.

The differentiator waveform is used by the afc circuit to maintain the horizontal oscillator output in phase with the synchronizing pulses.

The frequency stabilized horizontal synchronizing pulses are applied to a free-running multivibrator to develop a sawtooth output waveform. This multivibrator, the horizontal oscillator, operates at a frequency which is slightly lower than the synchronizing

pulse frequency. The synchronizing pulses, then, trigger the multivibrator into action at the synchronizing pulse frequency.

A portion of the output of the horizontal oscillator is fed back to the afc circuit to stablize the horizontal frequency, and the stabilized output is applied to a sweep amplifier, where it is amplified and coupled to the horizontal deflection coil through a transformer. A sawtooth current is developed in the horizontal deflection coil which electromagnetically sweeps the CRT electron beam horizontally. The horizontal output transformer is also used to furnish the high voltage for the CRT anode, and a damping circuit is connected across the deflection coil and output transformer secondary to prevent continuous shock oscillations from occuring in the horizontal deflection coil during the retrace time of the sweep. The damper circuit is also used to furnish an additional dc boost voltage for the horizontal oscillator as shown in the block diagram.

The integrated portion of the synchronized pulse waveform, when applied to the vertical oscillator, triggers the vertical oscillator stage and a free-ruining multivibrator when the value of the integrated waveform reaches a certain amplitude. The integrated vertical waveform reaches this triggering level at a specific, regular rate, which is much slower than the differentiated pulse rate. The output of the vertical oscillator, is also a sawtooth type waveform occurring at the triggering level rate of the integrated waveform.

The output of the vertical oscillator is applied to the sweep amplifier stage of the vertical sweep network. Here the vertical sweep waveform is amplified and coupled to the vertical deflection coils, causing a sawtooth current to be developed, which electromagnetically deflects the electron beam of the CRT in a vertical direction.

The resultant scan on the CRT is one in which the horizontal sweep occurs at a frequency of 15,750 Hz which is approximately 5000 times that of the vertical frequency. A total of 262.5 horizontal lines is swept by the time the horizontal scan has completed one top to bottom (vertical) sweep on the CRT. This vertical sweep occurs 60 times a second, however, this only constitutes half of a complete picture frame. During the next vertical sweep an additional 262.5 horizontal lines are scanned from top to bottom of the CRT at the same rate of 60 times a second. These lines interlace between those which were scanned during the first half frame. A total of 525 horizontal scanning lines are used to provide greater detail in the picture. The reason for scanning only 262.5 horizontal lines for ordy one vertical sweep rather than scanning the full 525 lines for one vertical sweep, is that if the 525 lines were scanned at one time the complete picture would only be repeated 30 times a second and cause the display to flicker.

The TV scan moves much as human eyes do in scanning a written page. The scan starts at the top left hand side of the CRT screen and proceeds horizontally to the right with a very slight downward movement at the same time. The scan is rapidly returned to the left side. After completing the first horizontal scanning line the CRT is blanked out so that it is incapable of producing a visible line during this retrace period. Upon being returned to the left side of the CRT, the next scan line is displaced slightly further down than the starting point of the first scanning line and the CRT is unblanked for the next line. Two hundred sixty two and one half lines are scanned in this manner, until the scan reaches the bottom center of the CRT. Upon reaching this point, the scan again is blanked out during the vertical retrace and is rapidly brought back to the top center of the CRT. The same scanning procedure as described for the first half-frame occurs for the second half-frame, only this time the scanning lines are interlaced between those scanned during the first half-frame. The result is that a complete picture appears on the CRT screen 30 times a second, with half of this picture changing 60 times a second to eliminate flicker.

Failure Analysis.

RHI Scan. In order for a no-output condition to exist, which is characterized by no indication of any kind on the CRT, a faulty power supply or a failure in each of the circuits comprising the system would have to occur. It is highly unlikely that every circuit in the system would fail, so the no-output condition would normally be limited to power supply failure. Check the power supply with a voltmeter to determine if the supply or a fuse is at fault.

There are several types of low or distorted outputs associated with the RI-H system. By looking at the trace on the RI-U indicator it is usually possible to determine the probable location of the failing circuit.

If there is no indication on the CRT, it is not necessarily true that a no-output condition exists. It only means that either improper potentials are being

applied to the CRT electrodes, the unblinking circuit is defective, or that the CRT, itself, is defective. First determine if the proper voltages and unblinking waveforms exist on the electrodes of the CRT, the deflection coils, and the centering control with a high resistance voltmeter, and an oscilloscope. If the proper voltages and waveforms are present, the fault is in the CRT. If the proper voltages and waveforms do not exist, proceed from the electrode showing voltage or waveform back towards the preceding stage to locate the defective component.

If, for example, the improper signal exists on the cathode of the CRT, the trouble may be in the intensifier and intensity compensation circuit stage, or in the gate circuit stage, or the sweep circuit stage. If the input of the intensifier or intensity compensation circuit stage is correct but the output is not, the trouble should be located within this circuit.

If improper input voltage to the intensifier and intensity compensation circuit stage exists the trouble preceeds this stage. If the gate circuit stage input is faulty, the intensity of the trace is not synchronized with the range sweep. If it is the gate circuit stage itself that is faulty there will be no range or height sweep. If the trigger smplifier and the gate multivibrator of this stage are functioning properly there should at least be height and range sweep. The trouble may then be in the countdown multivibrator of this stage.

If the range sweep generator stage is defective not only is the intensity of the sweep affected, but the range indication is also incorrect. If this condition is indicated by the trace on the CRT, check the input of the range sweep generator stage with oscilloscope to determine if the antenna cosine reference input is incorrect and if this is correct, check the parts within the stage.

If the correct potentird appears on the CRT cathode, but not on the control grid, the video amplifier stage or the preceding stages may be at fault. Check the several inputs of the video amplifier with an oscilloscope. If all the inputs are found to be correct, but the output is faulty the trouble must be in the video amplifier stage. If the video amplifier stage circuits are not faulty the preceding stages must be the cause of the trouble. The presentation on the CRT usually indicates which preceding stage is the cause of the specific fault in the CRT trace. If it is the video signal, itself, that is improper the trouble exists somewhere in the radar receiver, rather than in the RHI. If the trouble is in the sector gating stage the CRT presentation will indicate improper sector angle or improper selection of azimuth. If this indication is apparent check for the proper antenna bearing synchro input with an oscilloscope. If the sector positioning input signal is not apparent at the sector gating stage input the preceding synchro or the servo amplifier stage may be at fault. If the synchro is functioning correctly check the servo amplifier.

If the CRT presentation indicates that there is no height line available, the failure is either in the height line generator stage, the range sweep generator stage, the gate circuit stage, or the antenna sine reference input. If any of these stages, other than the height line generator stage, are faulty, other CRT presentation failures will also be indicated. If, however, it is the height line generator stage, only the height line will be missing from the CRT presentation.

If the CRT presentation indicates that there are no range marks, the trouble must exist in the range mark generator since any faulty stages preceding the range marker generator stage would affect the presentation in some other way.

If there is no indication of height (or vertical direction) on the presentation of the CRT, the faihrre is in either the antenna sine reference input or the height sweep generator stage. If the antenna sine reference input is proper and present, the trouble must be in the height sweep generator stage.

Spiral Scan. Failure of the CRT high voltage supply or loss of the unblinking pulse would cause the indicator to be blank and produce a no-output condition. Check the CRT anode voltage with a voltmeter, and check the start-stop multivibrator for a positive unblinking pulse using an oscilloscope. Usually observation of the indicator will indicate the stage or stages which might be faulty. For example, if there are no range marks visible on the spiral trace and the display otherwise appears normal, the marker generator is most likely at fault. Check the output of the marker stage with an oscilloscope and, if no markers appear when an input pulse is applied, the marker generator is defective. Likewise, if range markers appear on the trace but no targets appear, there is probably no video signal applied to the cathode of the CRT. Check the cathode voltage on the CRT with a voltmeter and use an oscilloscope to check the video limiter input and the video amplifier output. If no video appears at the output with video applied to the input, either the amplifier or limiter

stages are at fault. Check the video limiter output to determine if it is at fault. If there is either no video input, or improper video input at the limiter it is obvious that the trouble is not in the scanning system but somewhere in the radar receiving system.

If there is no sweep apparent on the CRT but a bright spot exists at the center of the CRT, check for proper grid and cathode voltage with a voltmeter. If normal, either the sweep amplifier, sweep generator, or trapezoidal generator may be at fault. Check the output of the sweep amplifier with an oscilloscope and both inputs. If the inputs are normal but the output is improper the amplifier is at fault. If either input is improper the stage supplying the improper output is faulty. Also check the input to the presumed faulty stage to make certain the proper input gate is applied. If normal sweep outputs are obtained, either the CRT is defective or the deflection yoke is open or shorted. Check the reistance of the yoke coils with an ohmmeter.

TV Scan. Failure of the CRT high voltage supply, the dc boost supply or a defective picture tube will usually produce a complete no-output condition with a blank CRT. Use a high resistance voltmeter and high voltage probe to check the high voltage, being careful to observe full safety precautions to avoid the possibility of dangerous shock. If the dc boost voltage is normal check the electrode voltages of the CRT. Failure of the dc boost supply can be caused by a shorted filter capacitor, a defective damper tube or circuit. Check the falter capacitor for a short with an ohmmeter and for proper value with an in-circuit capacitance checker. If the boost voltage is low, the darnper tube is bad. Usually failure of the damper circuit involving sweep components, such as a shorted output transformer or defective deflection yoke will also cause loss of sweep, and no raster will appear on the CRT screen. Check the coils for the proper resistance with an ohmmeter. Usually defects in the sweep will be found in the section at fault. If the horizontal sweep is faulty check the horizontal sweep stages from input to output with an oscilloscope. the point at which the waveform disappears or is distorted will usually indicate the circuit at fault. Likewise, for a faulty vertical sweep check the vertical sweep stages for input and output waveforms in a similar manner.

For example, if there is no vertical deflection, or a vertically rolling picture, or some other apparent trouble in the vertical scanning on the CRT, and the electrode and coil potentials have been checked, the trouble must exist in the vertical sweep stage or the integrator or clipper sections of the synch (pulse) separator. First check the input waveform of the vertical sweep amplifier with an oscilloscope. If the proper waveform is present but improper output exists, the trouble must be in this stage. If an improper input waveform is present check the input of the vertical oscillator with an oscilloscope. If the input waveform is proper, but the output waveform is improper, the trouble is within the vertical oscillator stage. If the input to the vertical oscillator is improper the trouble exists in the integrator or clipper sections of the synch (pulse) separator stage or in prior receiver stages. Also be certain to check that the vertical synch pulses appear in the input signal to the receiver.

If the picture on the CRT is horizontally rolling or if there are some other apparent horizontal scanning troubles, and the electrode and coil potentials have been checked and found correct, the trouble must exist in the horizontal sweep stage, the afc stage, or the differentiator or clipper sections of the synch (pulse) separator stage. First check the input of the horizontal sweep amplifier with an oscilloscope. If the input waveform is proper, but the output is improper, the trouble exists within the horizontal sweep amplifier. If the input of the sweep amplifier is improper check the input wavefomn of the horizontal oscillator. If the oscillator input is proper, the trouble is in the horizontal oscillator. If the oscillator input is improper check the inputs of the afc stage. If these inputs are correct, but the output pulse is incorrect, the trouble exists in this stage. If the input from the synch (pulse) separator stage is proper, but the input feeding back from the horizontal oscillator is improper, the trouble is in the feedback circuitry from the horizontal oscillator to the afc stage. If the feedback input is proper, but the input from the synch (pulse) separator stage is incorrect the trouble must exist in the differentiator or clipper of the synch (pulse) separator, or in preceding receiver stage, or in the horizontal synch pulse contained in the input signal to the receiver.

PART 9-3. ANCILLARY CIRCUITS

BLANKING CIRCUITS

Application.

Blanking is used in TV, radar, synchroscopes, and oscilloscopes to reduce the beam intensity and render invisible the retrace portion of the electron beam which produces the visible trace on the CRT.

Characteristics.

Blanking is dependent on the sweep signal.

Blanking reduces the intensity of the electron beam of the CRT.

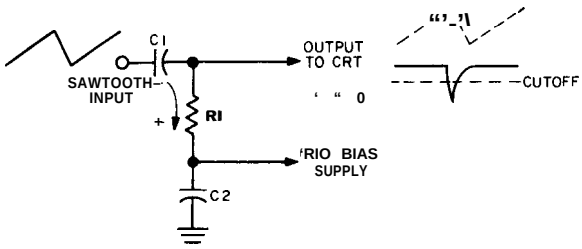
Blanking is accomplished by application of negative voltage to the control grid.

Blanking circuit is a resistor-capacitor combination.

Circuit Analysis.

General. Blanking circuits are used in CRT displays to prevent any indication of the retrace line from appearing with the display. This is accomplished by applying the sweep signal to an RC differentiating circuit, which develops a rectangular type waveform during the sweep discharge period. The rectangular (blanking) waveform is applied to either the control grid or the cathode of the CRT, depending on the polarity of the waveform. The rectangular waveform is usually connected in series with the CRT bias so that it increases the CRT bias and causes the electron beam to be cut off during the retrace time of the sweep, but has no effect on the beam during the active portion of the trace time of the sweep.

Circuit Operation. A typical RC blanking circuit is shown in the following illustration.



Blanking Circuit

Capacitor Cl and resistor R1 form a differentiating circuit. Capacitor C2 is a large a-c bypass capacitor which effectively places the lower end of RI at ground potentird. The sawtooth sweep voltage is applied to Cl and the charging current is relatively constant with the linear increase of the sweep voltage. Thus, the current flowing through R1 remains at a relatively constant and low value for the duration of the sweep trace. The voltage drop across Rl, likewise, remains at a small but constant value for the linear rise of the sawtooth sweep. This small positive voltage drop is small enough, however, so that it has little affect on the grid bias which it opposes. The intensity of the electron beam is, then, relatively unaffected.

When the sawtooth sweep voltage quickly retraces, however, the discharge current change is great and rapid. As Cl discharges the high discharge current through R1 produces a large voltage drop across R1 which is opposite in polarity to the drop produced across RI during the sweep. This retrace voltage series aids the normal negative grid bias applied to the control grid of the CRT. Hence, the bias voltage applied to the control grid of the CRT is now a large enough negative value to cut off the electron beam of the CRT, causing the CRT trace to disappear. The electron beam remains cut off during the entire retrace period, and for a short portion of the beg'inning of the trace period. Greater linearity of the sweep voltage and shorter retrace time of the sweep voltage causes the cutoff of the electron beam to extend less into the trace period.

A similar circuit may be used with a negative sawtooth applied to the input capacitor provided that the voltage across the resistor is applied to the cathode of the CRT. In this case a positive increase in bias is produced across R1, effectively driving the grid more negative and producing the same biasing-off of the beam.

Failure Analysis.

No Output. If capacitor Cl were open none of the sweep voltage would be applied to the differentiating circuit and thus no voltage would be produced across R1. In this case, only the normal gird bias would be applied to the control grid of the CRT and blanking would not occur. To determine if Cl is defective, check it with an in-circuit capacitor checker. If resistor RI were open, not only would no voltage drop across it, but no grid bias would be applied to

the CRT and the screen would be brightly illuminated. To determine if RI is open, check the resistance with an ohmmeter. If capacitor C2 were open there would be no ground return, which would also cause no output to result. In order to determine if capacitor C2 is open check it with an in-circuit capacitor checker. If, after checking these components, the no output condition still exists the sawtooth sweep voltage must be faulty, or the grid bias supply voltage must be faulty. By checking the sweep voltage input with an oscilloscope and the grid voltage with a voltmeter, the faulty voltage will be located.

Low or Distorted Output If capacitor Cl becomes shorted the full sawtooth sweep voltage will be placed across Rl, resulting in a sawtooth grid waveform with the grid bias voltage opposing it, and the resultant voltage appearing at the control grid of the CRT. To determine if capacitor Cl is shorted measure the voltage between each plate of Cl and ground. If they are equal the capacitor is shorted. If resistor R1 is shorted no voltage can be developed across it. The voltage applied to the grid of the CRT will then be distorted. To determine if R1 is shorted, check R1 with an ohmmeter. If capacitor C2 were shorted the lower half of R1 would beat dc ground, and the grid bias supply would be shorted to ground. A certain amount of self grid bias would be generated by the flow of grid current through R1 and any grid signrd would probably be distorted if it was large enough to overcome the bias and illuminate the CRT. To determine if C2 is shorted check the voltage between each plate of C2 and ground. If the voltages are equal the capacitor is shorted. If the low or distorted output condition still exists the sawtooth sweep voltage or the grid bias voltage must be faulty. Check the sawtooth sweep voltage with an oscilloscope, arrd the grid bias voltage with a voltmeter to determine which voltage is at fault.

DC RESTORER

Application.

The dc restorer is used in CRT display systems to re-establish the dc level of the composite-video signal, which is lost when the video signal is applied to the CRT control grid through a coupling capacitor from the preceding video amplifier.

Characteristics

Maintains a constant bias level on the CRT control grid.

Receives input from video amplifier load.

Basic components are a diode, a capacitor and resistor.

Output signal waveform varies between the reference level and some positive value, which is determined by the peak-to-peak amplitude of the input waveform.

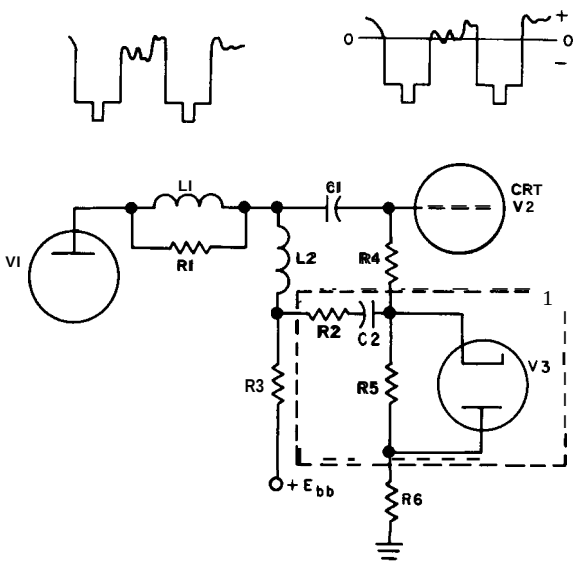
Circuit Analysis.

Generel. The dc restorer consists of a diode connected in parallel with the resistor of a conventional RC coupling network. The diode is connected so that whenever the waveform swings in a negative direction the diode conducts and produces a short RC time constant; whenever the waveform swings in a positive direction the diode does not conduct, and this results in a long RC time constant. Thus, two different time constants are produced–a short time constant during the negative half cycle of the input waveform, and a long time constant during the positive hrdf cycle. It is this difference in time constants that produces a clamped output voltage at the required dc value, which is applied to the control grid of the CRT.

This voltage restores the dc components which was blocked by the capacitor coupling the video amplifier signal to the control grid of the CRT.

Circuit Operation. A typical dc restorer circuit is shown in the accompanying illustration within the dotted lines. The circuitry outside of the dotted lines is included in the illustration to clarify the explanation and function of the dc restorer.

4



DC Restorer

V1 represents the plate circuit of the video amplifier. L1 and RI are the series peaking components of the amplifier. L2 is the shunt peaking coil and R3 is the plate load of the video amplifier. Cl couples the plate of V1 to the grid of V2, the cathode ray tube. Resistors R4, R6, and the dc restorer resistor R5 form a grid leak biasing network for the CRT. Resistor R2 and capacitor C2 couple the video signal to the cathode of dc restorer diode V3.

As the negative video output pulse appears at the plate of Vl, it is capacitively coupled to the CRT grid. Since the coupling capacitor blocks dc, only the ac waveform appears on the grid. Without any dc restoration arrangement the pulse would establish an average voltage on the CRT grid which would change slightly with each different pulse. As a result, the maximum and minimum levels of the pulse would produce different intensities than they normally would with a freed bias level. By inserting a dc restoration circuit which in effect automatically controls the bias on the CRT to compensate for the loss of the dc component through the coupling circuit, a more faithful waveform reproduction is obtained.

When a negative output is applied through Cl to the CRT grid, a portion of this output is applied to the cathode of dc restorer diode V3 through R2 and C2, causing the diode to conduct. Current flow through R2, meanwhile, charges capacitor C2 in such a direction that the end of R5 closest to the CRT control grid becomes positive and reduces the total CRT bias. When the video pulse goes positive (becomes less negative) diode V3 ceases conducting. Meanwhile, C2 discharges during the positive portions of the pulse but only very slightly, due to the long time constant to ground offered C2 by R5 and R6. When the video pulse again goes negative, diode V3 conducts and restores the charge on C2 back to its former value. Thus if the average brightness is high, the negative swing from maximum positive to maximum negative value is greater, and diode V3 conducts longer causing a greater peak current flow and a greater positive charge appears across C2. Hence the CRT bias decreases further producing the greater brilliance. Conversely, when the negative swing applied to V3 is smaller, conduction of V3 occurs for a smaller period and less voltage is developed across C2. Consequently, the CRT negative bias increases by the reduction of charge voltage developed across C2 and a less brilliant signal appears. Parts values are normally chosen so the CRT bias is normal with V3 operating.

Failure Analysis.

No Output. Normally, failure of the dc restorer circuit will cause the CRT presentation to appear darker than normal. A quick check on operation is to remove diode V3 and note if the presentation changes. If there is no change, either the diode is defective or a faulty component exists. Check resistor R5 for proper value with an ohmmeter. With R5 shorted the dc restorer will not operate. If R5 is open no bias voltage will appear on the CRT grid when checked with a voltmeter. Also check R2 with an ohmmeter for proper value. If capacitor C2 is open the restorer will not operate, check C2 for value with an in-circuit capacitance checker. If C2 is shorted a positive bias will be placed on the grid of the CRT, and in all probability the CRT will be constantly illuminated. Do not neglect to check the values of R4 and R6 with an ohmmeter since they are a portion of a voltage divider across which the dc restorer

operates. If either is open no output will occur, but a change in value will not necessarily cause no output.

Impropar **Output** A defective V3 can cause a dark or distorted presentation. A shorted C2 can cause constantly illuminated display, check C2 with an in-circuit capacitance checker. It is important to remember that distortion or improper waveforms can occur in circuits prior to the dc restorer.

Therefore, when in doubt check both sides of Cl to ground with an oscilloscope. If the trouble exists on the input side of Cl the cause is not the dc restorer. If the trouble appears on both sides of Cl it is still necessary to eliminate components other than the dc restorer. In most instances a simple resistance and capacitance analysis will quickly reveal if any portion of the dc restorer is defective.

DAMPER AND FLYBACK CIRCUITS

Application.

The flyback circuit uses the horizontal output transformer to supply sweep voltage to the horizontal deflection coils, while the flyback (retrace) portion of the horizontal sweep is used to develop the extremely high voltage necessary for the CRT anode. The damper circuit is necessary to eliminate any undesired oscillations occurring in the output circuit due to resonance in the horizontal deflection circuit, and to supply an additional dc low voltage boost.

Characteristics.

Receives its power from the horizontal output sweep circuit.

Uses a special flyback transformer and two diodes to furnish both a high voltage and a low voltage from the same source.

Flyback transformer secondary supplies both horizontal sweep voltage to the deflection coils and high voltage rectifier **filament** voltage.

Flyback transformer primary operates as an auto-transformer to furnish extremely high voltage developed at the sweep frequency ot the high voltage **rectifier.**

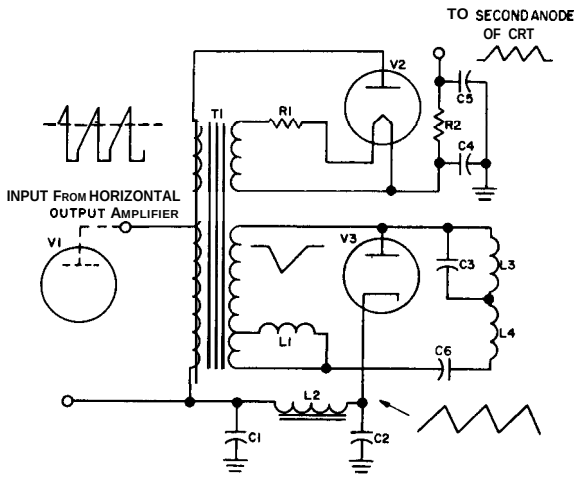
Damper diode prevents undesirable oscillation and provides dc low voltage boost.

Circuit Analysis.

General. The flyback transformer couples the horizontal sweep voltage output to the horizontal deflection coils. It also develops a high voltage for the second anode of the CRT. This high voltage is produced when the sharp trailing edge of the sawtooth sweep voltage (the flyback or retrace portion of the sweep) causes the current in the deflection coils to collapse and induce a sharp reverse pulse in the primary of the transformer. Here it is stepped up by auto-transformer action and applied to the plate of the high voltage rectifier, where it is rectified, faltered, and applied to the second anode of the CRT.

The damper circuit is essentially a diode rectifier connected between the top side of the secondary and the bottom of the primary of the flyback transformer. This diode prevents the collapsing current in the deflection yoke during the steep trailing edge of the sawtooth sweep from causing continuous oscillation in the deflection coils. In rectifying these oscillations it also provides an additional dc voltage, for boosting the out-put of the low-voltage dc power supply.

Circuit Operation. There are many circuit arrangements which can produce flyback and damper operation. Therefore, circuit operation is devoted to an explanation of one of the most commonly used flyback and damper circuit combinations. This circuit arrangement is shown in the following illustration.



Flyback and Damper Circuits

In this circuit arrangement the plate of the horizontrd sweep output amplifier is tapped across part of the primary of flyback transformer T1 (which

operates as a high voltage autotransformer). The secondary (output winding) of transformer TI is connected across horizontal deflection coils L3 and L4 and associated capacitors C3 and C6 which are used to balance out the distributed capacity of the circuit. Inductance L1 is a width control for the CRT display. It is a small coil with a tunable core, and is shunted around a portion of secondary winding of T1. Adjusting the value of the width coil changes the total inductance of the secondary. The larger the total inductance vrdue, the greater is the width. Diode V3 is the damper tube. Inductance L2 and capacitors Cl and C2 comprise a simple pi-falter network for the darnper low voltage boost supply. The top of the primary of T1 is connected to the plate of high voltage rectifier V2, while the small power needed to heat the filament is supplied by a small single turn tertiary winding on T1, and is connected in series with protective surge and load resistor RI. Resistor R2 together with capacitors C4 and C5 form a resistance type of pi-falter network to eliminate any sweep frequency ripple appearing on the high voltage applied to the second anode of the CRT.

A positive-going sawtooth current applied to the primary of the flyback and darnper transformer develops a positive going voltage in the secondary to T1. This produces a rising deflection current through horizontal sweep coils L3 and LA. Diode V3 conducts during this period because of the positive potential present on the plate of damper tube V3. During the rising sweep V3 acts as a light resistive load and dissipates" a very small amount of the total power present. The resistive load of V3 and the resistive load of the deflection coils require a slight linear increase in the amplitude of the induced square wave to produce the required sawtooth current for the deflection coils. This is provided initially by a small amount of stored voltage in the coils.

The retrace of the sawtooth sweep causes the secondary voltage of T1 to drop to zero. This, in turn, causes the current in the deflection coils to collapse, and shock excites into oscillation the resonant circuit formed by the deflection coils and distributed capacity (the oscillation frequency is in the vicinity of 75 KHz). The first alternation of the flyback oscillation is a sharp negative pulse of high potential and V3 does not conduct during this negative transient. This negative spike, however, also appears across the secondary of T1 and it is inductively coupled into the primary of T1. Here it is stepped up to a very high positive voltage by the large number of turns of the complete primary of T1. This voltage causes high voltage rectifier tube V2 to conduct and rectify the positive kickback pulses. The pulsating dc voltage from the high voltage rectifier is varying at a high ripple frequency and is easily faltered by the RC arrangement of capacitors C4, and C5, and series resistor R2, and is applied to the second anode of the CRT.

When a positive transient appears on the plate of V3, damper tube V3 conducts heavily. The oscillating transient is heavily damped by the load placed across the deflection coils by the damper tube. Before the transient oscillations are completed eliminated, however, the sawtooth sweep begins again. The combination of the heavily damped oscillations and the increasing sawtooth input produces a slight linear increase in the deflection coil current at the start of the sweep.

During the time that V3 is conducting, dc voltage is applied to the falter network consisting of capacitors Cl and C2 and inductance L2. This voltage is connected in series with the voltage from the low-voltage power supply and provides a small dc voltage boost.

Failure Analysis.

Note: Although this type of circuit is designed to supply ordy a small output current from the high voltage supply to prevent lethal shock, be careful to observe standard high voltage safety precautions. It is important to discharge ***both*** the CRT anode and the high voltage filter capacitors before making voltage or resistance checks on the high voltage portions of this circuit.

No **Output.** Assuming that the input of this circuit, which is the output from the horizontal sweep output amplifier, is correct, a no-output condition could occur if the primary of T1 were shorted or open. In either case no voltage would be coupled to the secondary of T1, and no voltage would appear on the plate of the high voltage rectifier V2. Thus there would be no sweep voltage produced by the deflection coils, or high voltage on the second anode of the CRT. To determine whether or not T1 is defective, measure the dc resistance of the primary of T1 with an ohmmeter. Likewise, if the secondary of T1 were open or shorted, no voltage could be coupled to the deflection coils, and no large negative kickback pulse would be developed for the production of the high

voltage for the second anode of the CRT. To determine if the secondary of T1 is shorted or open check the dc resistance value of the secondary with an ohmmeter.

if horizontal deflection coils L3 and L4 were shorted or open no sweep would be produced and, likewise, no negative pulse would be developed for the production of the high voltage and the CRT would not be illuminated. To determine if L3 and L4 are open or shorted measure their dc resistance value with an ohmmeter.

If capacitor C6 were open no sweep voltage would be produced and no high voltage would be produced. Check the value of capacitor C6 with an in-circuit capacitor checker to determine if it is open.

Low or Distorted Output. If the input of this circuit is correct a low or distorted output could exist if T1 were partially shorted. Check the dc resistance values of the primary and the two secondaries with an ohmmeter.

If either L3 or L4 is shorted, or partially shorted, the sweep voltage will be distorted and a distorted pattern will appear on the CRT. While an improper kickback voltage value may be coupled to the plate of the high voltage rectifier the distortion may not create sufficient difference in value to show on a voltage check. Measure the dc resistance of L3 and L4 with an ohmmeter.

If capacitor C3 were shorted the same effect as a shorted inductance L3 would occur. To determine if C3 is shorted check C3 with an in-circuit capacitor checker.

If inductance L1 were shorted or open, the voltage coupled from the primary to the secondary of T1 would be lower than normal resulting in a smaller sweep and a lower high voltage value. To determine if inductance L1 is shorted or open check the dc resistance value with an ohmmeter.

If diode V3 is shorted, the sweep voltage will be greatly decreased and show a smaller pattern on the CRT. The high voltage at the cathode of V2 will also be lower than normal, and the best voltage will also be low.

If falter components Cl, L2, or C2 were defective the boost voltage would be lower than normal. To determine if any of these components are defective, check capacitors Cl and C2 with an in-circuit capacitor check, and check the dc resistance of L2 with an ohmmeter.

If diode V2 were shorted or open no high voltage would appear on the CRT and the presentation would not appear. Check the voltage from the fdament of V2 to ground. If resistor R1 were open, V2 would not conduct and no high voltage would be available at the second anode of the CRT. Observe whether or not the fdament appears to be illuminated, if not check RI, for value with an ohmmeter.

If capacitor C4 were shorted, the high voltage would be grounded and none would be available at the second anode of the CRT. Measure the voltage from C4 to ground, if it is low or zero check C4 for proper value with an in-circuit capacitor checker. If resistor R2 is open no high voltage would be available at the second anode of the CRT. Measure the voltage of C4 and C5 to ground with a voltmeter. If the voltage on C4 is normal but voltage appears across C5, check the resistance value of R2 with an ohmmeter. If capacitor C5 were shorted the high voltage would be shorted to ground. Check C5 with an in-circuit capacitor checker.

SECTION 10
DETECTORS

PART 10-1. AM

AM DETECTORS

General.

Detector circuits are used to remove the modulation (transmitted intelligence) from a received r-f signal and transfer it back into its original form, so that it may be used for listening, viewing, communication, or other purposes. The process of detection is also called *demodulation,* which should not be confused with the special methods used for reducing the percentage of modulation.

There are many methods of detection and many circuit variations. Amplitude-modulation detectors will be discussed here. Other types of detectors are discussed later in this section. While the diode forms the basic detector, triodes (or other multielement devices can also be used to obtain additioml amplification, or can be connected to operate as diodes. When triodes (or other types of electron tubes) are used, the detector circuits are divided into two general classes – grid detectors and plate detectors. Square-law-detectors, small-signal detectors, large-signal detectors, or power detectors may be either grid or plate types. When detection occurs in the grid circuit, it is called grid ***detection;*** when it occurs in the plate circuit, it is called ***@rte detection.*** Grid detectors are usually small-signal detectors, and nearly always have a "square law" response, with the output varying as the square of the input voltage. This type of detection is characterized by extreme distortion (as high as 25 percent) at high percentages of modulation, in contrast to practically linear operation for diodes or plate detectors. Strictly speaking, from a technical standpoint every detector, whether considered linear or not, produces a certain amount of distortion; however, some circuits produce less than others.

Generally speaking, small-signal detectors are linear over a very small range of input voltages, and, as the input increases, so does the distortion. On the other hand, plate detectors are also linear when operating over small ranges at small amplitudes; but even though considered linear, the tube grid-plate transfer characteristic is never a perfectly straight line, so that for large-signal inputs some distortion is produced. Large-signal detectors are called power detectors. They are designed to handle large input signal swings with as little distortion as permissible, and to produce large output voltages capable of driving power amplifier tubes directly. The actual power involved is relatively small though being on the order of milliwatts; consequently, with the present day multipurpose tubes and techniques, the power detector is used mostly for special purpose applications. In fact, with the present day trend to superheterodyne receivers, which feed the large output of the i-f stages into the detector, most of the high-grain detector circuits are no longer used (or needed) and are supplanted by the simple diode detector. In the less complex types of receivers, however, the high-gain detectors are still favored.

The grid-leak type detectors depend on the flow of grid current for their operation, and are used where sensitivity is more important than lack of distortion. The grid-bias detector (also known as the ***linear plate detector,*** the ***infinite-impedance detector,*** etc) is used where a large output with low distortion is needed. The heterodyne detector is used for the reception of unmodulated (CW) signals and for single-sideband applications. The regenerative detector (which may be grid or plate) is used where high sensitivity provided by regenerative feedback is desired, usually in two or three-tube receivers. The super-regenerative detector, which utilizes maximum regenerative feedback without producing oscillations, is used where the lack of gain in the stages preceding the detector makes its use desirable. The autodyne detector is essentially a regenerative detector with sufficient feedback to produce oscillation so that it can be used for unmodulated CW reception, as well as AM reception.

The semiconductor diode detector for AM is used in one of two types of circuits: the ***voltage-output*** circuit and the ***current-output*** circuit. (In other texts these circuits may be called "series diode detector and shunt diode detector".) Although semiconductors operate basically by virtue of a changing ***current,*** when current is passed though a resistor a ***voltage drop*** is produced across the resistor. Therefore both types of circuits are applicable to either

tubes or semiconductors, and the functioning is similar regardless of whether tubes or semiconductors are used. The voltage output circuit is usually preferred for electron-tube applications.

Because of the lack of gain in the diode detector, transistors are also used for detection. The transistor detector provides amplification of the detected signal. With the proper circuit comections and bias it can be made the semiconductor equivalent of the grid, plate, or infinite-impedance electron-tube detector. By suitable arrangement of biasing potentials and proper selection of the transistor, either square-law or linear detection can be achieved.

While the semiconductor diode detector is used universally in electron-tube equipment, the transistor triode detector is generally used only in all-transistor equipments. When used, the transistor detector is limited to the common-base and common-emitter configurations because of the less-than-unity gain provided by the common-collector circuit.

DIODE DETECTORS (ELECTRON TUBE)

Application.

Diode detectors are used to remove the modulation from the received r-f carrier and convert it into the original intelligence transmitted. These types of detectors are usually used in superheterodyne receivers, or in receivers supplying a large input signal to the detector. They are also used in test equipment where linear detection is required (particularly in vacuum-tube voltmeter applications) and as field strength indicators for transmitters.

Characteristics.

Operates linearly over a large range of input voltages.

Has a relatively constant input impedance which is independent of the input voltage.

Does not amplify the input signal.

Distortion produced for normal operation is on the order of 1 to 2 percent.

Circuit Analysis.

General. The ideal detector produces no distortion in the process of detection, and reproduces the modulation signal exactly as it was before modulation of the carrier. There are three forms of distortion possible in the detection process, namely, amplitude, frequency, and phase distortion. When extra frequencies are developed in the demodulation process that did not exist in the original modulation, the result is a form of amplitude distortion. When the detector is more responsive to some frequencies than to others, frequency distortion results. When the phase relationships between the modulation frequencies are changed, phase distortion is produced. The diode operation, while considered linear, is not perfectly so; that is, instead of a straight line relationship between the input and output, the tube transfer characteristic is curved, especially at the low end. Thus, for small signals (on the order of millivolts), a nonlinear or distorted output is obtained. Actually, for small signals the diode operates as a square-law detector; that is, the output varies as the square of the input voltage. Thus like the grid detector, which also operates on a curved transfer characteristic, the greater the percentage of modulation, the greater the distortion (a maximum of 25% distortion). To minimize this form of amplitude distortion, which is inherent in the diode construction and cannot be eliminated, the diode detector is usually operated with large input voltages. In other words, it is used only after numerous stages of r-f or i-f amplification, so that the signal to be demodulated is on the order of volts. It is evident that while a steady signal can be made to produce no distortion, a signal which varies in amplitude from zero to some maximum value will produce a slight amount of distortion whale operating near its zero value, even with many stages of amplification. Hence the nominal rating of 1 to 2 percent distortion for diode detection. Finally, excessive capacitive reactance shunting the detector load will cause a dropping of output at the high audio frequencies (above 10 kHz), producing a phase shift of the high frequencies as compared with the low and medium frequencies, and thereby causing distortion. Thus it is clear that, while the diode is considered the best of the large-signal detectors, it does produce some distortion.

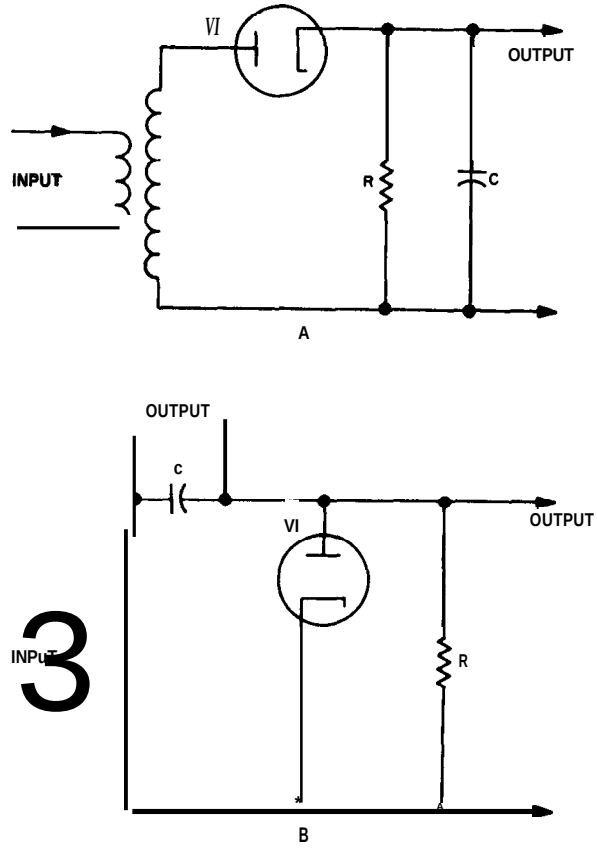
Since the diode is a two-element electron tube, it operates essentially as a simple half-wave rectifier, similar to the power rectifier used to supply plate voltages, except that it operates at radio frequencies

4

rather than at powerline frequencies. Like the power rectifier, the diode detector must also have a filter (rf) to minimize ripple voltage at the carrier frequency. Similarly, it produces a dc output voltage, plus the audio-frequency modulation component. Since the detector supplies a voltage to the audio amplifier stages following it, full-wave rectifier circuits are occasionally used to supply greater output with less faltering. For most applications, however, the simple half-wave rectifier connection is used because it requires fewer components, is cheaper to produce, and has sufficient output for present-day audio stages.

Although the diode consumes little power in the detection process, it does place a load on the input stage; it is usually considered to act as if it were a resistor of half the load-resistance value, shunted across the input circuit. Normal efficiency ratings are better than 80 percent, with 90 percent being the rule rather than the exception. This is true because the loss in the diode is small, since the diode plate resistance is usually much less than the detector load resistance.

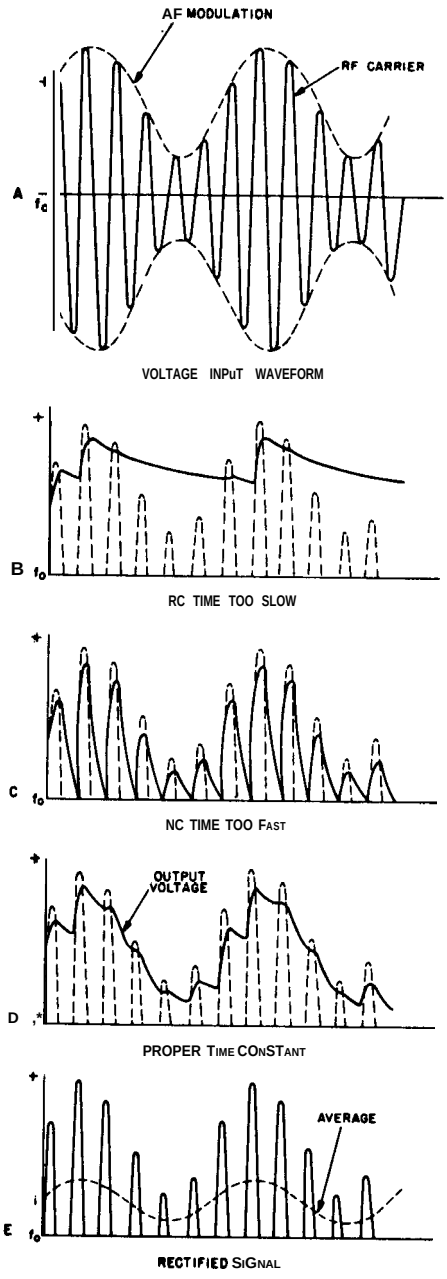
Circuit Operation. Two forms of the basic diode circuit are shown in the following illustration, with circuit A being the most prevalent in use. Both diode circuits are identical in operation, but circuit B offers an alternative output connection (accross capacitor C) if desired, and, since the capacitor is in series with the input and the diode, it prevents the low dc resistance of the input transformer secondary from shunting the diode local at the signal frequency.



Basic Diode Detector Circuits

For simplicity, the following illustration shows an untuned input transformer; actually, in most modern receivers, both the primary and secondary circuits are tuned. Where high-Q circuits with extreme selectivity are employed, some of the high-frequency sidebands are removed by the narrow pass band; as a result there is a lack of high-frequency response in the detector output. This effect, however, is not inherent in the detector–it is due to poor design of the tuned circuits.

Basic operation consists of the charge and discharge of the R-C circuit, which uses the voltage developed across R to charge C to nearly the peak voltage of the input signal. When the plate is positive with respect to the cathode, the diode conducts and charges capacitor C. Since there is a small voltage drop in the diode between cathode and plate when conduction occurs, it is apparent that the maximum developed detector voltage can never be exactly equal to the peak applied voltage, but will depend upon the ratio of load resistor R to the resistance of the diode. Therefore, the detector efficiency can never reach 100 percent, though it does average around 90 percent. However, if C is too large, its low reactance in parallel with R will shunt the signal, and a lower output will result. Detector charge action and discharge action are shown in the accompanying figure for the tone-modulated input waveform of A; B, C, and D illustrate the charge and discharge of the capacitor. On each positive half-cycle of the radio-frequency signal, capacitor C charges to a maximum value as determined by the percentage of modulation. On each negative half-cycle, capacitor C discharges at a rate fixed by its circuit time constant. As shown in waveform B, the time constant is too slow, and C cannot discharge fast enough to follow the modulation on the negative swing before the next positive r-f half-cycle begins; consequently, the negative portion of the modulation signal is effectively chopped off, and a distorted output results. The time scale is exaggerated to convey the idea more clearly. In contrast to the time constant just considered, the time constant of example C is too fast, and the average output drops to a low value. Example D shows the effect of a proper time constant. It is evident from the examples that either too fast or too slow a discharge rate (time constant) will distort the received-signal waveform.

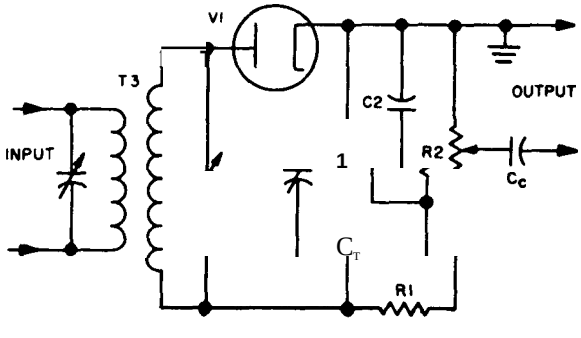


Detector Charga and Discharge Action

From part E of the figure, it is evident that the modulation consists of pukes at the carrier frequency and that the amplitude is proportional to the modulation percentage. Also, it can be seen that at zero modulation a carrier frequency voltage exists which is proportional to the carrier amplitude. Thus across load resistor R is developed a dc voltage for automatic volume control use, which will be discussed more fully in a following paragraph. It can also be seen that a carrier-frequency ripple will exist; that is eliminated by use of a low-pass falter (in addition to the bypassing action of C, whose reactance is small at the carrier frequency).

From part E of the figure, it is also evident why the diode detector can be considered as a half-wave rectifier. For linear operation and assuming perfect rectification, the diode would conduct only on the positive excursions of the modulation signal, remaining inoperative on the negative signal excursions. In this case, the positive excursions are the signal above the f. line, and the negative excursions are the signal below the line. Thus, only the positive portion of the modulation signal is rectified, and the output consists of pulses of current at the modulation frequency. These pulses of current are used to charge and discharge capacitor C and thereby produce the audio output voltage of part D, as explained previously.

A typical diode detector circuit with an r-f filter is illustrated in the foIlowing figure. The input transformer (T3) has both primary and secondary tuned for maximum selectivity.



Typical Diode Detector

The r-f filter consists of Cl and R1 acting as a low-pass filter arrangement assisted by C2. Capacitor C2 performs a dual function: in conjunction with R2 it can be considered to form a low-pass r-f filter, and it can also be considered as a straight bypass across load resistor R2. In either instance, however, it helps eliminate any r-f remaining in the i-f carrier, and also develops an audio output voltage in accordance with the average value of the diode load current passing through load resistor R2.

Design Considerations. When the plate of the diode is more positive than the cathode, current flows, producing a voltage drop across load resistor R2 which follows the modulation signal. Current flow on the positive signal swing is limited only at saturation, which normally does not occur even with very strong signals at 100 percent modulation. As the modulation signal swings in the negative direction, the current flow diminishes until the negative peak is reached, where it again reverses and increases (assuming a sine-wave signal). On strong signals with high percentages of modulation (over 75%), however, peak clipping may occur. The clipping effect is produced by the inability of the diode to conduct when the plate becomes negative with respect to the cathode. Even with the unmodulated carrier signal, noise effects produce conduction in the diode and provide a small residual average dc voltage which makes the cathode positive with respect to the plate, Thus, on the negative peaks of the modulation signal, with large signal swings and percentages of modulation between 80 to 100 percent, the output voltage is driven to zero, the extreme portions of the negative peaks are clipped off, and the output voltage no longer follows the modulation signal, With improper design, this distortion can be as great as 10 to 12 percent; the practical diode detector, however, is not operated at levels which produce such excessive distortion, and a normal value of 1 to 2 percent is maintained.

The diode detector is also subject to a reduction of output at the higher audio frequencies (above 10 kc) because of the capacitive shunting effect of C2 on load resistor R. Note also that when the reactance values of any of the detector bypass capacitors become low for the frequency of the modulation signal being detected, R1 and R2 are effectively connected in parallel, reducing the load resistance and output voltage. The same effect holds true for the resistance-coupled load of the amplifier stage following the detector. When the reactance of the coupling capacitor becomes a low-resistance path for

the audio signal, then the grid input resistance of the audio stage is effectively in parallel with both RI and R2, and the reduction in output voltage is particularly noticeable at high gain settings of the volume control. This a-c shunting of the diode load is taken into consideration in the design, so that normally no effect on operation is noticed unless parts values have changed.

Failure Analysis.

No Output. A no-output condition is usually limited to an open or short-circuited component or a defective diode. With an open input transformer, stray capacitive coupling may feed enough signal through to produce an output. With an open diode load resistor or a short-circuited bypass capacitor, however, no output will be obtained. Usually, a resistance analysis will quickly locate the defective component.

Low Output. Lack of sufficient input signal will cause a low output, and could be due to poorly soldered (high-resistance) joints or to a defective input transformer. Low tube emission may also cause a weak output, although it usually shows up as a fading signal on a strong local station. An open load bypass capacitor will reduce the output, as only the average current flow through" the load resistor will now prcrduce an output. A lack of r-for i-f amplification preceding the detector can also cause low output; therefore, it is necessary to isolate the detector by checking with a TVTM for adequate input and output. Since no amplification is produced in the diode detector, but the detection efficiency is high, an output indication lower than 10 percent of the input indication would be indicative of possible detector trouble.

Distortad Output Since diode detection is linear, a distorted output signal usually indicates component changes. Amplitude distortion is a definite indication of nonlinearity in the detector, provided that the input signal to the detector is linear. Lack of high audio frequency response would be directly traceable to excessive selectivity, caused by regeneration in the preceding i-f stages or to excessive capacitive shunting of the detector, particularly in video applications. Distortion at high volume levels with a strong, heavily modulated local signal would indicate normal peak-clipping effects. Poorly soldered (high-resistance) joints can be suspected when component values and tube emission are normrd. Fringe howl or a tendency toward oscillation would indicate a lack of r-f filtering. Because of the simplicity of the circuit, an oscilloscope waveform check should quickly locate the trouble.

VOLTAGE OUTPUT DIODE DETECTOR (SEMICONDUCTOR)

Application.

The semiconductor diode detector with a voltage output is usually used as the second detector in superheterodyne receivers, or as a linear detector where large input signals are supplied. It is also used in test equipment where linear response is desired, as in VTVM'S and field strength indicators.

Characteristics.

Operates linearly over a large range of voltage.

Does not amplify the input signal.

Has an average efficiency of approximately 90 percent.

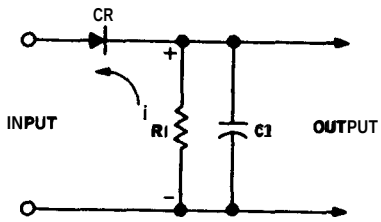
Normal large-signal distortion is on the order of 1 to 2 percent.

Is not restricted to any particular frequency range, but is operable on the entire electronic spectrum.

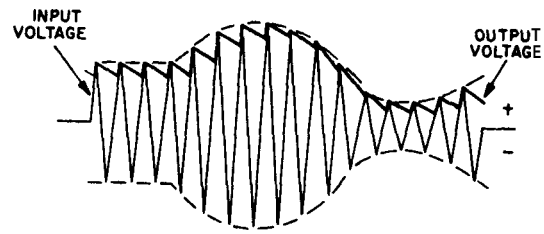
Circuit Analysis.

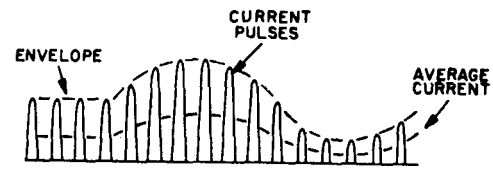
General. The principal difference between a tube diode and a semiconductor diode is the reverse-leakage current of the semiconductor, plus a difference in current and voltage ratings. As far as the diode detector is concerned, the reverse-leakage current is usually negligible. Although it does produce a slightly increased loading effect on the input circuit, this increased loading is of interest only when the - diode is operated as a small-signal detector. In this instance operation is not linear, but observes a square-law response (output varies as the square of the input voltage). It is this weak-signal square-law response which creates the inherent distortion in the diode detector. As normally operated, the diode voltage-output detector is employed after a number of stages of amplification. Thus, the input signal to the detector is relatively large in amplitude, the response is relatively linear, and the basic fidelity of the diode detector is achieved.

Circuit Operation. A simplified schematic of the voltage-output diode detector is shown in the following figure.



Voltage-Output Diode Detector





Detector Waveforms

From this figure it can be seen that diode CR is in series with the input voltage; it acts as a simple rectifier, with RI as the load and Cl as the filter. The diode conducts only during the positive half-cycle of the input signal. During the negative half-cycle it remains inoperative, since it is then reverse-biased. When the diode conducts, current flows through R1 and produces a voltage drop across the resistor. The voltage developed across RI is equal to the peak value minus the drop across the diode (which is very small and much less than in an electron tube diode). Since capacitor Cl is connected in parallel with R1 it changes to the same voltage. Since the diode response is considered linear, the larger the input voltage the greater the current through R1 and the larger the charge on Cl. As the positive half-cycle ceases, the diode ceases conducting and capacitor Cl discharges through RI for the duration of the negative half-cycle. The capacitor discharge is controlled by the time constant of RI and Cl, and is not quite completed before the positive half-cycle again begins. The diode again conducts, and capacitor Cl is again charged for the duration of the positive half-cycle. Since these alternations are at radio-frequency rates and the RC time constant is on the order of seconds, the voltage to which Cl is charged never has time enough to reach the full peak value of the input voltage, and the voltage to which Cl is discharged never has time enough to reach zero value. The voltage is, however, proportional to the envelope of the modulation, rising as the input signal amplitude increases, and falling as the input signal amplitude decreases, as shown in the following illustration. Thus, the voltage across Cl is a nearly linear replica of the original modulation.

When the time constant of R1 and Cl is too short (capacitor, resistor, or both are too small), the capacitor voltage cannot follow the envelope (it reaches full charge before the signal reaches its peak), part of the signal is lost, and the detected modulation is distorted. When the time constant is too long, the capacitor tends to smooth out variations in the modulation (it cannot respond to very fast voltage variations–only slow variations), and distortion occurs. With the proper time constant, the capacitor is never fully charged or fully discharged, but rather follows the peak excursions of the envelope in accordance with the audio modulation.

Failure Analysis.

No Output. A no-output condition can occur from failure of the diode to conduct, from an open or shorted load resistor, or from a defective capacitor. A resistance and continuity check will determine whether the resistor is satisfactory, whether the diode front-to-back resistance is normal, and whether the capacitor is short-circuited. With the resistor and diode checked out, it is a simple matter to connect a capacitor in parallel with the suspected capacitor to determine whether it is open (an output will appear if the capacitor is open). If an oscilloscope is available,

491-044 0-73 -57

it may be used to observe the waveform across the load resistor.

Low Output. Low output can occur from a change in the time constant of the circuit, or from a lack of sufficient input to the detector to produce the desired output amplitude. Poorly soldered connections, a leaky capacitor, or a defective diode can cause this condition. Under normal operation, the amplitude of the signal across the detector should be from 80 to 90 percent of the input amplitude. Less than this value indicates lack of efficiency due to increased resistance in the diode or leakage in the capacitor.

Distorted Output. This can result from a change in capacitor value. Either too large or too small a capacitor will cause distortion. A change in a resistor or capacitor value, producing too short or too long a time constant, will also cause distortion. The parts should be within 10 to 15 percent of their rated values. If the values are normal, the trouble must be in the diode. A high-resistance condition caused by a poorly soldered joint is always a possibility.

CURRENT OUTPUT, DIODE DETECTOR (SEMICONDUCTOR)

Application.

The current output diode detector is used to detect the audio modulation in semiconductor receivers, where the voltage output is small and does not vary sufficiently to produce full output from the audio amplifier states.

Characteristics

Is usually self-biased.

Linear current swings produce linear output voltage swings.

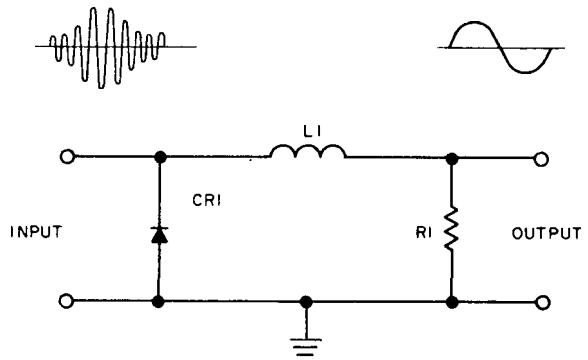
Impedance at the output is low, and usually direct coupling is employed.

Is inherently a small signal detector.

Circuit Analysis.

Generel. The current form of diode detector operates similarly to the voltage form of diode detector. Except that the output variations are in the form of current pulses rather than voltage pulses. However,, by passing this current through a shunt resistor, a voltage output is developed across the resistor. The voltage output is, however, much reduced so that a current amplifier is required to build up the signal to a respectable output level. Thus, while the voltage detector will supply an output which can drive the following audio stage, the current detector usually utilizes direct coupling and an additional transistor stage to control another transistor stage in the output. Because of the direct coupling, response is somewhat better. On the other hand, the higher frequency signals are slightly attenuated by the coil reactance of the series inductor, which operates similar to the power supply low pass filter. This has the effect of eliminating any high frequency ripple - and distortion in the output, so that practically the response is identical to the voltage diode but of lesser magnitude. Actually the current detector operates as a square law detector and is usually used in circuits other than the superheterodyne (which uses the voltage form of detector). Therefore, the shunt diode (current) detector is used mainly in regenerative receivers of the pocket variety and is usually combined with reflex audio circuits to provide a loud but distorted output.

Circuit Operation. The circuit of a typical current diode detector is shown in the following illustration.



Current Diode (Shunt) Detector

As shown, the diode is connected in shunt with the input circuit, and L1 is connected in series, with load resistor RI also connected in shunt to ground. The LR combination of L1 and R1 have a combined time constant which is satisfactory for detection.

When the input signal is applied across CR1 the output is shunted to ground for the negative half cycle of the r-f input signal because CR1 conducts

and no output occurs. During the positive half-cycle the signal is applied to L1 and current flows through RI to ground and produces an output current which follows the r-f envelope. This action occurs because of the integrating effect of the LR circuit. During the current flow through Ll and RI to ground a field is built up around L1 with tends to keep current flowing in the same direction when conduction ceases, and during the time that the detector diode is shunting the signal to ground, the field discharges through RI. Thus an integrating action occurs similar to that which would be produced if R1 were shunted by a capacitor, and the output current follows the peak waveform closely. Because of the reactance offered to high frequencies by L1, there is always a loss of voltage which makes the output smaller than the applied signal. Since a conducting path to ground is offered on the positive half-cycle of input signal, the rectification efficiency is lower than for a series connected diode (voltage detector) hence this circuit is not often used. In addition the low shunting effect during conduction and the low overall impedance to ground during the nonconducting period provide a heavy load on the source, and creates distortion when sufficient driving power is not available. Thus, the shunt detector is usually less preferred than the higher impedance, voltage-output form.

Failure Analysis,

No Output. If the diode is shorted, or if either L1 or R1 are open there will be no output. Because of the few components involved a resistance check with an ohmmeter will usually locate the defective part.

Low Output. A defective diode CR1, high resistance soldered joints, or large changes in L1 or R1 can reduce the output. Check the values of L1 and R1 with an ohmmeter.

Distorted Output. If the output is continuously distorted, check the diode. If the distortion still persists, use an oscilloscope to observe the input and output signals, since the distortion is probably located in an earlier r-f stage or a later audio stage.

DIODE DETECTOR WITH AVC (ELECTRON TUBE)

Application.

The diode detector with AVC is universally used in broadcast, TV, communications receivers, and other high-gain superheterodyne circuits to provide automatic gain or volume control with detection, in a signal tube or envelope.

Characteristics.

Operates linearly over a large range of voltage.

Input impedance is relatively constant and independent of the input voltage.

Does not amplify the input signal.

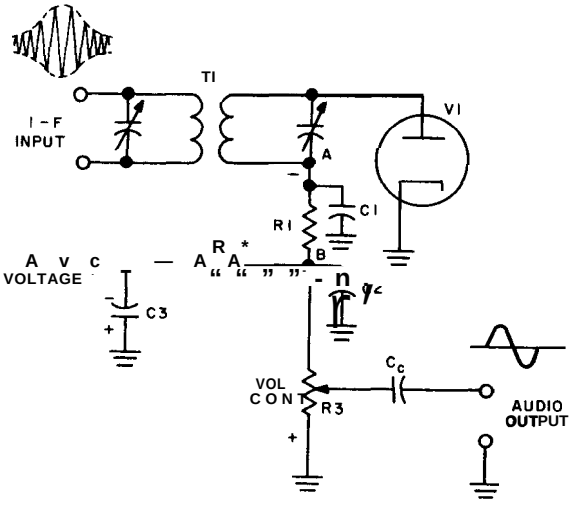
Maximum distortion is of the order of l-to-2 percent.

AVC output voltage varies directly with the amplitude of the input carrier.

Circuit Analysis.

General. The diode detector with AVC is identical to the diode detector without AVC, except for the circuit arrangements provided for AVC take-off. Discussion of the operation of the detector in stripping-off the modulation from the carrier is covered completely in the discussion of the Electron Tube Diode Detector earlier in this section of the Handbook. The reader should refer to the previous discussion for proper background before preceding with this discussion.

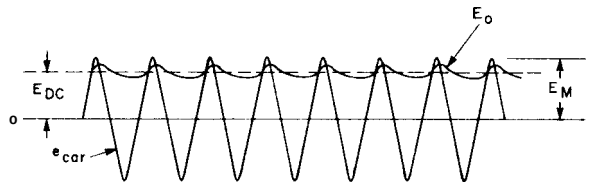
Circuit Operation. The schematic of a typical diode detector arranged for AVC take-off is shown in the following illustration.



Diode Detector With AVC

The plate of VI is connected to IF input transformer T1 and the cathode is grounded. Resistor R1 with capacitors Cl and C2 form low-pass RF filters, while C3 and R2 are audio and decoupling falters. The audio voltage is developed across volume control R3, and applied through coupling capacitor C_c to the following audio amplifier stages.

When unmodulated, the input consists of a single frequency. When modulated, the input consists of a basic carrier frequency plus an upper and lower sideband containing the modulation. Thus the diode detector output always contains a dc component which is directly proportional to the carrier amplitude or strength. This is the voltage which is used for AVC. For large signal detection the diode detector is considered to be a simple half-wave rectifier, which conducts as long as VI plate is positive with respect to the cathode. When VI conducts, election flow is from the grounded cathode to the plate, through the secondary coil of IF transformer T1, R1, and R3 to ground. Thus current flow through R1 produces a negative voltage at point A (which is not used), and the AVC voltage is developed across volume control R3 at point B. This negative voltage drop is applied through R2, back to the grids of the r-f and i-f stages. Because the feedback of the AVC bias is to the grids of the preceding stages it is clear that there must be no extraneous modulation or RF on this lead. Otherwise, both the audio and RF components could again be amplified and redetected causing distortion and unwanted feedback. Therefore, R1 and Cl and C2 are connected as a conventional low-pass falter in series with the current flowing through R3. The output waveform at point A consists of the dc and r-f component as shown in the following waveform illustration for an unmodulated carrier for ease of discussion. The instantaneous r-f carrier component (e_{car}) is bypassed to ground partially by Cl. During the positive portion of each carrier cycle C2 is charged through R1, and during the negative portion of the carrier signal the capacitor tends to discharge.



Detector Voltage Relationships

The result is the heavy curve labelled E_o. The average value of pulsating voltage E_{DC} is the actual AVC voltage. Since these pulsations occur at radio frequency rates, the effective voltage variation between charge and discharge of the capacitor is so small as to be negligible. Recall from the above discussion that the modulation component of the signal is also present. However, when modulated signals are detected, these audio ripples are smoothed out by another low-pass falter consisting of R2 and C3. In this instance, the value of the filter time constant are such that output voltage E. appears as a straight line (pure de). The time constant of R2 and C3 is made sufficiently large so that it takes more than a single audio cycle to charge or discharge. Although this increase of time constant prevents on instantaneous change of AVC voltage for an instantaneous change in carrier level it is usually satisfactory for most types of fading encountered. Particularly, since decoupling RC networks similar to R2 and C3 are also inserted at each tube grid associated with the AVC and increase the effective values of R2 and C3. The fast time - constant response necessary for single sideband or CW use is obtained by making the value of C3 much lower than is normally used in AM circuits. Since the grids of the controlled stages do not draw grid current, there is no flow of current through R2,

other than that required to charge the other decoupling capacitors on the AVC line. Hence there is no large voltage drop, and the RC filter can be used without encountering any losses because of excessive current drain. The detected audio or ac component appears across volume control R3 and is applied through coupling capacitor C_c to the audio amplifier stage.

Failure Analysis.

No Output. Lack of an input signal due to failure of the associated receiver circuits, a detuned or defective IF transformer, T1, a defective diode, V1, or open or short circuited parts will cause a no-output condition. Measure the voltage to ground at points A and B with a high resistance voltmeter. A negative voltage at these points indicates normal functioning. Lack of voltage at these points indicates either lack of an input signal or a defective component. Use a VTVM or an oscilloscope to determine if an input is present, With an r-f signal on the primary, but not on the secondary, T1 is defective. If the secondary voltage is much lower than the primary the secondary tuning needs adjustment. When adjusting, if it still provides a low output and does not respond to the adjustment, T1 is defective. If either R, R2 or R3 is open, the series circuit will be interrupted and no AVC voltage will appear at points A or B. If R1 or R3 is shorted, no AVC voltage will be developed; however, if R2 is shorted the circuit will still operate. With normal AVC voltage but no audio output, either volume control R3 is tuned down, R3 is defective, or coupling capacitor C_c may be open. A resistance check will determine if these parts are open or shorted. If Cl or C2 are shorted, no AVC voltage or detected output will be obtained. Use an ohmmeter to measure the resistance to ground, or an in-circuit capacitance checker Cl and C2. If the parts are satisfactory, diode V1 must be at fault.

Low Output. A weak input signal, or low emis-sion in the detector diode are the prime cause of low output, as well as mistuning of T1. The effects of humidity can also cause circuit leakage which reduce the output. Although a slight change in parts values with age may cause a reduction of output, it most probably would go unnoticed, since turning up the volume slightly would restore the output to normal. If it becomes necessary to turn the volume control excessitively for a known signal, first check the preceding circuits to be certain that they are operating properly and are not at far.dt, before trouble-shooting the detector.

Distorted Output. If the values of Cl and C2 changed sufficiently to produce the wrong time constant, either too fast or too slow, distortion would occur. Likewise, if the emission of V1 is so low as not to supply the full peak current demand, distortion caused by clipping will also occur. Check the values of Cl and C2 with an in-circuit capacitance checker. A change in the values of R2 and C3 will change the attack time of the AVC loop but will not normally cause distortion. However, if C3 should short-circuit, the AVC voltage would be grounded out and the stages preceding the detector would operate at maximum sensitivity, and probably cause overloading with consequent distortion.

DIODE DETECTOR WITH NOISE LIMITER (ELECTRON TUBE)

Application.

The diode detector with noise limiter is usually used in radiotelephone reception to prevent noise pulses from interfering with, or garbling, voice transmissions.

Characteristics

Operates linearly over a large range of voltage.

Input impedance is relatively constant and independent of the input voltage.

Does not amplify the input signal.

Noise peaks are clipped without excessively increasing the distortion.

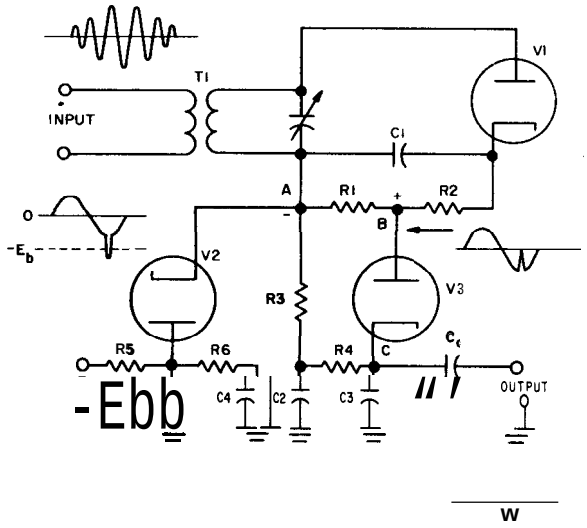
Circuit Analysis.

General. The diode detector with noise limiter is identical in operation with the Diode Detector described earlier in this section of the Handbook, except for the noise limiting circuitry. The reader should refer to the previous discussion for proper background before proceeding with this discussion.

Both shunt and series types of noise limiters are used. The series type continually conducts but stops conducting when a noise pulse arrives, and thus leaves a gap in the signal in place of the noise pulse. The shunt type noise limiter conducts only when the noise pulse exceeds a predetermined bias level, shorting the input to ground, and also leaves a void in the signal. Since these noise pulses and consequent

signal holes are of short duration, the integrating effect of the ear on the sound minimizes this effect. In most practical noise limiters, the limiter becomes effective at around the 85 percent modulation level, so that subsequent peak flattening causes some distortion and a slight loss of audio volume. The voice, however, is understandable through heavy noise interference, which would otherwise completely mask or garble the intelligence being transmitted.

Circuit Operation. The schematic of a typical diode detector with noise limiters is shown in the following illustration.



Diode Detector With Noise Limiters

Diode VI is the detector diode which rectifies the input signal from I-F transformer T1. Resistors R1 and R2 form a voltage divider load for diode detector VI, bypassed for RF by Cl. The detector voltage appearing across R1 is applied to the anode of series noise limiter V3. Resistors R5 and R6 form a bias voltage divider from a separate negative supply to ground, to supply a fixed negative cutoff bias to the anode of shunt diode limiter V2. Resistor R6 is bypassed by capacitor C4 so that any instantaneous voltage change appearing at the anode of V2 is bypassed to ground. Resistors R3 and R4 together with capacitors C2 and C3 form a low-pass falter and load circuit for series diode V2. Capacitor C_c is the detector output coupling capacitor.

When an unmodulated input signal is applied to the primary of IF transformer T1, the secondary voltage appears across diode V1 and V1 conducts for the duration of each positive r-f pulse, causing a flow of current from the cathode to plate, through T1 secondary, R1 and R2, back to the cathode and ground. A negative de voltage thus exists at point A on the schematic and varies in amplitude directly with the r-f carrier amplitude. This is the AVC voltage discussed in the previous circuit for the Diode Detector (with AVC), in this section of the Handbook. When the input signal is modulated, the negative voltage at point A also varies slowly at audio frequencies in accordance with the modulation. At point B the detected voltage is identical with that at point A except that it is smaller than at point A because of the drop across resistor RI. The RC low-pass filter combination of R3 and C2 charges capacitor C2 relatively slowly so that audio frequency signals are effectively smoothed out. Low pass falter R4, C3 operates similarly except that the time constant is faster to ensure that no r-f component appears at point C to cause feedback. Thus both falters place the cathode of series diode V3 on a common negative bus, and the drop across RI (between points A and B) appears as a forward bias on the anode of V3 (point A is more negative than point B). Thus diode V3 normally conducts, and the detected pulsating voltage at point B appears undistorted at point C, and is applied through coupling capacitor C_c as the audio output of the detector. Because RI and R2 form a voltage divider, the detected voltage to ground which appears across R2 is considerably smaller than the developed AVC voltage. When a negative noise burst appears at point B, the anode of series limiter V3 is instantly driven highly negative, while the cathode voltage changes very slowly because of the slow filter time constants provided by R3, C2, and R4, C3. Thus for most of the noise burst, conduction of diode V3 is stopped and no output appears (a hole occurs in he output). Thus the noise spike is chopped off the detector waveform, and because it occurs for such a short time, the instantaneous loss or signal goes unnoticed. When the noise burst occurs for a long period of time or is a repetitive occurrence, the loss of sigml may be noticed. For random short noise pulses this type of limiter is fairly effective.

Note also that when the negative noise bursts occur, the negative voltage at point A is increased,

and if it is fed back as an AVC voltage change the overall sensitivity of the receiver will simultaneously decrease, just when a strong signal is needed to overcome the adverse signal to noise ratio. Therefore, shunt limiting diode V2 is connected from point A to ground. Normally, the negative plate voltage, which appears on V2 from voltage divided R5 and R6 connected across the separate negative bias supply, holds V2 in a nonconducting condition. When a negative noise burst appears and is of sufficient amplitude to drive the cathode of V2 more negative than the fixed biased anode, V2 conducts and the voltage at point A is temporarily shunted to ground via V2 and resistor R6. Capacitor C4 bypasses R6 and allows the instantaneous noise burst to be discharged to ground. Meanwhile, the relatively slowly moving dc component produced by AVC action remains relatively unaffected. Consequently, the AVC voltage does not instantaneously increase (or decrease) and is effectively prevented from desensitizing the receiver during the noise burst. Thus conduction of diode V2 effectively removes the noise spike from the signal. Although the entire noise spike is not eliminated, the large peak amplitude above the fixed-bias level is removed so that the effect of the noise is considerably reduced by the shunt diode. In addition, the shunting effect of diode V2 on the detected audio temporarily reduces the signal supplied to the audio stage via series diode V3, and produces a noise silencing effect. The use of both a shunt and series diode although not absolutely necessary provides better overall noise limiting performance.

Failure Analysis

No Output. Any open circuited or short circuited condition as well as defective diodes can result in a loss of output. Lack of a negative voltage to ground at point A indicates a possible defective IF transformer T1, diode VI, or that RI or R2 are open, or Cl is shorted. Use an oscilloscope with an r-f probe to determine if an input exists on the primary of T1. A large signal on the primary, but none at all or a very minute one on the secondary indicates that T1 is defective. With an input across the diode, check the resistance of RI and R2 with an ohmmeter, and check Cl for a short. If an output can be observed at point C with the oscilloscope, but not on the other side of Cc, check coupling capacitor C_c with an in-circuit capacitance checker. If these parts are satisfactory diode V1 or V2 is at fault (an output at point C indicates that V1 is not at fault). Failure or defects of the remaining parts and diodes will not normally produce a no-output condition, but instead will produce a low output or ineffective noise elimination.

Low Output. A partial shunting of the detector output through diode V2 can occur if V2 is shorted, if the negative bias supply voltage fails, if R5 or R6 change in value, or if capacitor C2, C3, or C4 is either shorted or leaky. The capacitors may be checked for shorts with either an ohmmeter or an in-circuit capacitance checker, and the resistors can be checked with an ohmmeter. If diode V3 is defective, the output will probably be very low and distorted, depending upon the stray capacitance in the circuit.

Distorted Output. Since in normal operation the noise limited effectively eliminates a noise signal, it is evident that the output waveform will always be different than the input waveform to a certain extent. Thus a slightly distorted output will practically always be obtained. The degree of the distortion depends upon the design of the circuit. Theoretically, the limiter should operate only on noise pulses which are larger in amplitude than the signal; however, most practical circuits start operating at about the 85 percent modulation level. Hence some peak clipping of the signal usually occurs and causes distortion on the modulation peaks. In normal operation, a slight amount of distortion will be noticed and the strength of the output signal will drop noticeably when the noise limiters are activated. Follow the signal through the circuit with an oscilloscope and notice where the distortion occurs, Further resistance checks of the associated parts with an ohmmeter will usually locate the defective part.

GRID-LEA K DETECTOR

Application.

The grid-leak detector is used in simple two-or-three tube receivers, such as the regenerative type. Since this type of detector is particularly susceptible to overload and distortion at high levels of modulation, it is never used in modern high-gain superheterodyne receivers.

Characteristics.

Is self-biased by a grid-leak.

Provides good sensitivity with increased signal gain.

Operates as a square-law detector for small signals and as a linear detector for large signals.

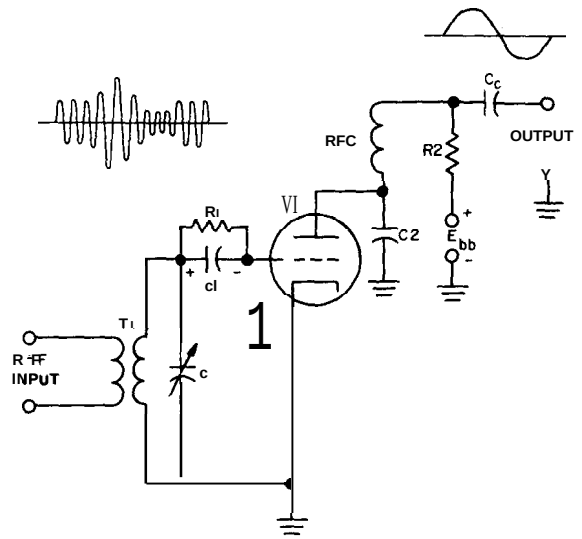
Is subject to overload and blocking effects on strong signals.

Although it produces a relatively larger output voltage than other comparable AM detectors, it is subject to more distortion.

Circuit Analysis.

General. The grid-Ieak detector, basically, uses a triode electron tube, and is considered to operate similarly to a diode detector with the added advantage of triode amplifkation. Although pentodes have been used to provide additioml gain, the triode with a low plate voltage is usually preferred because of a reduction in tube noise and distortion. In operation, the grid and cathode of the triode operate similarly to the anode and cathode of the conventional diode detector (discussed previously in this section of the Handbook). The dc bias produced by carrier rectification and the detected modulation appear across an RC network known as the grid-leak, and the modulation appears in amplified from in the plate of the triode. Since the detection occurs in the grid circuit it is known as grid detection. Because the developed grid bias is automatically controlled by the carrier amplitude, the grid-leak detector operates over a wide range of input voltage. On weak signals it operates near zero bias and uses the curved lower portion of the grid-current, grid-voltage characteristic to provide an output which varies as the square of the input signal, and is known as non-linear (square-law) operation. For large signals and large self-bias it operates over the linear portion of the characteristic curve. When overloaded by extremely strong signals, the bias reaches cutoff and conduction occurs for only part of the cycle, and the peaks are clipped, creating excessive distortion. The detailed operation of this detector under different conditions is discussed in the following paragraphs.

Circuit Operation. The schematic of a typical grid-leak detector is shown in the following illustration.

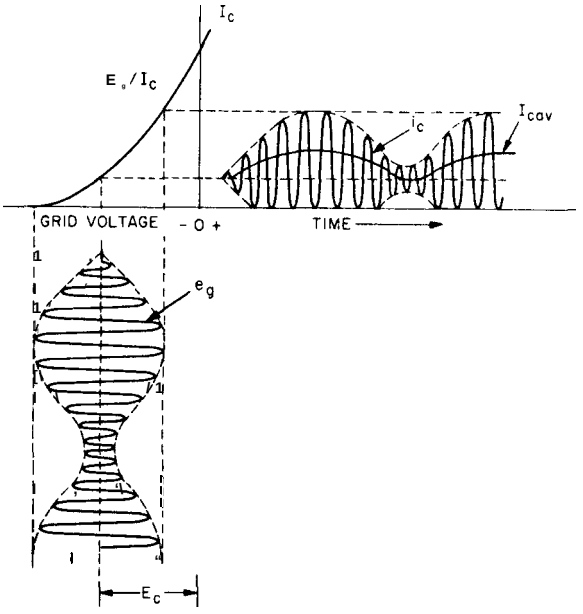


Basic (Series) Grid-Leak Detector

The r-f input is applied through r-f transformer T1, and the grid-leak network consisting of RI and Cl are connected in series with the grid of V1 and the output of T] secondary, while the cathode is grounded. In the plate circuit, resistor R2 is the plate load, and is isolated from the plate r-f component by radio frequency choke RFC. The plate is also bypassed to ground by capacitor C2, which is small enough to act as a shunt for the r-f carrier voltage appearing in the plate circuit but not the modulation. Thus only the amplified modulation appears across load resistor R2 and is applied to the output through coupling and plate voltage blocking capacitor Cc.

In the absence of an input signal, V1 is contact-biased by grid-leak resistor RI, and operates near zero bias. In this condition, only a small potential is built up across RI by grid current flow, biasing and grid slightly negative. Thus V1 is in a position to respond to both positive and negative signal variations for small signal detection. The following waveform illustration demonstrates how the curvature of the grid current versus grid voltage characteristic of V1

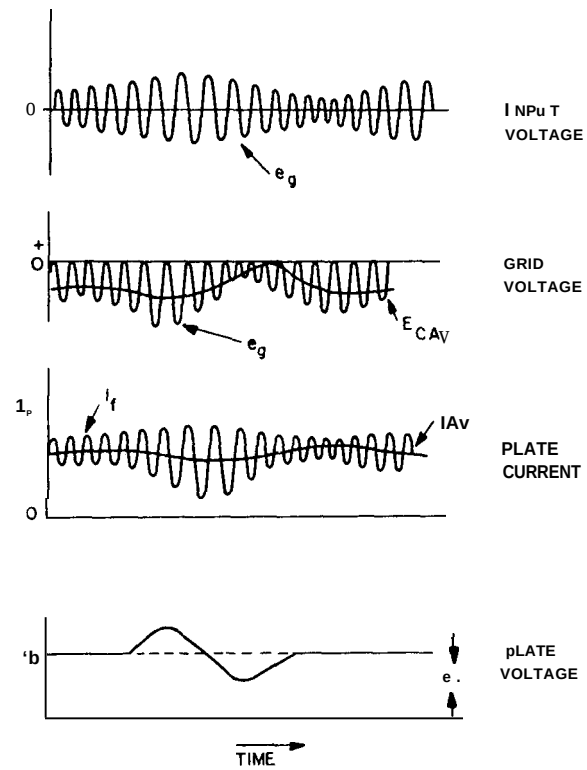
distorts the basic signal and produces amplification with distortion.



Small Signal Detection Characteristics

As shown in the illustration, when the input signal increases in amplitude grid current increases, flowing in the direction of the arrow on the schematic. Thus grid capacitor Cl is charged negatively during the positive grid swing. On the negative grid swing, grid current flow is reduced and the capacitor discharges slightly through the grid-to-cathode resistance which is lower than the high resistance grid-leak. Because of the curvature of the grid characteristic curve, the positive excursions are larger than the negative excursions. Therefore, a slowly increasing average grid current is developed as the signal modulation rises, and the average grid current falls when the signal modulation decreases, in synchronism with the modulation envelope. This develops a negative voltage across RI, which varies at the audio rate of the modulation around the negative bias level produced by the constant amplitude carrier pulses. Since the grid of V1 controls the operation and plate current of the triode, the change of grid voltage produced by the detected signal causes an identical but amplified plate current fluctuation. As this plate current varies in accordance with the modulation, a similar but amplified voltage is developed across plate load resistor R2. This is the audio output voltage which is coupled through C_c to the following audio amplifier stage. Because the r-f carrier voltage appears between the grid and the cathode of V1 it also appears in the plate circuit. Therefore, there is an r-f plate component of voltage which must be eliminated so that it can not cause spurious beats with the modulated signal, or unwanted oscillation by feedback within the tube. This is the function of RFC and C2. The r-f choke offers a high inductive impedance at the carrier frequency, while capacitor C2 offers a low impedance shunt path to ground. Hence, the r-f component is bypassed around the load resistor and power supply, and has no effect on circuit operation. Only the relatively slowly moving audio frequency current component flows through load resistor R2, to produce a corresponding audio frequency output voltage.

For large signals, the average carrier amplitude also rises, so that the grid is biased considerably negative, and only the positive excursions of r-f voltage on the input signal are effective in causing grid current flow. In this condition the detector operation is similar to a half-wave rectifier, and operates as a linear detector. The positive signal excursions produce a negative voltage across the grid leak by charging capacitor Cl. During the negative signal excursions the charge on Cl keeps VI inoperative so that the tube operates for a half cycle or less. Because maximum modulation peaks produce maximum negative grid voltage, the plate current of V1 is reduced during modulation. The reduction of plate current occurs at an audio rate and produces a corresponding audio output. As the current through detector output load resistor R2 reduces, the voltage across it and the output rises, as shown in the waveforms illustrated in the following figure of large signal detection characteristics.



Large Signal Datection Characteristics

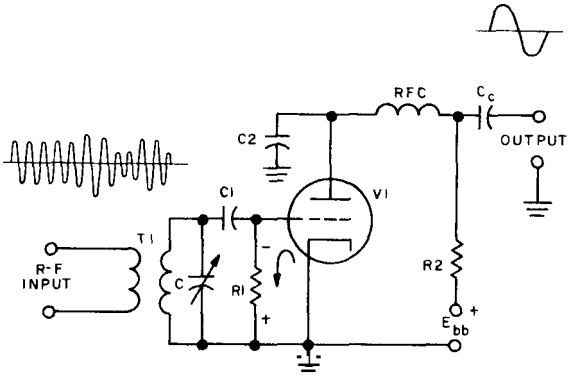
The linear grid detector is also known as a grid-leak *power* detector. In the small-signal or square-law grid-leak detector the output voltage although amplified is usually greatly distorted, therefore, large output voltages create greater overall distortion. In the power detector, the grid-leak values are reduced to prevent excessive distortion, and the input signal and the detector plate voltage are increased to provide a greater output. Thus the larger input signal produces operation over a larger output voltage swing, producing a greater output voltage with less overall distortion.

In operation, the major difference between the two types of detectors is obtained by making the large-signal, power-detector grid potential swing sufficiently negative that the flow of grid current is stopped for the major portion of the negative half cycle. During the positive half cycle of carrier voltage, grid current flow charges the grid capacitor negatively. During the next negative half cycle, some of this accumulated charge leaks off through the grid-Ieak resistor (which is connected across Cl), and is replenished during the next positive swing. Thus grid current can only flow for a small portion of the positive cycle. In the small-signal grid detector, however, grid current flows continuously, since the grid is never driven sufficiently negative to reduce grid current flow to zero. Under these conditions, the charge on the grid capacitor leaks off through the internal grid-to-cathode resistance, which is much lower than the high value of grid leak resistance used. -- In the large signal power detector the grid-to-cathode resistance is practically infinite during most of the cycle (because grid current is cut off'). Operation of both detectors is essentially the same as shown in the waveform illustration for the small signal detector, except that the grid amplitude of the large signal detector is greater, and the grid current cut-off point corresponds to the value of bias developed by the carrier signal. Whereas in the small signal detector the grid bias is always less than grid-current cutoff.

As in all electron tube amplifiers, the plate-current, grid-voltage characteristic curve is linear up to the point where saturation begins. So that both the lower and upper regions of operation are curved. If the large signal power detector is driven sufficiently, the bend on the upper portion of the curve will also cause plate rectification to occur. Thus second and third harmonic distortion components will be produced and the overall detector distortion will increase. It is also necessary that the charge and discharge of the grid-leak follow the signal amplitude during large signal detection, otherwise, blocking and distortion will occur. With proper choice of grid-leak constants (which is inherent in good design) and an adequate plate voltage which does not exceed tube ratings, the distortion can be kept to low values almost equivalent to that of the diode detector. If the input signal is reduced to a very small value, the large signal power detector merely operates as a small-signal, square-law detector with a low output and the advantages of power detection are lost.

The schematic of a typical shunt grid-leak detector is shown in the following illustration. Components are symbolized identical to. and operate exactly as explained for the series grid-leak detector discussed above. This circuit is generally used for the power type detector because slight advantages are claimed for avoiding blocking effects. The shunt grid resistor

provides more loading on the tuned r-f input circuit, however, and produces a reduction in selectivity.



Shunt Grid-Leak Detector

Failure Analysis.

No Output. An open or shorted grid of plate circuit, a defective tube, or an open coupling capacitor, Cc, can cause loss of output. Measure the plate supply and plate voltage with a high resistance voltmeter. Normal plate voltage indicates that load resistor R2 and the RFC are probably satisfactory and that C2 is not shorted. Apply a modulated signal from a signal generator to the input terminals of r-f transformer T]. Use a VTVM, electronic voltmeter or an oscilloscope (it must offer high impedance so as not to load or disturb the circuit operation) connect between grid and ground, to determine if the input signal produces a slight negative bias and if a signal is present. If no signal is present, T1 is defective. If the detected signal can be observed in the grid circuit but not in the plate circuit, VI is defective. If the signal is present in both grid and plate circuits but no output exists, check coupling capacitor C_c for an open circuit. (Use an in-circuit capacitance checker).

Low Output. Low plate voltage, a defective tube or too weak an input will each cause a reduced output. The weak input signal may occur because r-f transformer T1 is not tuned to resonance. If T1 will not tune to resonance, either the signal frequency is out of range or T1 is defective. When in doubt, apply a modulated input from a local signal generator and note that the signal peaks in intensity as the resonance point of T1 is reached. If this occurs but the desired signal is still weak, additioml r-f amplification or a better antenna are required. If the signal generator cannot produce a strong output, the detector is probably at fault, Check the plate voltage of VI; if the plate voltage is normal, either V] is defective or output coupling capacitor C_c is leaky or paretically open. If the plate voltage is not normal but is lower than usual, R2 may have changed value, the rfc may have developed a high resistance, or C2 may be leaky or shorted. Use an ohmmeter to check the resistance of R2 and the RFC, and check the resistance of C2 to ground. Replace any part which has a resistance higher or lower than that specified in the technical manual for the equipment. If the detector seems to be operable but the receiver output is low, it is possible that the audio stages following the detector are at fault, and not the detector circuits. To check the audio stages, use an audio signal generator and apply it to the output stage plate, then to the grid and note if the signal increases. Follow this procedure back to the detector to locate the defective audio stage.

Distorted Output. Excessive distortion can be produced by a change in the constants of the grid-leak network, by too high a plate voltage, or as a result of low emission from VI. If replacing the tube with a known good one does not eliminate the distortion, check the plate voltage with a high resistance voltmeter. If the plate voltage is normal, check the value of R1 and Cl with an ohmmeter and capacitance checker. If the grid-leak components are within tolerance value and distortion still occurs, it is possible that the input signal is too strong and overloading is causing the distortion. It is also possible that T1 is only tuned near resonance and the sidebands are being clipped. Tune T1 properly, and reduce the input signal, if possible.

PLATE DETECTOR

Application.

The plate detector is used in small receivers as a power detector. It is usually used in tuned r-f receivers to supply a large audio output. While it can be used in the modern superheterodyne, it camot be used to supply a simple AVC voltage. Thus, it is usually more economical and simpler to use a diode

detector. The plate detector is, however, extensively used as the detector circuit in vacum tube voltmeters and similar test equipment.

Characteristics.

May use either self- or fixed-bias (self-bias is most prevalent).

Provides good sensitivity and increased signal gain.

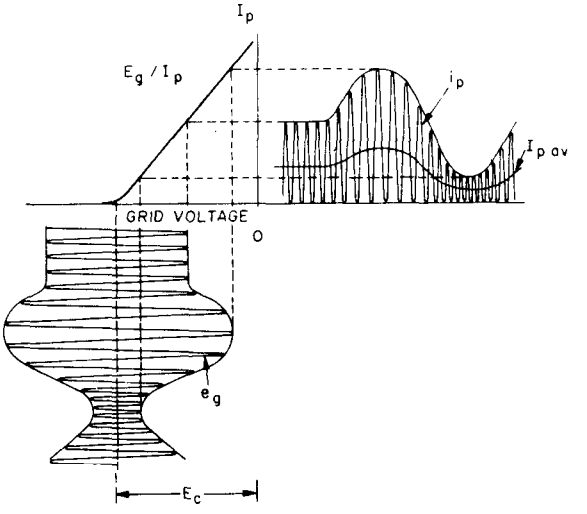
Operates as a linear detector for large signals.

Is normally operated with large input signals as a power detector.

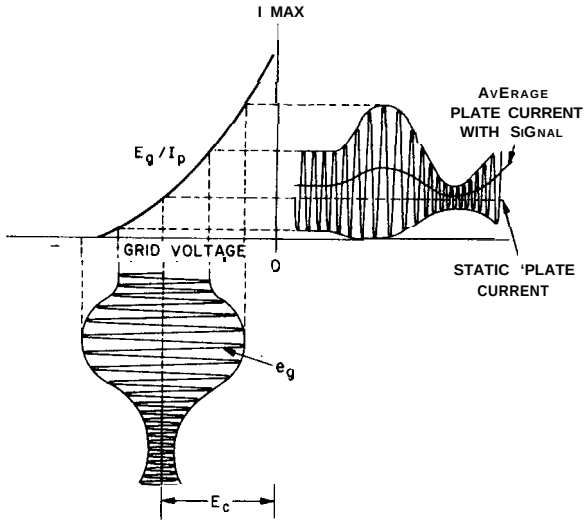
Distortion is considered to be slightly less than that of the grid-leak detector, and not better than the diode detector.

Circuit Analysii.

General. The plate detector usually operates class B, that is, it is biased to plate current cutoff, and for this condition it operates as a large signal linear detector. When used for small signals, or as the detector of a vacuum-tube voltmeter it operates on the lower curvature of a class A biased tube characteristic, and is a square law detector. In the plate detector there is no rectification of the signal in the grid circuit. The r-f input signal causes the ac grid voltage to vary the tube plate current, producing both amplification and detection. Detection occurs in the linear plate detector because only one side of the signal (the positive portion) causes the tube to conduct, while the negative portion remains below cutoff and has no effect. Thus the plate output varies in accordance with the r-f envelope of the modulated carrier as shown in the following waveform for linear detection. The square Iaw detector operates over both the positive and negative variations of the input signal. Because of the curvature of the tube e_g/i_p characteristic for small input signals, an amplified but distorted plate output results. The large positive grid swing produces a greater plate current than the smaller negative swing. Thus the average output is greater during modulation than without modulation, as shown in the following waveform illustration.



Linear Operation



Square Law Operation

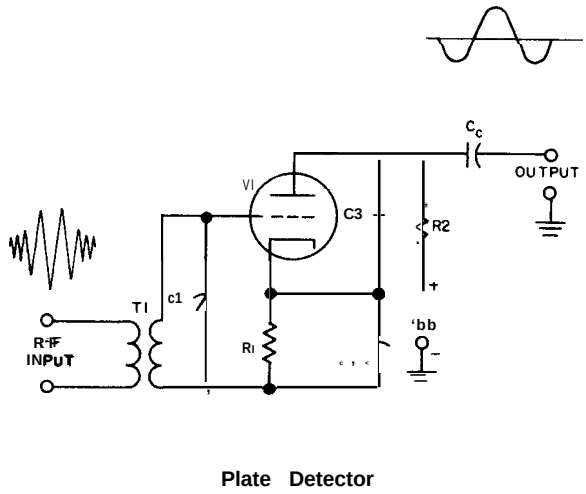


Plate Detector

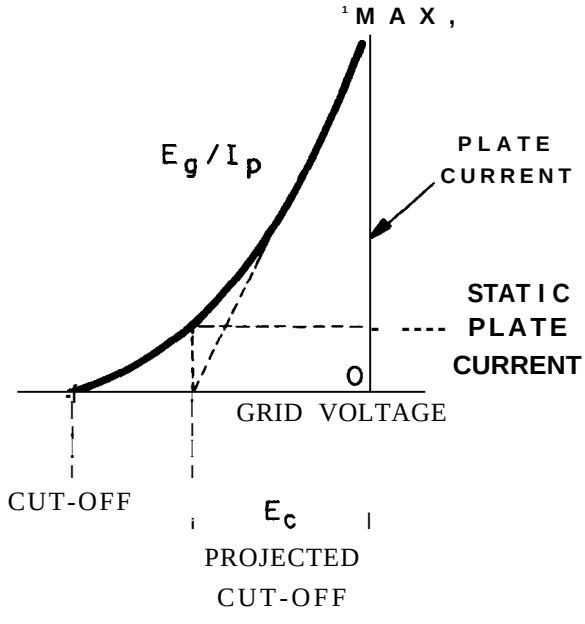
Since the output varies as the square of the input signal, at 100 percent modulation the maximum distortion can be as high as 25 percent. Operating as a linear detector the distortion is considerably less, as long as the signal is strong enough to keep it from operating in the lower curved portion of the tube characteristic, and not so large as to include operation over the upper curved portion. However, since the e_g/i_p characteristic curve of a tride is never perfectly straight but has a slightly howed appearance, there is greater basic distortion than in the half-wave diode detector.

Circuit Oparation. The schematic of a typical plate detector is shown in the following illustration.

Transformer T1 is the r-f input transformer, with the transformer secondary tuned by Cl. Cathode bias is obtained from R1 and C2. The plate load R2, is bypassed for R-f by C3. The output is capacitively coupled through Cc.

With no signal applied, the average bias produced by cathode current flow through RI holds the grid to plate current cut off. Although spoken of as cutoff bias, the tube is actually biased to projected cutoff, as shown in the following illustration. (See the introduction to the Amplifier Section of this Handbook for a detailed explamtion of cathode bias.) Therefore, negative input signal excursions occur over the curved portion and produce some slight distortion. For full linear operation a separate and higher fixed bias is always applied and the complete negative

excursion of the input signal is eliminated with a consequent reduction of overall distortion.



Detector Operation Characteristic

When an input signal is applied, the positive portion of the signal increases the grid voltage, and the plate current of VI follows, likewise. Thus the plate waveform of **V1** consists of pulses of current at the input frequency, whose peak values trace out a curve which varies exactly as the modulated r-f. Thus the audio frequency component of plate current developes a similar plate voltage output waveform across the plate load resistor R2 of opposite polarity or phase. Thus at the peak of current, the plate and output voltage is a minimum, while at the minimum value of plate current the output voltage is maximum. Capacitor C3 bypasses any r-f which might appear on the plate of V1 after rectification, to avoid feedback through the plate to grid capacity causing oscillation or unwanted beats. In some instances, C3 may be bypassed to ground instead of to the cathode, this is usually done in receivers operating at the higher radio frequencies.

Normally, no grid current is drawn and the plate detector offers an extremely high input impedance with practically no input loading. Since the input circuit is not loaded down, a slight improvement in selectivity is usually observed over that of the grid-leak detector. If, however, the input is large enough to draw grid current (signal exceeds the bias), additional plate distortion is obtained by curvature of the upper portion of the tube characteristic, and the lowered grid input impedance also reduces the selectivity, so that the overall performance is lower than for the grid-leak detector.

Failure Analysis

No Output. An open input or output circuit, or a defective tube, as well as lack of plate voltage, will cause a **no-output** condition. Check the plate supply and plate voltage with a high resistance voltmeter. No output with a normal supply voltage, but with no plate voltage indicates that plate load resistor R2 may be open, or that bypass capacitor C3 is shorted. Check the resistance of R2 with the plate voltage off, and check C3 with an in-circuit capacitance checker. If plate voltage is normal but no output is obtained, use an oscilloscope and r-f probe to observe that an input signal exists on the grid of V1. If it does and no output exists, either cathode resistor R1 is open or V1 is defective. Check the bias voltage across R1 with a voltmeter. Since bias bypass capacitor C2 may be shorted, it is usually simpler to measure the resistance of R1. If the resistance across R1 is zero, the C2 is shorted. If RI is infinite it is open. Also, do not neglect the possibility of a shorted secondary winding or tuning capacitor Cl.

Low Output. A low plate voltage, a defective tube, or a small input signal will produce a low output. Check the supply voltage with a voltmeter. If normal, check the plate voltage of Vl; lower than normal voltage on the plate indicates that R2 has increased in value, or that an abnormal plate current exists. Check the voltage between cathode and ground, if it is normal or slightly low check R2 for the proper resistance value (with plate voltage off). If T1 is defective, or if Cl is not tuned to resonance a low output can also occur. If T1 primary is open, a weak output signal may still be obtained if there is sufficient capactive coupling between primary and secondary, or to VI grid. In this case, while Cl will tune through resonance there will not be the normal large build up of output signal as the resonant point is passed. If T1 is defective, a resistance analysis can be made with an ohmmeter to verify if the windings are

open, but there is also the possibility of a short circuit or leakage across one of these windings. To determine if T1 is at fault, temporarily disconnect it from VI grid and connect the input signal through an isolating capacitor direct to VI grid. A large increase in signal indicates that T1 must be defective. The output of a modulated signal generator tuned to the input frequency can be used to supply an input directly to the grid of VI, if a known strong local signal is not available. If the output signal obtained in this case still is weak, but increases considerably when the generator output is applied to the plate circuit, tube VI is at fault. Where all signals fade in and out and the output is low, VI is usually at fault because of low emission.

Distortion. Since there is normally some distortion from the linear detector, particularly on strong signals at high percentages of modulation, there may be some doubt as to whether or not the distortion is normal or excessive. When distortion is suspected, check the plate voltage and cathode bias with a voltmeter. Abnormal voltages indicate that the detector is probably at fault. If, however, it is found that tuning Cl eliminates the distortion, or that it only exists on extremely strong signals, the detector is most likely performing normally. When the distortion continuously occurs with either weak or strong signals the detector is definitely at fault. Note, however, that when strong fading exists it is possible that selective fading is phasing out some of the sideband frequencies and causing the distortion. Such distortion will not appear on signals having a steady amplitude.

COMMON-EMITTER DETECTOR

Application.

The common-emitter transistor detector is usually used in semiconductor superheterodyne receivers to supply a detected and amplified output.

Characteristics.

Uses self-bias.

Offers a high input impedance.

1s equivalent to the diode detector in quality, with more gain available.

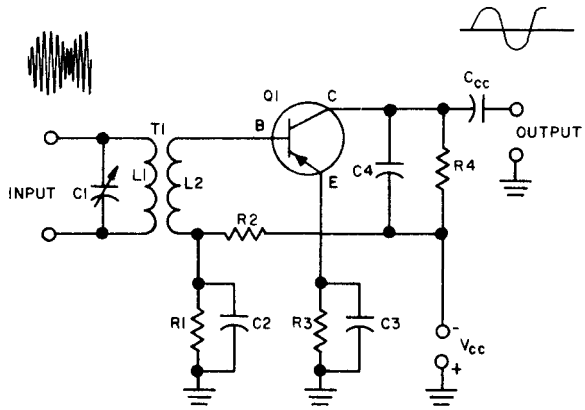
May be operated as either a small-signal, or a large-signal detector, depending upon bias voltage.

Circuit Analysis.

General. This detector is equivalent to the grid and plate detector used in electron tubes. The base-emitter ,junction acts as a diode rectifier for large-signal linear detection when biased sufficiently, or as a square-law, small-signal detector when operating with low bias. When used in a receiver with only a few transistors it operates as a small signal detector, when used in superheterodynes it is used as a large signal detector. The operation is similar to that of the electron tube counterparts (grid and plate detectors) described earlier in this section.

Diode detection occurs in the base-emitter junction and amplification occurs using the emitter-collector junction. The combination can be considered the same as that of a diode and a transistor used separately.

Circuit Operation. The schematic of a typical transistor common-emitter detector is shown in the following illustration.



Common-Emitter Detector

Tuned input transformer, T1, has a primary and secondary winding. The primary winding, L1 is tuned by capacitor Cl to the operating frequency (in superheterodyne receivers it is tuned to the IF), while secondary L2 remains untuned and inductively coupled. Resistors RI and R2 are fixed-bias voltage dividers connected from the supply to the base and ground. Resistor RI is bypassed by C2 for radio frequency and this RC combination also acts as the load

resistor and bypass capacitor as used in a diode detector. The audio is detected in the base-emitter circuit and is applied as a dc bias varying at audio frequencies to control collector current. The output is developed across collector load resistor R4, which is bypassed for r-f but not for audio frequencies. The emitter is connected to ground through a conventional swamping resistance (R3) for temperature stabilization, and is bypassed by C3 for both RF and audio.

In the absence of an input signal, transistor Q1 rests in a Class A-biased condition, drawing a moderate but steady collector current, and no output is obtained. When an input signal appears on the base of QI it is rectified by the base-emitter junction (operating as a diode) and appears as a dc bias voltage with a varying audio frequency component across RI. This a-f component is developed across RI as in the conventional diode detector previously discussed earlier in this section. Variations in base current flow caused by the input signal develop a voltage across R1 which follows the modulation envelope of the signal, any degenerative bias which tends to develop across emitter resistor R3 is eliminated by bypass capacitor C3. The output is developed by collector current flow from the supply through R4 which varies under control of the bias voltage across R1. Any radio frequency ripple in the output is bypassed across the collector load resistor by capacitor C4. The audio frequency variations, however, are not bypassed, and as the base is forward-biased by the negative half-cycle of input, it increases collector current flow, and a positive output voltage is developed across load R4. Likewise, when the base current is made to decrease on positive portion of the input signal (which reverse-biases the junction) collector current flow is reduced, and the collector output voltage rises towards the supply (becomes more negative). Thus since the output rises and falls in accordance with the modulation envelope, an amplified output of similar waveform is obtained and passed through coupling capacitor Ccc to drive the base of the following audio stage.

When a small fixed-bias is applied Ql, operation is on the lower (curved) portion of the base-emitter transfer curve and square law detection is obtained, with an increase of distortion. When biased higher (on the straight portion of the curve) the transistor operates as a linear diode detector with the additional amplification supplied by the collector circuit. The type of operation is determined during design by selecting the proper values of RI and R2 to provide the desired bias for square law detection, and by choosing the proper value of emitter resistor R3 and bypass capacitor C3 for linear detection. The output in both instances is equivalent to that from a separate diode, amplified by a separate transistor operating at the same bias voltages. Usually when operating as a high-level (large signal) detector it is capable of driving an audio output stage directly. In this respect, it is the transistor equivalent of the electron tube power-detector.

Failure Analysis.

No Output. *Loss* of an input signal, lack of bias, a defective transistor, loss of supply voltage, an open load resistor, or an open output capacitor can produce a no-output condition. Check the bias, supply, and collector voltages with a high resistance ohmmeter. If normal base bias is obtained, L2 and bias, divider Rl, and R2 are satisfactory, and C2 is not shorted. Likewise, with normal collector voltage R4 is okay and C4 is not shorted. An emitter voltage slightly larger than the bias applied and still no signal indicates that R3 and C3 are operating satisfactorily and that either L1 is open or Cl is shorted. Check the input circuit for continuity and shorts with an ohmmeter. The possibility exists that coupling capacitor Ccc may be open. In this instance, use of an oscilloscope would immediately show an output on the transistor side of Ccc, but nothing on the output side. When an oscilloscope is available, follow the signal through the circuit and note where it disappears or changes in shape or amplitude to locate the trouble.

Low Output. Improper bias, low collector voltage, or a defective transistor are the most likely causes of low output. Check for proper bias and collector voltage, and also check the supply to be certain that a blown fuse or the supply itself is not the cause. With normal voltages, the transistor must be defective.

Distortion. Normally the output is distorted to a certain extent, however, the modulation should be intelligible. When it is so distorted that it is garbled, check the output circuit to make certain the trouble is not in the following audio stage. When the distortion appears in the output stage but not in the detector, the trouble is in the output stage. Improper bias is usually the foremost cause of excessive distortion, and should be checked first with a ***voltmeter.***

If the bias voltages are normal, use an oscilloscope and follow the signal through the circuit until the pattern changes and shows the part at fault. It is important to remember to use an r-f probe when checking with the oscilloscope, since distortion in the r-f portion of the circuit will not show unless it is first detected by an r-f probe.

COMMON-BASE DETECTOR

Application.

The common-base detector is usually used in small portable semiconductor receivers to provide detection with some amplification, and where extreme fidelity is not required.

Characteristic%

Employs grid-leak bias.

Is equivalent in output to a diode and a separate amplifier stage.

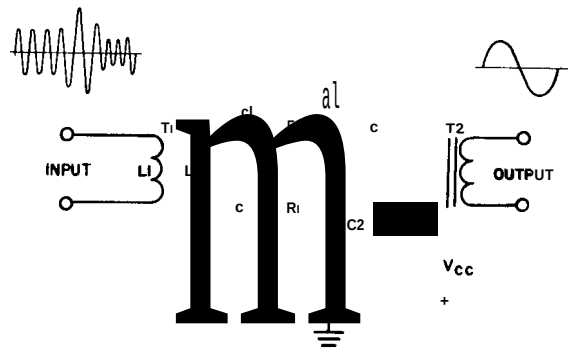
Produces more distortion than the common-emitter detector, or a diode detector.

Operates as a small signal detector which can easily be overloaded.

Circuit Analysis.

General. The common-base detector is the transistor equivalent of the electron tube grid-leak detector. Detection occurs in the base+ mitter junction and amplification occurs through use of the collector junction. The output is the equivalent of a diode detector followed by a stage of audio amplification, but with more inherent distortion. Where less distortion and better quality are required a separate diode and transistor audio stage are used.

Circuit Operation. The schematic of a typical common-base detector is shown in the following illustration.



Common-Base Detector

Transformer T1 is an r-f transformer when used in simple two or three stage receivers, or an i-f transformer when used in superheterodynes. It is tuned to either the i-f frequency or the operating frequency, as applicable. In the drawing TI is single tuned in the secondary, but may also be tuned in the primary. Resistor R1 and capacitor Cl form a grid-leak bias network which sets the operating point of the emitter junction. The audio output is taken from the collector circuit through audio output transformer T2, however, RC coupling may be used to help improve fidelity if a smaller output is satisfactory. The primary of T2 forms the detector output load and is bypassed for r-f ripple by capacitor C2.

The input signal is applied to either the tuned or untuned primary and inductively coupled to the L2 secondary. When tuning capacitor C is tuned to the proper frequency, the input signal is coupled through Cl to the emitter. In the absence of a signal, contact bias exists as determined by resistor RI. The small

491-044 0-73-58

flow of reverse current develops small bias voltage across R1 which is near zero and only the small normal reverse current flows. When the positive portion of the input signal occurs, current flows through the emitter-base junction driving the emitter positive (forward bias) and capacitor Cl is charged negatively, establishing the operating point. On the negative excursion of the input signal capacitor Cl is discharged through RI creating a negative, reverse-bias which reduces conduction in the emitter junction. The bias developed follows the wave envelope of the modulated signal and produces a dc emitter bias which varies at audio frequencies. Variation of the emitter bias causes the collector current to flow in accordance with the audio frequency variations of the modulation, and the output voltage is developed by collector current flow through the primary of audio transformer T2. Capacitor C2 effectively acts as a low pass filter, and filters out any r-f or i-f component (ripple) existing in the collector circuit. Thus only the audio variations induce a voltage in the primary of T2, and the field around the secondary of T2 varies in accordance with collector current changes, inducing an output voltage in the secondary. Strong signals may develop to much bias on the emitter, cut off collector current flow, and cause blocking. Since the bias ordinarily is small, the transistor operates on the lower portion of the emitter-base transfer characteristic curve and is a square law detector. Thus, at 100% modulation, distortion up to a maximum of 25 percent can exist. Such high values of distortion render this type of detector unsuitable for music or high fidelity broadcast use, except in cheap receivers in which the distortion can be tolerated for the sake of simplicity, economy, and portability.

Failure Analysis.

General. When making voltage checks use a vacuum-tube voltmeter to avoid the low values of shunting resistance employed on the low voltage ranges of conventional voltohmmeters. Be careful, also, to observe proper polarity when checking for continuity with the ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output. Lack of collector voltage,** an open input or output circuit caused by a defective transformer (T] or T2), or a defective transistor can cause a no-output condition. Measure the collector voltage with a VTVM. Normal collector voltage on Q1 indicates that T2 and the output circuit are satisfactory. If no collector voltage exists, either T2 is open or C2 is shorted. Use a volt-ohmmeter and a capacitance checker to check these two parts. When collector voltage exists but there is no output, check TI primary and secondary for continuity with an ohmmeter and tuning capacitor C for a short circuit. There is also the possibility of Cl being open. Use an ohmmeter and capacitance checker to check continuity and the capacitor for proper value. If T1 is satisfactory the transistor must be at fault.

Low Output. Lack of collector voltage or an open output circuit, as well as a defective transistor can cause a reduced output. Measure the collector voltage, if it is normal, either output transformer T2 is open or shorted, or Q1 is defective. Check the transformer for continuity or short circuit with an ohmmeter, and check C2 with a capacitance checker.

Distorted Output. The output will normally be distorted, but should be intelligible. If the distortion is so bad that the modulation is garbled, check the input and output waveform with an oscilloscope. If the waveform is undistorted in the base circuit but appears distorted in the collector circuit, check the values of Cl and R1. Since these parts set the bias point, a change in the value of either one can cause clipping or peck distortion effects. If these parts values are proper and within the tolerance indicated in the instruction book on the equipment, the transistor is most likely at fault.

INFINITE IMPEDANCE DETECTOR (ELECTRON TUBE)

Application.

The infinite impedance detector is used in tuned radio frequency receivers where less distortion than that supplied by the conventional plate detector is required, and no gain through the detector stage can be tolerated. Its light loading effects improve sensitivity and selectivity.

Characteristics.

Uses self-bias, but can be fixed-biased, if desired.
Provides good sensitivity, with reduced distortion.

Operates as a linear detector for large signals.

Is normally operated as a modified power detector.

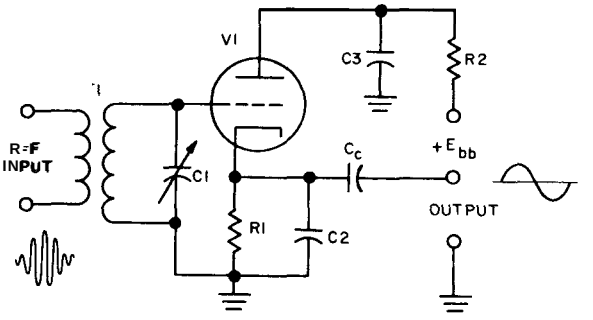
The cathode output connection prevents any large increase of gain.

Presents a very high or infinite impedance to the input signal.

Circuit Analysis.

General. The infinite impedance detector is also known in other texts as a ***reflex*** detector because of the large value of degenerative feedback provided in this arrangement. However, this nomenclature is misleading since it also applies to reflex circuits where detection and amplification through positive feedback occur in the same stage, and these circuits are not infinite impedance detectors. The basic infinite impedance detector used a bypassed plate load to achieve more than unity gain. In effect, it combined the advantages of plate detection with the equivalent of diode detection which offered no load to the source. The circuit is always easily recognized because of the cathode output comection, large cathode resistance, and relatively small r-f bypass (about 250 picofarads), plus the fact that when the plate resistor is used the plate bypass is sufficiently large enough for both RF and audio bypassing (about 0.1 microfarad). Because of the infinite impedance offered this circuit does not load the input. Consequently, greater sensitivity and selectivity is obtained than with conventional plate detectors. On the other hand, it is not as sensitive as the grid-leak detector, but the output is practically distortionless and much lower than is normally obtained by either the plate or grid types of detectors previously discussed. If not better, it is at least as good as the conventional diode detector. The two major disadvantages which restrict its use, is that it cannot supply a simple source of AVC, and the negative feedback through cathode degeneration produces less than unity gain.

Circuit Operation. The schematic of a typical infinite impedance detector is shown in the accompanying illustration.



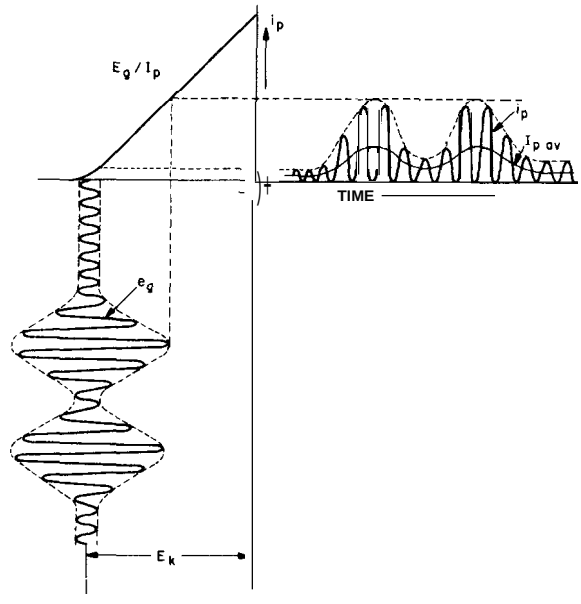
Infinite Impedance Detector

Transformer T1 is the r-f input transformer, and is tuned by Cl (in superheterodyne receivers T1 represents the i-f input transformer). Cathode bias is supplied by R1 which is only bypassed for RF by C2 so that it is degenerative at audio frequencies. The output is taken from across R1 through coupling capacitor Cc. Resistor R2 and capacitor C3 form a plate filter and voltage dropping network, which reduces the plate voltage and bypasses to ground any rf or audio currents in the plate circuit. In some circuits R2 is not used, while in other circuits both R2 and C3 are eliminated. In either event, there is no change in circuit operation.

By using a large value of resistance for R1, the average plate current flow through this resistor develops a high bias. Thus, in the absence of an input signal only a small plate current flows because of the cathode bias is almost at plate current cutoff value. Since current flow through the tube is from cathode to plate, any increase in cathode current develops a positive voltage at the cathode with respect to ground and increases the instantaneous bias. However, RI is bypassed by C2, which is chosen to offer a low impedance to ground for radio frequencies, but not for audio frequencies. Consequently, the r-f signal does not pass through the load (cathode resistor Rl)

but the audio frequency variations of the modulation on the detected signal do. Thus a degenerative voltage is developed on the cathode, which makes the output signaI amplitude always less than the input signal which produces it. This is a form of negative feedback which places the output signal in series with the grid-cathode circuit. Since the output signal appears in opposite polarity to the input it helps cancel a portion of the input signal, eliminates distortion, and improves linearity. (See the Amplifier Section of this Handbook covering Feedback Amplifiers for a complete discussion of inverse or degenerative feedback.) Because of the degenerative feedback inherent in a cathode output connection, the output signal amplitude can never exceed the input signal, and the gain is always less than unity.

Another result of the feedback action is to prevent the flow of grid current. The increase of bias with increase of signal ensures that the input signal never exceeds the bias, hence grid current will never flow. Thus the infinite impedance detector always presents a very high (infinite) impedance between grid and cathode, and produces no load on the input circuit. Consequently, there is no shunt load across the secondary of T1 and Cl, and the selectivity of the tuned input circuit depends only on the Q of the tank circuit. Thus better selectivity is obtained. When the input signal reduces in amplitude, the decreased grid voltage produces a reduction of plate and cathode current, accordingly. Since cathode resistor R1 is not bypassed for audio frequencies, the instantaneous audio current variations through RI develop an output voltage which varies with a modulation envelope of the received signal. The process is practically identical to that of the diode detector discussed previously in this section of the Handbook, since only the positive portion of the input is effective as shown in the following illustration, (the negative portion is biased off).



Detection Characteristics

With a large input signal the circuit always operates over the straight (linear) portion of the plate current-grid voltage characteristic. Since plate load resistor R2 is bypassed by C3, any instantaneous r-f or audio current variations are bypassed to ground, and the plate voltage remains constant regardless of cathode current fluctuations.

Failure Analysis.

No Output. An *open* or shorted input or output circuit, lack of plate voltage, or a defective tube can create a no-output condition. Check the supply voltage with a high resistance voltmeter to determine that

the fault is not in the power supply, and then check the plate voltage. No plate voltage indicates possibility of R2 being open or C3 being shorted. Check R3 for proper resistance with an ohmmeter, and C3 for a low resistance to ground. Check the cathode bias voltage developed across RI. If no bias exists, either VI is defective, RI is open, or C2 is shorted. Check RI and C2 with an ohmmeter. If normal plate and cathode voltages exist use a VTVM to check the grid input voltage. If no grid signal voltage is found, make certain that Cl is set to, the proper frequency for the desired input signal, and if still no input exists, check T1 for continuity with an ohmmeter. If an input signal exists on the grid of V1, check coupling capacitor C_c to make certain it is not open (use an in-circuit capacitance checker).

Low Output. A weak input signal can cause a low output. A low emission tube usually causes erratic fading on all signals and a low output. Low plate voltage will also cause a reduced output. Check the plate and cathode bias voltages. If the plate voltage is low with a normal supply voltage, check R2 for an increased resistance value and C3 for a partially shorted or leaky condition. If the cathode bias is low, RI may have changed value, C2 may be leaking and shunting R1 with a low value of resistance, or V1 plate current may be weak because of low emission. Check R1 with an ohmmeter and C2 for leakage. A weak input signal can also be caused by defective r-f transformer, TI, or by a defective or mistuned tank tuning capacitor, Cl. If there is any change in signal as Cl is tuned, the tuning capacitor is probably satisfactory and the primary of TI is probably open. Check T1 for continuity with an ohmmeter. If the transformer continuity is complete and weak signals still occur on a known local signal, there is still the remaining possibility that T1 is shorted.

Distortion. Since the infinite impedance detector is noted for its fidelity and lack of distortion, it is evident that noticeable distortion indicates improper performance. Check the bias with a voltmeter. Low bias will place the operating point on the bend of the E_g/I_p curve, and square law detection with its high distortion products will result instead of linear detection. Distortion accompanied with a low output can also be caused by a defective tube.

REGENERATIVE DETECTOR (ELECTRON TUBE)

Application.

The regenerative detector is used in simple one or two tube receivers, particularly in the high frequency regions where normal r-f amplifiers do not provide much gain. It is mostly used for CW and voice reception.

Characteristics.

Uses a grid-leak detector with regenerative feedback from plate to grid.

Has better sensitivity than any non-regenerative detector.

Has better selectivity than any non-regenerative detector.

Has poor fidelity with relatively high distortion for music and, therefore, is mostly used for voice and CW (code) reception.

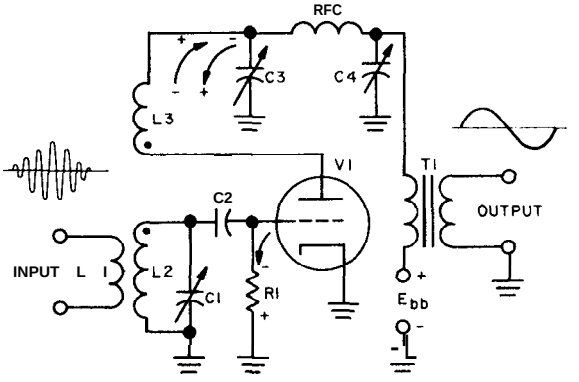
Circuit Analysis.

General. The regerative detector utilizes the high sensitivity of a grid-leak detector, together with the increased amplification afforded by regenerative feedback to provide a unique detector with extreme sensitivity and high gain. Since grid-leak detection is used, the distortion level is high, and because regeneration increases the selectivity of the tuned input circuit, a narrow band-width is obtained. Thus, the high frequency components of a modulated signal are effectively eliminated by circuit selectivity of the order of a 2-to-3 kHz. Hence, this circuit is restricted in use mainly to communications applications involving only voice and code reception.

There are a number of circuit variations, most of which involve the method of controlling the regenerative feedback. Because feedback varies with the frequency range covered, fixed forms of feedback are suitable only over a very narrow range of operation. With smooth control of feedback, it is possible to increase the regeneration until the feedback reaches the critical point where any further regeneration will cause continuous oscillation of the circuit. Voice reception is amplified the greatest just below this point. For code reception, the amount of regeneration is increased until the circuit just oscillates, and

the desired signal is tuned in by adjusting the tuning capacitor slightly off resonance until an audible note is produced. This type of reception is known as *autodyne* reception, which uses a single tube to perform detection and oscillation simultaneously; as contrasted with *heterodyne* reception, which uses a separate oscillator to produce a heterodyne signal.

Circuit Operation. The schematic of a typical regenerative detector is shown in the following illustration.



Regenerative Detector Circuit

The r-f input signal is applied to Ll, the primary winding of the r-f input transformer, of which L2 is the secondary, tuned by capacitor Cl. Feedback winding L3 is inductively coupled to L2, and consists of a few turns wound in the same direction as those of the secondary coil and located at the ground end of the secondary coil (L3 is called the "tickler" coil). Variable capacitor C3 is connected in series between ground and tickler coil winding to control the amount of regenerative feedback. The radio frequency choke, RFC, and capacitor C4, form a low-pass filter which bypasses any r-f component in the plate circuit to ground. Capacitor C2 and resistor RI form a conventional parallel grid-leak arrangement. The audio output is applied *to* the primary of transformer T1, used to provide a step-up in output voltage between primary and secondary. Although any other method of audio coupling may be used, the transformer is usually used because of the large output it produces in comparison with other types of coupling.

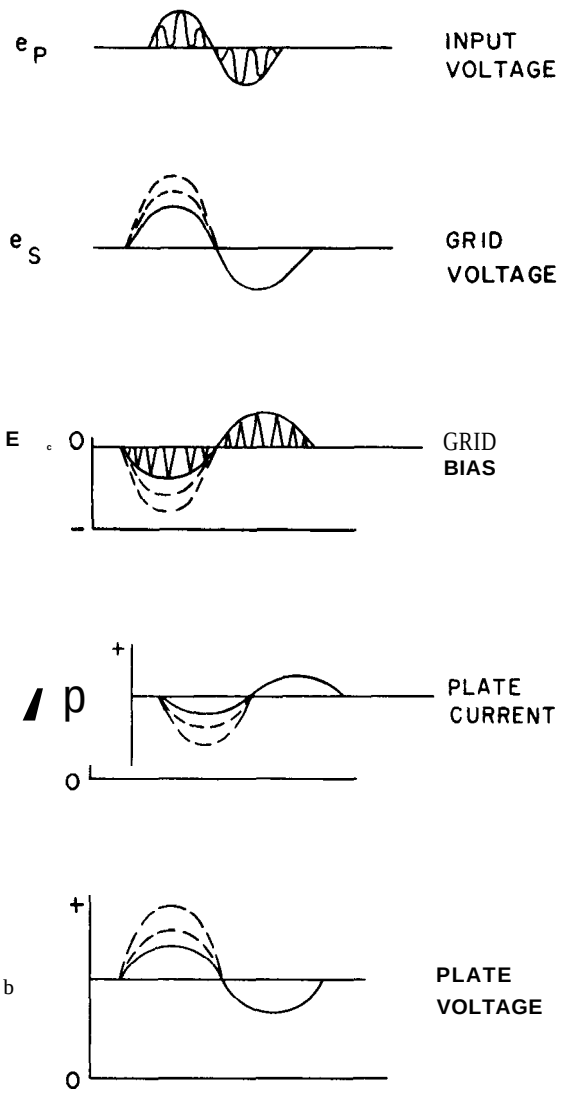
Initially, the circuit rests in its quiescent condition with no signal applied, and draws heavy plate current because only contact bias is supplied by R1 (see the introduction to the Amplifier Section of this Handbook for a complete explanation of contact bias). We shall also assume that feedback capacitor C3 is set to the middle of its range and offers a low capacitive reactance to ground. Tickler coil 1.3 is freed-coupled to L2, and wound so that both grid and plate ends of the winding are of additive polarity.

When an input signal is applied to L1 it is inductively coupled into the resonant tank consisting of L2 and Cl. The low reactance of the grid-leak capacitor, in turn, allows the tank signal to appear at the grid of V1, across R1. On the positive half cycle grid current flow is increased, and capacitor C2 is charged negatively as shown by the polarities and current flow arrow on the schematic. Thus as the signal rises in a positive direction the negative grid bias on V1 increases. This negative grid bias increment decreases plate current flow because of control grid action within the tube. In the quiescent condition, plate current flows through the tickler coil winding in such a direction as to produce a polarity similar to that of L2 across L3. Thus the plate end of the tickler is negative when the grid is positive. Since, in the absence of an input signal there is a steady unchanging flow of plate current, the field built up around L3 remains steady and constant so that no feedback voltage is induced into L2. When the input signal is applied, however, the reduction of plate current with the increase of grid-leak bias produces a change in the lines of magnetic flux cutting the two coils, and a feedback voltage is induced in L2 by the current change in L3. The reduction of plate current causes the field around L3 to collapse and induce a voltage of opposite polarity to that normally produced in the increasing current direction. Hence a positive voltage is fed back to further activate the grid of VI. Since the input signal and the feedback voltage are of the same polarity they add, and produce a still greater negative grid bias. The increased bias, in turn,

causes a further reduction of plate current, and a larger feedback voltage. This cycle of signal build-up by regenerative feedback continues until the input signal amplitude changes. As the amplitude changes, the feedback action follows. That is, as the signal increases the feedback increases, and as the signal decreases the feedback, likewise, decreases. With feedback, the combined signal value is always greater than without feedback. Thus, weak signals are greatly enhanced and the sensitivity of this type of detector is greater than for non-regenerative types.

On the negative half-cycle of input signal, the flow of grid current is reduced, and a small amount of the charge on capacitor C2 leaks off to ground through grid-leak RI. Therefore, the grid bias on V1 is reduced and an increased plate current flows. The increased current flow is in the direction of original (quiescent) current flow and produces a feedback voltage of negative polarity, which adds to the negative signal voltage on the grid. This regenerative build up in the opposite direction during the negative half-cycle of operation is limited to a value less than zero bias, since the tube is operating on the lower bend of the characteristic transfer curve. Hence the positive and negative swings developed across the primary of audio output transformer T1 are unequal and distortion is produced.

The following waveform illustration shows the relationships between the grid and plate voltages and currents. The dotted lines in the waveforms indicate the build up of signal by regenerative action during the positive half-cycle. When the input voltage increases, the secondary voltages increases and is further enhanced by feedback, while the detected signal produces a grid bias which increases and is further enhanced by the feedback. The plate current, in turn, is progressively reduced, while the plate voltage increases. The changes of plate current occurring at audio frequencies in the primary of T1 induces a similar output voltage in the secondary.



Grid and Plate Voltage Waveforms

When the capacitance of feedback capacitor C3 is increased, the reactance to ground is reduced and a greater r-f current flows through tickler coil L3, and produces a larger feedback voltage. As long as the feedback is kept below the point of oscillation, maximum amplification is obtained. Once the feedback becomes great enough to drive the grid to cut-off and beyond, the tube conducts only during the peak of the signal and for less than a half cycle (class C operation). During the cutoff period the tank circuit supplies the missing portion of the signal and continuous amplitude sine-wave oscillations occur.

Although the r-f component in the plate circuit is effectively bypassed to ground by regeneration capacitor C3, radio frequency choke RFC, is placed in series with the plate lead to offer a high r-f resistance (impedance) and prevent the possibility of r-f feedback through the load consisting of audio output transformer T] and the power supply. To ensure that no RF remains to cause a fringe howl and deteriorate detector performance, capacitor C4 is also used to bypass the primary of T1. Thus, any remaining RF which might exist at the load end of the RFC is bypassed to ground by C4, so that only the slow current variations caused by modulation and occurring at audio frequencies appear in the transformer primary, and induce an output voltage in the secondary.

When voltage is fed back from the plate to the grid circuit, the result is to effectively reduce the losses in the grid circuit. Since the Q of an inductance is the ratio of the reactance to the resistance in the circuit. It is evident that when the r-f resistance in the circuit is decreased and the same reactance exists, a higher Q results. Thus, with a higher Q tank circuit resulting from feedback, a greater selectivity exists. This improved selectivity makes for sharper tuning, and will cut off the higher modulation frequencies in wideband transmission such as is used for music at broadcast frequencies. At high frequencies, however, the side bands are a much smaller percentage of the signal so that not as much sideband clipping occurs and usable voice reception is possible without excessive distortion. Since code transmissions occupy a very narrow frequency spectrum of one thousand cycles or less the increased selectivity of the tuned circuit during feedback is not sufficient to affect code reception. One of the major disadvantages of this circuit for Military use is that, when oscillating it reradiates and produces a low powered CW output; which, besides interfering with nearby receivers tuned to the same frequency, offers a convenient means for the enemy to locate the source with direction finders. This radiation can be eliminated by use of an r-f stage between the detector and antenna, which acts as a buffer stage when properly neutralized.

Failure Analysis.

No Output. Lack of an input signal, loss of plate voltage, an open or shorted input or output circuit, or a defective tube can result in a loss of output. First measure the supply voltage with a high resistance voltmeter to make certain that the supply or a blown supply fuse is not at fault. Then measure the plate voltage to ground. If the plate voitage is normal, plate circuit components C3, C4, RFC and the primary of T1 are not at fault. If removing and replacing the tube produces a click in the output device it indicates that the secondary of T1 is not open or shorted, and that the trouble is most probably located in the grid circuit. Turn regeneration control C3 past the point where oscillation usually begins and touch the grid of V1 with your finger. A click in the output indicates the circuit is oscillating and that the tube and feedback portion of the circuit are operating. If there still is no output, the input coil is probably open or shorted. Use an ohmmeter to check the input coil for continuity. If the coil is not open, the possibility of a grid to ground short or an open grid capacitor, C2, still exists. Therefore, it is usually easier to connect the antenna or the output of a signal generator direct to the grid of V1. If the input or tuning portion of the circuit is at fault and C2 is not open, a weak signal will usually be heard. Also rotate tuning capacitor Cl, and listen for a noise indicating shorted tuning capacitor plates.

If no plate voltage is obtained, either T1 or the RFC is open, or capacitors C3 or C4 are shorted, or tube VI is defective. An infinite resistance when measuring across T1, RFC, or L3, indicates an open circuit.

Low Output. Low plate voltage, a defective tube, or partially shorted or open parts can cause a reduced output. If the plate voltage is low, check T1 primary, the RFC, and coil L3 for high resistance soldered joints and partially open windings, as indicated by a high resistance reading on an ohmmeter. Also check C3 and C4 for leakage to ground with an in-circuit capacitance checker. If the plate voltage is normal but the output is low, check the secondary of T1 for

continuity with an ohmmeter (if sufficient stray capacitance coupling between primary and secondary windings exists weak signals may be heard even though the secondary is open). Rotate tuning capacitor Cl to determine if it is tuning. If it tunes the signal, check input coil L1 for high resistance or an open, since a small, stray capacitive coupling from primary L1 to secondary L2 will produce an output signal even if L1 is open, especially at the higher radio frequencies. Where a strong local signal exists, touching the input winding (or VI grid) with the finger will increase the signal if the antenna is defective or too small (this type of indicator may not be too effective below decks or in a well-shielded compartment).

Distorted Output. Since grid-leak detection is used there will normally be noticeable distortion, particularly on strong, heavily modulated signals. A continuous tone beat-note heard with the modulation indicates the detector is oscillating and that a readjustment of the regeneration control is necessary to prevent self-oscillation. A high-pitched audio squeal which occurs when the audio gain is increased is known as fringe howl, and occurs only if the RFC and capacitor C4 are not operating properly to bypass the excess r-f plate component to ground. This could occur if the RFC were shorted or C4 were open. First substitute a good RFC, then if the squeal persists shunt C4 with a capacitor of similar value. If V1 is low in emission, there will usually be distorted signals coupled with continuous fading and a weak output. Should the values of the grid-leak resistor or capacitor change noticeably, both blocking and excessive distortion may occur.

SUPER-REGENERATIVE DETECTOR (ELECTRON TUBE)

Application.

The super-regenerative detector is used in cheap, one or two tube receivers for the VHF and UHF regions where RF amplification does not provide much gain, and good selectivity is not required. It is particularly popular in portable-mobile transceivers and walkie-talkies, where small size and low power consumption is important.

Characteristics

May be separately quenched or self-quenched.

Uses a low quenching frequency to obtain high *in.

Selectivity is much less than for any other form of detector.

Has an inherent noise reducing and limiting action.

Responds almost equally as well to strong signals as to weak signals.

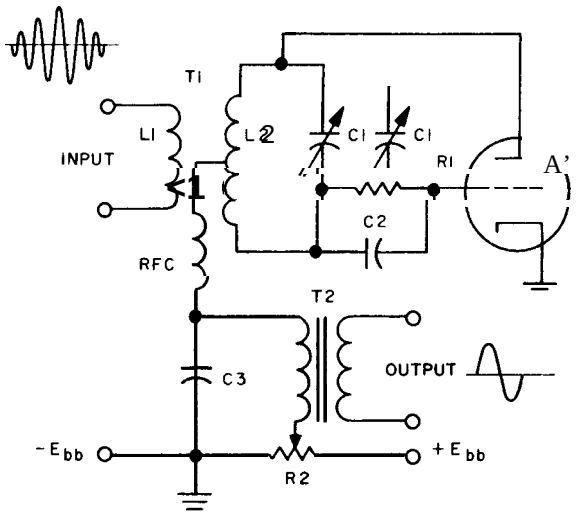
Provides high sensitivity and gain in a single tube.

Circuit Analysis.

General. The super-regenerative detector uses a low frequency (from 15 kHz to 100 kHz) as a quench oscillator, generated either internally or separately, to control the regeneration applied to a grid-leak detector, and thus supply an extremely high gain from a single tube. The use of a quenching frequency effectively broadens the selectivity of the tuned input circuit to the point where it acts almost as if it were not tuned. Hence, a major disadvantage is that any strong signal within a few hundred kilocycles of the desired frequency will override it and blank out the desired signal. It also responds somewhat logarithmically to input signal strength so that an amplitude limiting and AVC action is obtained. Thus, extremely weak signals below the threshold level are not detected, and both weak and strong signals above the threshold appear at the output with nearly the same intensity. In addition, high amplitude noise interference, such as produced by spark ignition systems is minimized without the necessity of adding a limiter stage. Signals with low levels of modulation (less than 50 to 60 percent) produce only a weak or garbled output, whereas signals with high percentages of modulation produce a loud output, accompanied by high distortion. In most instances, the interruptions of the quenching oscillator produce an audio output in the form of a high-pitched hiss caused by noise, which appears between stations, and disappears as the signal is tuned in (on extremely weak signals the hiss will mask out the signal). Since the super-regenerator is oscillating, except during the quench period, it is usually necessary to use an r-f amplifier as a buffer to prevent reradiation and interference with other reception. This is also a major disadvantage when used in

Military equipment, since interception by enemy direction finders is still possible even with an r-f stage if it is not perfectly neutralized.

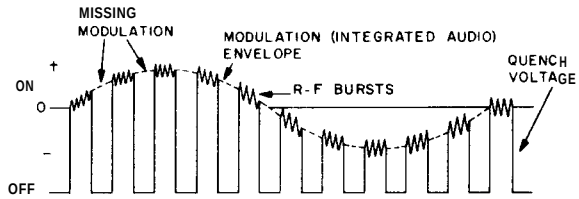
Circuit Operation. The schematic of a typical super-regenerative detector is shown in the following illustration.



Typical Self-Quenched Supar-Reganerative Detector

Transformer T1 is an r-f input transformer, with primary L1 (antenna winding) untuned, and secondary L2 tuned by Cl. The tuned secondary tank is connected between the grid and plate of triode VI as a conventional ultraudion oscillator. Grid-leak bias and low frequency quenching is provided by RI and C2. The audio output is taken through r-f isolating choke RFC and applied to the primary of audio output transformer T2. The plate voltage is varied to control regeneration by potentiometer R2, and the primary of T2 is bypassed by C3 to prevent r-f feedback.

In the absence of an input signal, the grid-leak produces contact bias, and a steady plate current flows. When an unmodulated carrier signal is applied to the input, the grid is driven positive on the positive peaks, and grid current flows from cathode to grid and back to ground via grid-leak R1, charging grid capacitor C2 negatively. This negative grid bias, in turn, causes a slight reduction in plate current, and a consequent rise in plate voltage. When the carrier is modulated by an audio signal, the grid bias varies at an audio rate in accordance with the modulation. When the grid bias increases, the plate current decreases. So far, this is conventional grid rectification and detection. In the regenerative detector this change of plate current induces a field around tank coil L2 which produces an in-phase voltage in the grid portion of the tank coil. Hence, as the plate current decreases a positive voltage is fed back to the grid, and causes still smaller plate current to flow. In the conventional regenerator, this feedback is limited to an amplitude which is just below the point where continuous oscillations are produced. Consequently, even though this type of regenerative feedback results in a gain, it is not as large a gain as could be obtained if the circuit were prevented from oscillating until a larger feedback amplitude was obtained. Such action is accomplished in the super-regenerator by developing a low frequency oscillation in the grid circuit known as the ***quench*** voltage. In the self-quenched circuit described above, the quench voltage is obtained by using a large grid-leak resistance and capacitance to provide a long time-constant. Because of the large time-constant very little voltage can leak off capacitor C2 during the negative portions of each r-f input cycle, so a cumulative build-up in negative bias voltage develops as the input signal is applied, until the bias is sufficiently large to drive the grid to plate current cut off and beyond. When C2 is charged to this cut-off voltage, grid and plate current flow ceases while capacitor C2 discharges through the long time-constant grid-leak. During this discharge period the detector circuit is inoperative.



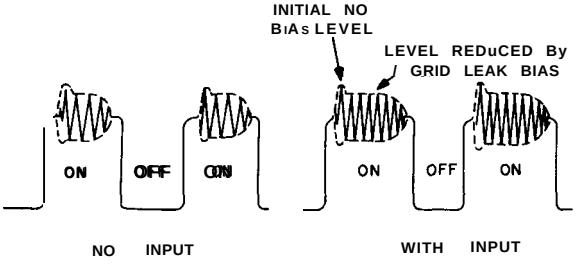
Output Waveforms

Thus, the action consists of an ON period followed by an OFF period. During the ON period the audio output is developed, while during the OFF period no output is developed, although this action results in a signal consisting of chopped up pieces of the original modulation, the modulation frequencies are very low

in comparison to the operating frequencies (cycles compared with megacycles), so that only a small portion of the modulation is lost during any one OFF cycle, as shown in the exaggerated waveform in the preceding illustration. It is evident that the overall waveform shape is retained, but a ripple component at the ***quench*** frequency is introduced. This ripple of quench voltage is filtered out by capacitor C3 which bypasses it to ground. Thus, only the audio frequencies pass through the primary of output transformer T2, and induce an output voltage in the secondary. Since the output waveform is chopped up and is not exactly the same as the input waveform, distortion is produced (this is in addition to any normal distortion caused by grid-leak detection). Thus, it is evident that the output of the super-regenerator must always contain more distortion than in the ordinary regenerative detector. However, this inherent distortion is somewhat nullified by the large gain possible through super-regeneration. The gain is of the order of one hundred times or more than that of the ordinary regenerative detector.

When a separate quench oscillator is used, it is connected in series with either the grid or plate circuit, and the grid-leak values are changed to provide additional gain, since the tube does not have to develop its own quench voltage. However, for the sake of economy and simplicity the single tube self-quenching circuit is usually used. Since the super-regenerator is unique in its action, operating at very high frequencies, at low frequencies and at audio frequencies practically simultaneously, it is necessary to examine the operating sequence more closely to completely understand operation. First consider the quench voltage, regardless of whether or not it is externally supplied, or is generated internally, it primarily serves to gate the grid circuit. During the positive half cycle it permits operation, and during the negative half cycle it reduces operation to almost zero. At the same time, this quench voltage control permits the circuit to oscillate at a very high frequency (the tuned tank frequency) during the conducting half cycles and prevents these oscillations during the non-conduction half-cycle. In the self-quencher, the off period allows time for the grid-leak network to discharge, so that a' train of r-f pulses may be generated during each on-period. Grid-leak bias is developed by rectifying the positive half cycles of this train of r-f pulses each time they cause a flow of grid current. Thus, the grid-capacitor is charged negatively at an r-f rate, and since the discharge time constant is longer than the charge time constant (the conduction of grid current presents a low resistance charge path), the charge cannot leak off the grid between r-f pukes and, therefore, builds up and eventually reaches cut-off bias. This cut-off bias point in the self-quencher determines the start of the off-period, and the tube is held inoperative during this period until grid capacitor C2 discharges through the large grid-leak resistance.

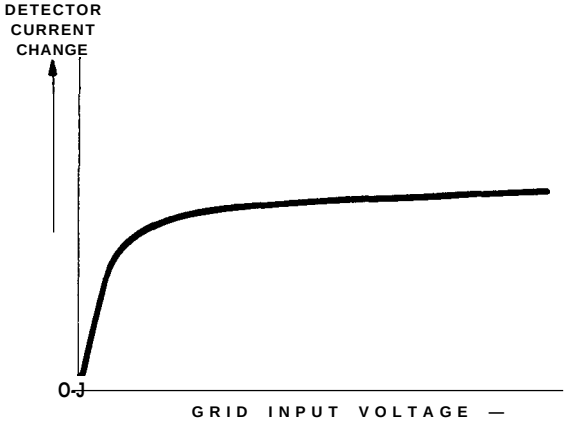
It is important to note that during the on-period r-f oscillations occur at the tank frequency, regardless of whether or not an input signal is applied. This action occurs because of the large feedback from plate to grid. Thus, in the absence of an input signal, the tank circuit is started oscillating by random current flow in the tube due to noise, which through feedback quickly builds up to a high amplitude and develops a dc bias across the grid-leak. This grid bias, in turn, reduces the amplitude of the r-f oscillation slightly and maintains it at this value for the remainder of the on-period. When an input signal is applied, the amplitude of the r-f oscillation does not change, but instead, the oscillation starts sooner (it has the signal to help it), and the duration of oscillation for the on-period lasts for a slightly longer time than without an input signal, as shown in the following illustration.



Typical Grid Waveforms

Since a negative grid bias is produced by the rectification of this r-f oscillation, the plate current is decreased slightly when a signal appears. Because the high-frequency oscillations exist even when no input signal is applied, the output response is limited to the average change of plate current which can occur from the start of the on-period to the beginning of

quiescent oscillation. The result is that if the incoming signal is strong enough to mask out the hiss noise, there is little difference between weak and strong signals, since the detector output current varies logarithmically as shown in the following graph. As a result, large amplitude noise variations caused by ignition interference, static, and similar impulse sources are also reduced in intensity. What would be a loud crash in the conventional detector appears as a rather small noise in the super-regenerator, and can be more easily tolerated without distraction from the desired signals. In a similar manner, small variations in amplitude caused by low percentages of modulation produce weak and unreadable signals, while the large variations in 100 percent modulated signals are sufficient to produce an appreciable output.



Detector Response Characteristics

The amount of feedback and plate voltage is controlled by potentiometer R2. For larger feedback and greater amplification the plate voltage is increased, while for less amplification and feedback it is reduced. For each setting of the control the r-f oscillations will reach a maximum value limited by the saturation voltage for this operating condition, and fixed by the developed grid-leak bias.

Failure Analysis.

No Output. A defective tube, loss of plate voltage, or open or shorted input or output circuits will cause a loss of output. Use a high resistance voltmeter to measure the supply and plate voltages and eliminate the possibility of an inoperative power supply or blown fuse. Since the plate voltage will depend on the position of plate potentiometer R2, it is good practice to vary R2 over its range to determine whether or not an output can be obtained. If R2 is open at some point between the slider and ground, the plate voltage wiJI be higher than normrd, if open on the slider side there will be no voltage (provided T2 primary and the RFC and upper half of coil L2 have continuity). No voltage for any setting of R2 indicates that T2 primary, the RFC, or coil L2 is open. Check for continuity with an ohmmeter or measure voltage to ground. If there appears to be sufficient plate voltage present, check the values of the grid-leak resistor and capacitor using a voltohmmeter and an in-circuit capacitance checker. Check L2 for possibility of a defective tuning condenser Cl which will usually create a noise when rotated, if shorted. If still no output exists it is possible that T2 secondary is open or shorted. Place a pair of headphones across the primary winding or couple a speaker to the primary by a coupling capacitor. Any output indicates the secondary of T2 is at fault. Note also, that if C3 is shorted, plate voltage will appear about normal but no output 'will occur because of the shorted load winding. However, this condition usually is determined at the time that continuity checks are made of L2, T2, and R2. It is important to note that lack of an input signal will not result in a no-output condition, since the circuit will still operate, and produce a hiss.

Low Output. A low or reduced output can be caused by a weak input signal, a partially shorted input circuit, an improperly modulated signal, a defective tube, low plate voltage or a defective output transformer, T2. Signals below the threshold level for detection and those signals with low percentages of modulation (say 50% or less) will not be detected, this is normal operation. If, however, the signal is weak because of an open or a partially shorted input transformer, it can be found by checking the coils with an ohmmeter. Likewise, with a low plate voltage indicated on the voltmeter, both feedback and output will be low. If the trouble is not in the plate supply, most likely bypass capacitor C3 is at fault and leaky, check it with an in-circuit capacitance checker. Check the values of the grid-leak and grid capacitor, using an ohmmeter and capacitance checker. Continued Iow output indicates L1 is either open or partially shorted,

Distorted Output, The output will normally be somewhat distorted, particularly on voice peaks, however, the signal should be intelligible. If distortion is such that the voice is badly garbled, improper biasing is usually the cause. Check the grid-leak resistor with an ohmmeter and the grid capacitance with an in-circuit capacitance checker. To eliminate the following audio stages from suspicion, place a pair of headphones across the primary of T1. If the distortion disappears, the distortion is caused by the audio amplifier stages after the detector.

PRODUCT DETECTOR (ELECTRON TUBE)

Application.

The product detector is universally used as a detector for heterodyning and demodulating single-sideband transmissions in modern communications type receivers.

Characteristics.

Is usually self-biased.

Operates as a combined heterodyne mixer and detector.

Has excellent selectivity.

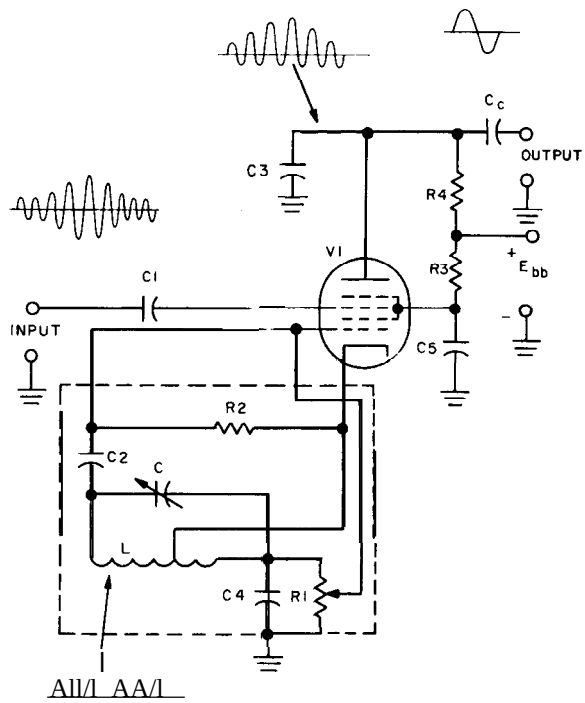
Offers a slight improvement in gain.

Is more linear than the diode detector.

Circuit Analysis.

General. The product detector can be considered a form of heterodyne mixer with an audio output instead of the usual r-f output. The purpose of this detector is to mix locally generated low frequency carrier oscillations with the incoming r-f sideband signals to generate beat notes in the audio frequency range. For single-sideband the beat varies in both pitch and amplitude, producing the detected audio. The product detector may also be used for code reception using the beat frequency oscillator (BFO) to produce a single-tone audio beat. The use of mixing to develop the beat signal reduces the tendency to grid-block, when strong signals from a local oscillator are applied to the grid simultaneously with a weak input signal. Ordinary double-sideband AM signals can also be detected with the product detector, provided the BFO is tuned to zero-beat. When used with a strong BFO input and a weak signal input ***exulted carrier*** reception is simulated. With a strong (exalted) local carrier inserted, phase cancellation of the sideband frequencies during fading is minimized, as the local BFO substitutes for and fills in the carrier. Although during extreme fading this represents an improvement in ordinary AM reception it has the disadvantage that it is usually necessary to continually adjust the local BFO find tuning control to keep the local oscillator at zero beat. Otherwise, the steady CW beat note produced by the two carriers (input signal and BFO) beating together garbles the signal.

Circuit Operation. While there are a number of product detector circuits, one of the most prevalent in use is the typical pentagrid converter illustrated in the following schematic.



Pantagrid Product Detector

A single pentagrid tube is connected as a heterodyne converter, with the triode portion connected as a simple series-fed Hartley oscillator and operating as the beat frequency oscillator (BFO) to supply a carrier signal. The r-f input with its carrier missing is

injected in mixer grid no. 2, which is shielded by the screen construction around it, and the audio output is taken from the plate of the pentode section. Tuned tank L and C is connected in a Hartley circuit with VI, and the lower end of the tank is bypassed to ground by C4, while C2 is the grid capacitor with R2 acting as a shunt grid-leak to supply the bias for the oscillator. The screen receives its supply voltage from dropping resistor R3 from the plate supply. Capacitor C5 bypasses the screen to ground and effectively connects it to the lower end of the tank thereby forming the triode oscillator portion of the circuit. The BFO signal is electron-coupled to the pentode section by electron flow from cathode to screen and plate. The input signal is capacitively coupled through Cl to the mixer grid, and RI is the dc return resistor supplying grid bias for the mixer grid. This resistor is made adjustable to set operation at the proper point for complete mixing and reduction of intermodulation distortion from input signals. The BFO signal is thus mixed with the r-f input signal and is heterodyned to produce audio beat signals, which vary in accordance with the modulation of the r-f input signal. Since the plate of V1 is bypassed to ground for rf by C3, only the audio frequency current variations appear in the plate circuit. These audio current variations develop an output voltage in passing through load resistor R4, and thus develop the audio output which is coupled through C_c to the following audio amplifier stage.

With no signal applied, V1 rests in its quiescent state with the triode section oscillating at the i-f (carrier) frequency, and with no input signal there is no output developed. Operation of the BFO is by feedback through tank coil L between the grid and screen @ate) to supply a continuous feedback from screen to grid and produce continuous oscillations at the frequency determined by the tuning of tank capacitor, C. Since C4 has a low r-f reactance to ground, and C5 which grounds the screen also has a low reactance to r-f, the screen is effectively connected to the lower end of the tank. During the oscillation period, grid-leak network C2 and R2 alternately charge and discharge. During the conduction period on positive half-cycles the grid capacitor is negatively charged, and develops a Class C bias on the grid of V1 through grid current flow from the cathode through R2 to ground. On the negative half of the oscillation, grid capacitor C2 discharges to ground through grid-leak R2, so that the bias is reduced to a value which will permit conduction on the next positive r-f excursion. MeanwhiIe r-f is supplied to the circuit by the tank during the non-conducting period thus producing continuous oscillation at the tank frequency. (See the Oscillator Section of this Handbook for a complete discussion of Hartley oscillator operation.)

When an input signal is applied to the mixer grid of V1 through coupling capacitor Cl the input signal appears on the mixer grid. During the positive half-cycle of the input signal plate current flow is increased, and during the negative half-cycle it is decreased. As the electron flow from cathode to plate occurs, the electrons pass through the screen, and the BFO oscillations are heterodyned with the input signal to produce an audio beat note in the plate circuit. A portion of these electrons also flows through the mixer grid and return resistor R1 to provide bias for the mixer grid. Since the pentode section of V1 is connected as an amplifier, this bias fixes the operating point of the number 2 (mixer) grid at the position for maximum undistorted operation (usually in the Class A region). However, when undesired signals close to the tank frequency are strong, the strong signals tend to over-ride the weaker signal and cause response to both signals regardless of the tuning of tank capacitor C. Therefore, if RI is adjusted to produce clear undistorted reception on the strongest signal, weak signrds will not be pulled in frequency and the strong signal will not cause saturation and produce intermodulation distortion. The change in plate current caused by the input signal alternately increasing and decreasing plate current flow through load resistor R4 develops an output voltage across R4. Since C3 bypasses any r-f signal component and any BFO signal component to ground, only the audio beat note will be effective in producing output voltage across the load. Thus, the modulation amplitude variations of the r-f sideband signal, in effect, modulate the oscillating electron stream and produce the output. If the BFO stopped oscillating there would be no output, since there would be no beat note developed between the low frequency i-f signal and the high frequency r-f signal to produce audio variations in the electron stream between cathode and plate.

Although R1 is shown as variable in the schematic, some circuits use a freed value of resistance which, together with screen resistor R3, is selected to provide optimum operation. In other circuit variations a separate BFO is employed and pentagrid tube VI is connected as a simple mixer with both control grids biased to operate as amplifiers, so that only a simple

mixing function is accomplished. The combined circuit discussed above represents a saving in tubes and economy of circuit components, hence its more prevalent use. Regardless of circuitry, the two signals are always heterodyned to produce a beat output which is in the audio range and thereby demodulates the sideband signal.

Failure Analysis,

No Output. Loss of plate or screen voltage, lack of oscillation in the triode section of V1, an open or shorted input or output circuit, as well as a defective tube can produce a loss of output. Check the plate and screen voltages with a high resistance voltmeter, to make certain that a faulty supply or blown fuse is not at fault. If plate voltage is lacking, either R4 is open or C3 is shorted. Likewise, if no screen voltage is present, either R3 is open or C5 is shorted. Measure the resistors with an ohmmeter and check the resistance to ground across the capacitors, or use an in-circuit capacitance checker to check for shorts, leakage, and proper value. Determine if' the BFO is oscillating, and if there is an input signal. Use an oscilloscope and r-f probe connected between the no. 1 grid and ground to check that oscillation occurs. An alternative procedure is to use a high-resistance voltmeter, and place a l-rnegolun resistor in series with the probe, and measure the voltage across grid-leak R2. If oscillating, usually a 10-volt or better indication is obtained and, in addition, when grid-leak is shorted with your fingers the oscillation will cease as indicated by a drop in voltage to about 1 volt or less. If oscillations do not occur check coil L for continuity, and tuning capacitor C for a short or leakage (use an in circuit capacitance checker). Check grid-leak R2 for proper resistance value and C2 for leakage and proper value. If still no oscillation, check C4 for an open circuit (if shorted it would still oscillate). With the BFO operating it is still possible that RI is shorted and is bypassing the input to ground through C4, or for Cl or C_c to be open, check each capacitor with a capacity meter. Usually it is only when the BFO is not oscillating that a true no-output condition occurs, and the set sounds dead. There will probably be some hum or occasional noise noticed, except of course if output coupling capacitor C_c is open.

Low Output. Low plate or screen voltage, a defective tube or a change in some parts values can produce a weak output. Measure the plate, screen, and supply voltages with a high resistance voltmeter. Low voltage indicates that C5 or C3 is leaky or that VI is shorted and drawing larger than normal current. Check the capacitors with a capacity checker. With normal plate and screen voltages check the voltages on both grids with an oscilloscope and r-f probe. On some detectors it is still possible to get a weak output even though the BFO is not operating. Also check the adjustment of RI since the signal may be biased off too far and provide a weak output. Normally both the oscillator and incoming signal should be about the same level, but in no case should the BFO voltage be greater than the r-f sideband voltage. Check also the setting of the receiver RF GAIN control since it may be set too low.

Distorted Output. If the input signal is too strong, the detector can be overloaded and cause distortion, make certain the receiver R-F GAIN or AVC system is holding the input signal to the proper level. ALSO check the adjustment of RI, since if it is set up for weak signal reception the detector wilf overload and distort on strong signals. When it is adjusted so that the strongest signal is clear, the weaker signals will still be readable, It is also necessary that the receiver be tuned to the proper sideband in single-sideband reception otherwise, the modulation may be present but inverted and be garbled and unintelligible. In this case on a receiver equipped with upper and lower sideband switching, placing the switch to the opposite sideband position will eliminate the distortion. Since it is necessary to keep the inserted carrier within 10 to 12 cycles of the proper frequency, slight frequency instability in the receiver local oscillator may constantly keep the station frequency drifting. This will show up as distortion which disappears as the BFO tuning is slightly , readjusted. In the last case the trouble exists in previous receiver stages, not the detector. It is, however, advisable to check the BFO for drift first using a stable primary standard, if available.

COHERENT (SYNCHRONOUS) DETECTOR (ELECTRON TUBE)

Application.

The coherent (synchronous) detector is used in electronic equipments where a phase change between

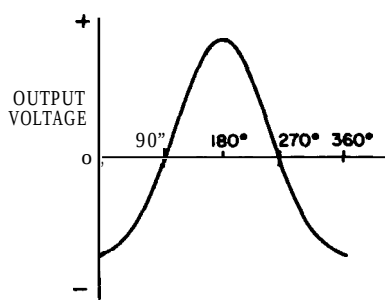
two frequencies is used to provide an output signal. It is extensively used in color television and for other special applications.

Characteristics

May use diodes, triode, or pentode tubes.
May use balanced or unbalanced arrangements.
Requires a reference oscillator signal.

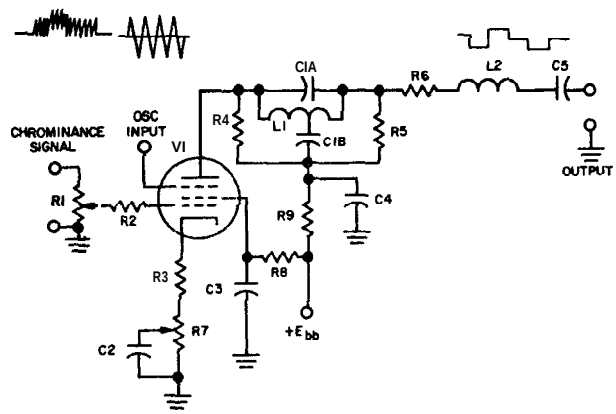
Circuit Anelysis.

General. The synchronous detector is phase-sensitive with respect to a reference oscillator signal which is applied simultaneously with the desired modulated signal. When both signals are in-phase, a negative output is obtained, when the signals are out-of-phase, a positive output is produced. Jn a TV color receiver the I and Q components of the chrominance signal are always in quadrature (90 degrees out-of-phase), therefore, a synchronous detector may be used to separate the color components, since at a phase difference of 90 degrees the output is always zero, as shown in the following illustration. As can be seen from the illustration, the maximum output occurs at zero, 180, and 360 degrees phase difference between the input signal and the reference signal, while no out-put is obtained at 90 or 270 degrees. Since a reference signal is always necessary to produce an output, the synchronous detector can also be considered as a special form of product detector.



Synchronous Detector Response Curve

Circuit Operation. A typical pentode demodulator is shown in the following illustration and is one form of coherent (synchronous) detector commonly used in color TV receivers.



Synchronous Detector

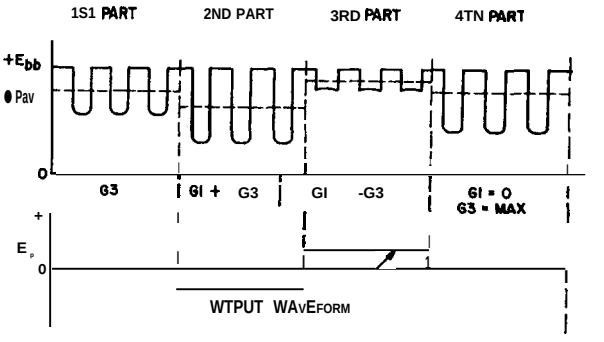
Potentiometer R1 is the input control and R2 is a grid current limiting resistor. Cathode bias is supplied by resistors R3 and R7, with R7 adjustable and bypassed by capacitor C2. Fixed cathode resistor R3 is unbypassed to provide a slight amount of degeneration and improve linearity. (See paragraph 2.2.1 in Section 2 of this Handbook for a complete discussion of cathode bias.) Screen voltage for VI is supplied by R8, which drops the supply voltage to the proper value. Capacitor C3 is the screen bypass capacitor which places the screen at ground potential as far as any signal voltages are concerned. Resistors R4, R5 and R9 are the plate load resistance, with capacitor C4 serving as the ground bypass for resistor R9. In addition, resistors R4 and R5 act as terminating resistors for the lowpass filler network (CIA, CIB and Ll). Series resistance R6 and inductance L2 provide, in effect, a high impedance output, which is capacitively coupled to the next stage by capacitor C5. Both the low pass plate filter and the series reactance in the output are used to ensure that a minimum harmonic output of the reference oscillator is obtained. Normally, with ordinary RC coupling, a strong second harmonic output of the reference oscillator would be produced in the output.

The chrominance subcarrier input signal is normally applied to grid one of pentode tube V1; the reference oscillator signal, which is a CW sine wave of

the same frequency as the chrominance subcarrier, is applied to the suppressor grid (grid three). Since the suppressor grid is located between the plate and screen grid, it acts as a gate. During the half cycle that the reference signal is positive, and increased flow of electrons is attracted to the plate; during the negative half cycle, plate current flow is effectively cut off. With no input signal applied to grid one and the reference signal to grid three, the positive and negative plate voltage excursions are equal and average out to zero, so there is no plate output and the coupling capacitor charges to the average plate voltage value, establishing the zero axis.

When an in-phase signal is simultaneously applied to grid one, while the reference signal is applied to grid three, both voltages add and produce a larger plate current flow. Thus, a higher plate voltage drop occurs in the plate load and a negative output voltage is developed. When the input signal is out-of-phase with the reference signal a lower than normal plate current is produced. With a lower than normal plate current, the average plate voltage increases and effectively produces a positive output.

When the input signal is either 90 or 270 degrees out-of-phase with the reference signal their voltage maximums occur at opposite times. Hence, when one signal is at a maximum, the other is at a minimum or zero. Thus, the effect is as if only one signal were applied (the reference voltage with no input signal), and the average output is zero. Between the angles of zero degrees and 90 degrees, and between 90 degrees 180 degrees the output varies in accordance with the cosine of the phase angle difference. A similar situation exists between 180 and 270 degrees, and 270 and 360 degrees, except that the output polarity is reversed. A typical series of waveforms showing the conditions explained above is shown in the following illustration. For ease of illustration each of the basic waveforms is considered to be of the same amplitude though in practive they may vary from cycle to cycle. The first part of the waveform shows the reference voltage alone applied to grid three with no input to grid one, producing zero output. The second part shows the addition of grid one and grid three waveforms when inphase, producing a negative output. The third part shows the subtraction of the grid one signal from the grid three signal during out-of-phase conditions, with a consequent positive output voltage. In part four both waveforms are 90 degrees out-of-phase and zero output is obtained.



Operating Waveforms

When used for I and Q signal demodulation separate synchronous detectors are required for each signal component; by inserting the proper phase delay in the reference oscillator for one of the components, both signals may be obtained with similar coherent detector circuits. In the discussion of operation, constant amplitude signals were assumed for ease of discussion; in normal operation, the output is also dependent to a slight extent on the amplitudes of the reference and chrominance signals. Usually the reference signal amplitude remains relatively constant, while that of the chroma signal will vary with brightness and hue, and the output will vary accordingly.

Failure Analysis.

No Output. Loss of line or supply voltage, a defective tube, a constant 90 degree phase shift, or no input signal can produce a no-output condition. Measure the line and supply voltage to make certain that a blown fuse or defective power supply is not at fault. Check the phase of the input signal against that of the reference oscillator. If a constant 90 degree phase difference exists either the imput signals are at fault or the reference oscillator is incorrectly tuned. If no chrominance signal is visible on the grid of V1, either RI or R2 may be open, or the grid may be shorted to ground. check the resistance of RI and R2, and between grid and ground.

491-044 0 - 73 59

Measure the cathode bias, screen, and plate voltage of VI. If the bias is almost at cut off, the output will be so low as to be practically no output *at* all. Check the plate and screen circuits for a short to ground, particularly capacitors C3 and C4. If the capacitors are not shorted, V1 may be defective. If no screen voltage appears on grid two, either R8 is open or C3 is shorted. Check the values of R8 and C3. If no plate voltage appears at the plate there will be no output and the screen of VI will glow red. Check R4, R5, and R9 for proper value or an open circuit, and C4 for a short. If there is no bias voltage present, but both screen and plate voltage exist check R3, and R7 for an open. If the input, bias, and plate circuits are satisfactory, it is still possible for R6 or L2 to be open since they are in series with the output.

If no reference signal is present either no output will be present, or it will be the same as the imput signal and very weak. No voltage indicates that no reference signal is present. If an oscilloscope is used, it should show on RF pattern if the reference signal is present. Do not neglect the possibility that output coupling capacitor C5 may be open.

Low Output. Low plate or screen voltage, high bias, or a defective tube can cause a low output. If the supply voltage is low the trouble is in the power supply or line. Low screen voltage can be caused by an increase in the value of R8, a leaky capacitor, C3, or a defective tube. If the plate voltage is low check the resistance of R9 and capacitor C4 for leakage, and check the resistance of R4 and R5, and L1. Also check R6 and L2 for the proper resistance, since they are in series with the output signal. A change in value of coupling capacitor C5 may also reduce the output. If alI voltages and parts check out normal and the output is low there is still a possibility that R1 is set for too low an imput. Potentiometer RI should be adjusted for sufficient drive to produce normal output without distortion. It is also possible that R7 can be set for insufficient bypassing by C2, and excessive cathode degeneration may be causing the reduction of output. If an adjustment of R1 or R7, or both, will return the output to normal the circuit most likely is in normal operating condition.

High Output. An abnormally high supply, plate, or screen voltage, or misadjustment of input control R1 can produce a larger than normal output. First, check the adjustment of R1 to determine whether or not the output may be restored to normal by a simple readjustment of the control. Then measure the supply voltage to determine that the input voltage is not excessive. If the supply voltage is normal, but either the plate or screen voltage is higher than normal, either resistors R8 or R9 have changed value or the through these resistors is less than normal. If these resistors are normal, either low tube emission or a change in value of bias resistors R3 or R7 can be causing the low current.

PART 10-2. FM

FM (OR PM) DETECTORS

General.

The process of detection (demodulation) removes the modulation (transmitted intelligence) from a received r-f signal and transforms it back to its original form so that it may be used for communications or other purposes. While the Am detectors explained previously in this section ‘of the Handbook are used to demodulate an amplitude-modulated (AM) r-f signal, the FM detectors explained in the following paragraphs are used to demodulate a frequency-modulated (FM) r-f signal. Because of the similarity between a frequency-modulated (FM) signal and a phase-modulated (PM) signal, FM detectors may also be used (with minor circuit changes or adjustments) to demodulate a phase-modulated signal.

Although the circuits used in FM transmission and reception are more complex than those used in AM, FM has a number of advantages which far outweigh this disadvantage. An important advantage of FM over AM is the reduction of distortion due to natural and man-made noise. Most noise occurs in the form of amplitude variations in the r-f signal, and in AM, the intelligence is also carried by the amplitude variations. The AM receiver can not distinguish between the amplitude variations caused by the intelligence and those caused by noise, and consequently reproduces both the noise and the intelligence. In FM however, the intelligence is carried by frequency variations in the r-f signal and the FM receiver is designed so that it does not respond to amplitude variations. Consequently, the noise is not reproduced in the FM receiver output. Another important advantage of FM over AM is the possibility of wide-band transmission. Because of the higher carrier frequencies normally used in frequency

modulation, it is possible to use a much wider band of modulating frequencies. This allows FM to be used for such applications as high fidelity transmission (such as in the FM broadcast band) and for multi-channel communications (such as in commercial communications). Moreover, FM transmitters can also be designed to produce a narrow-band output signal (comparable to AM band-width) when it is desired to operate many FM transmitters within a small portion of the frequency spectrum.

The FM signal contains the transmitted intelligence in the form of instantaneous frequency variations to a constant amplitude r-f signal. Therefore, to demodulate the received FM signal without distortion, the FM detector must convert these frequency variations into voltage variations which are identical to the variations in the original modulating voltage. Any variations in the amplitude of the received FM signal are the result of unwanted noise or fading, and will result in distortion of the output signal if passed through the FM detector. Therefore, the FM detector must respond to input frequency variations, but not to input amplitude variations.

Three types of Electron Tube FM detectors are presently in common use: discriminators, ratio detectors, and gated-beam detectors. Discriminator circuits exhibit excellent response to frequency variations, but also respond to amplitude variations, and therefore, must be preceded by limiters to ensure that the discriminator input is of constant amplitude. Ratio and gated-beam detector circuits exhibit slightly poorer response to frequency variations than discriminator circuits, but when properly adjusted, do not respond to amplitude variations. Therefore, ratio or gated-beam detectors are used when economy and simplicity are desired, or precise control of frequency (AFC) is needed.

Semiconductor FM detectors also can be divided into roughly three groups of circuits, namely, discriminators, ratio detectors, or slope detectors. These detectors are very similar in circuitry to that of their electron tube counterparts in that crystal diodes are merely substituted for the vacum-tube diodes. Although these diodes do not have the practically infinite back resistance of the electron tube, otherwise, their performance is similar. And, they do have the advantage of not requiring filament power. For precise frequency response or frequency control discriminator circuits are usually employed. Whereas, the reduced response of the ratio detector is reserved for receivers where economy and simplicity are desired.

FOSTER–SEELEY DISCRIMINATOR (ELECTRON TUBE)

Application.

The Foster-Seeley discriminator is used as the detector in high quality FM receivers to demodulate the received r-f signal, and in automatic frequency con t rol (AFC) circuits to transform frequency changes into d-c control voltage changes.

Characteristics.

Converts instantaneous frequency variations into instantaneous dc voltage variations.

Employs a double-tuned transformer and two diodes.

Has very low inherent distortion.

Must be preceded by a limiter since the output is affected by input amplitude variations.

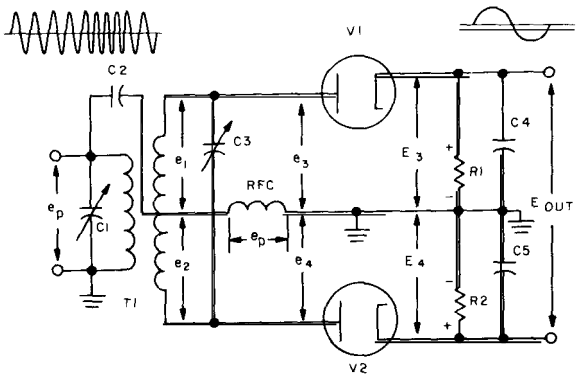
Circuit Analysis.

General. The Foster-Seeley discriminator (also known as the phase-shift discriminator) uses a double-tuned transformer connected in such a way that the instantaneous frequency variations of the input FM signal are converted into instantaneous amplitude variations. The amplitude variations are then rectified and filtered in a manner similar to that employed in AM detectors to provide a dc output voltage which varies in amplitude and polarity as the input signal varies in frequency. The output voltage is zero when the input frequency is equal to the ***center frequency*** (unmodulated carrier frequency). When the input frequency- rises above the center frequency, the output voltage increases in one direction (for example, become more positive), and when the input frequency drops below the center frequency, the output voltage increases in the other direction (for example, becomes more negative). The specific polarity of output voltage obtained for an increase or a decrease in input frequency is determined by the design of the circuit and may vary in different circuits.

The output of the Foster-Seeley discriminator is dependent not only on the input frequency but also, to a certain extent, on the input amplitude. Since variations in the amplitude of the FM signal are due

to unwanted noise or fading, they must be prevented from reaching the discriminator. Therefore, the discriminator is normally preceded by a limiter stage. The limiter produces an output of constant amplitude regardless of variations in the input amplitude, and thus, effectively removes the noise from the received FM signal. (Refer to the Special Circuits Section of this Handbook for a complete explanation of limiter circuits).

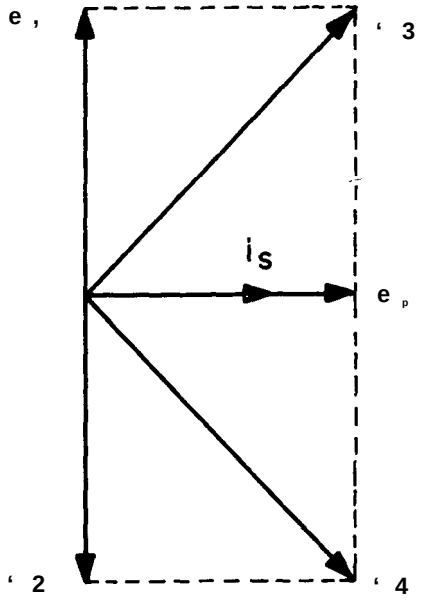
Circuit Operation. The accompanying circuit schematic illustrates a typical Foster-Seeley discriminator.



Foster-Seeley Discriminator

The input tank circuit, made up of capacitor Cl and the primary winding of transformer T1, is tuned to the center frequency (f_R) of the received r-f signal. Capacitor C3 and the secondary winding of transformer T1 also form a tank circuit tuned to the center frequency. Capacitor C2 couples the input signal to the center tap on the balanced secondary winding of transformer T1, which is returned to ground through radio-frequency choke RFC to form a dc return path for the diodes. Diodes V1 and V2 rectify the signal from the secondary tank circiut and develop opposing voltage drops across load resistors R1 and R2, respectively to the applied input frequency. The secondary of T_1 is a series tuned c ircu it. Capacitors c4 and C5 are r-f filter capacitors which remove any rema ining r-f signal from the output . The output is taken from across the series combinat ion of the two load resistors (from the cathode of V1 to the cathode of V2) .

The operation of the Foster-Seeley discriminator can be best explained with vector diagrams whic' show the various phase relationships between the voltages and currents in the circuit. The accompanying vector diagram illustrates the circuit phase relationships when the input frequency (f) is equal to the center frequency.



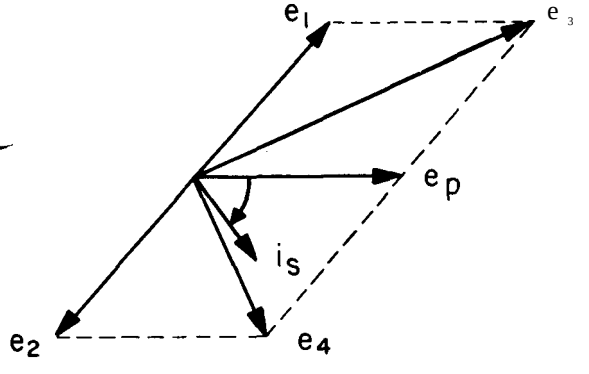
Vector Diagram at Resonance

The input voltage applied to the primary tank circuit i_s shown as vector e_p on the diagram. Since coupling capacitor C2 has negligible reactance at the input frequency, and r-f choke RFC is effectively connected in parallel with the primary tank circuit, voltage e_p also appears across the choke. When voltage e_p is applied to the primary winding of transformer T1, a voltage is induced into the secondar' winding which causes current to flow around the secondary tank circuit. When the input frequency is equal to the center frequency, the tank is at resonance and acts resistive. Therefore, tank current is in phase with primary voltage e_p, as shown in the vector diagram. The current flowing in the tank causes voltage drops to be produced across each half of the balanced secondary winding of transformer T1, which are of equal magnitude and opposite polarity with respect to the center tap of the winding. Since the winding is predominately inductive, the voltage drop across it is 90° out of phase with the current through it. Because of the grounded center top arrangemen

the voltages to ground at each end of the secondary vindingare180° out of phase, and are shown as e_1 'and e_2 on the vector diagram.

The voltage appfied to the plate of V1 consists of the vector sum of voltages e_p and e, shown as e_3 on the diagram. Likewise, the voltage applied to the plate of V2 consists of the vector sum of voltages e_p and e_2, shown as e_4 on the diagram. Since at resonance there is no phase shift, voltages e_3 and e_4 are equal as shown by the same length vectors. Equal plate voltages on diodes VI and V2 produce equal plate currents, and with identical load resistors produce equal and opposite voltages (ε_3 and ε_4) across R1 and R2, respectively. Thus capacitors C4 and C5 are charged to equal voltages, and, since these voltages are of opposite polarity, the output voltage at resomnce is zero. Since the opposite ends of the secondary winding are out of phase, only one diode conducts at a time, and conduction occurs as a series of dc pulses occuring at the center radio frequency. Although the output of the diode is a direct current it contains a ripple component at the center frequency. This r-f component is filtered out by capacitors C4 and C5 since they offer a low reactance path to ground (action is similar to a power supply filter capacitor except for the frequency).

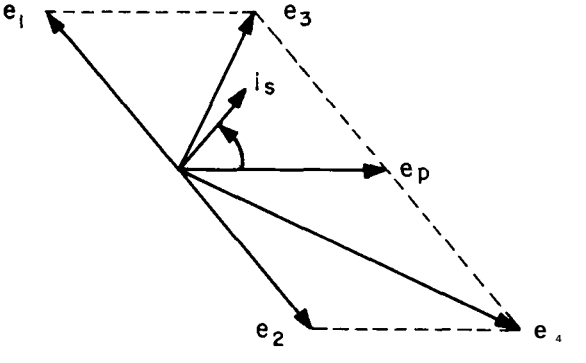
When an input frequency higher than the center frequency is applied to the discriminator circuit a phase shift occurs, and the current and voltage phase relationships change as shown in the following vector diagram.



Vector Diagram For Higher Input Frequency

When a series tuned circuit operates at a higher frequency than resonance, the inductive reactance of the coil increases, while the capacitive reactance of the tuning capacitor decreases. Therefore, above resonance the tank is predominately inductive and acts like an inductor. Hence, secondary current *lags* the primary tank voltage e_p. Although secondary voltages e_1 and e_2 are still 180 degrees out of phase, they are also 90 degrees out of phase with the current which produces them (is). Thus the change to a lagging secondary current rotates the vector in a clockwise direction. Referring to the vector diagram it is seen that e_1 is brought nearer in phase with e_p, while e_2 is shifted further out of phase with e_p. Thus the vector sum of e_p and e_1 is larger than that of e_p and e_2. Therefore, above the center frequency, diode V1 conducts heavier than diode V2. Consequently, voltage e_3 developed across RI is greater than e_4 developed across R2, and the voltage on capacitor C4 is likewise greater than on C5. The combined output voltage is therefore, a positive voltage.

When an input frequency lower than the center frequency is applied to the discriminator circuit a phase shift also occurs, and the current and voltage phase relationships change as shown in the following vector diagram.

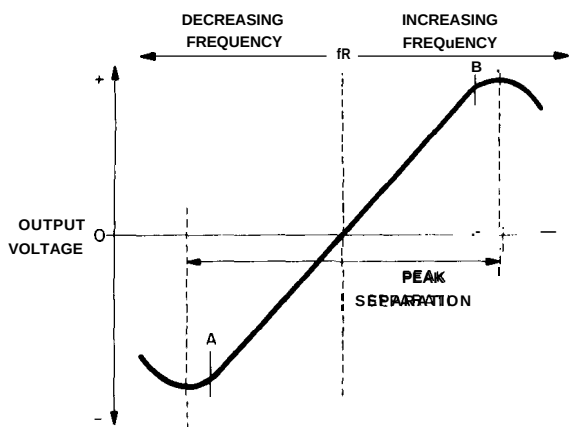


Vector Diagram for Lower Input Frequency

When a tuned circuit operates at a lower frequency than resonance, the capacitive reactance of the tuning capacitor increases, while the inductive reactance of the coil decreases. Therefore, below resonance the tank is predominately capacitive and acts like a

capacitor, Hence, secondary current is ***leads*** the primary tank voltage e_p. Although secondary voltages e_1 and e_2 are still 180 degrees out of phase, they are also 90 degrees out of phase with the current which produces them. Thus the change to a leading secondary current rotates the vector in a counterclockwise direction. From the vector diagram it is seen that e_2 is now brought nearer in phase with e_p, while e_1 is shifted further out of phase with e_p. Thus the vector sum of e_p and e_2 is larger than that of e_p and e_1. Therefore, below the center frequency, diode V2 conducts heavier than diode V1. Consequently, voltage drop e_4 across R2 is greater than e_3 across RI, and the voltage on capacitor C5 is, likewise, greater than on C4; thus the combined output voltage is a negative voltage.

When the input voltage is varied from a lower frequency through the resonance point of the discriminator and is then raised higher in frequency, the typical discriminator response curve shown in the following illustration is obtained. The usable portion of the typical "S" shaped response curve is from point A to point B in the illustration. Between these points, the curve is linear and the instantaneous output voltage is directly proportional to the instantaneous frequency deviation.



Discriminator Response Curve

When weak A-M signals which are too small in amplitude to reach the limiting level pass through the limiter stage, the amplitude variations cause primary voltage e_p to fluctuate with the modulation and induce a similar secondary voltage in T1. Since the diodes are connected as half-wave retifiers, these small A-M signals are detected as in a diode and appear in the output. This unwanted AM interference is cancelled out in the ratio detector (to be discussed later in this section of the Handbook) and is the main disadvantage of the Foster-Seeley circuit in comparison with other FM detectors.

Failure Analysis.

No Output. A defect in the primary winding of transformer T1, in the RFC, or in capacitors C 1, C2 or C3 may cause a no-output condition. Use an ohmmeter to check the primary winding of transformer T1 and the RFC for continuity; also check both for leakage or shorts to ground. If these checks fail to locate the trouble, use an in-circuit capacitance checker to check capacitors C 1, C2 and C3. Note that the failure of either diode will cause distortion rather than a no-output condition; if both diodes fail, however, there will be no output.

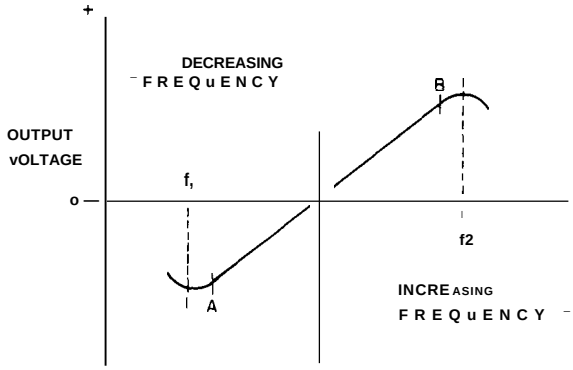
Low or Distorted Output. A defect in nearly any component in the discriminator circuit may cause the output to be either low to distorted. Therefore, it is good practice to use an r-f sweep generator and an oscilloscope to isolate the trouble. First, use the oscilloscope to observe the input to the discriminator to be certain that the preceding (limiter) stage is not at fault. If the input signal does not change in amplitude as the input frequency varies, the trouble is most likely in the discriminator circuit. To determine if the discriminator is at fault, ground the grid of the preceding limiter stage, connect the r-f sweep generator to the discriminator input, and connect the oscilloscope to the discriminator output. With the sweep generator set to produce an output which varies above and below the center frequency, the pattern observed on the oscilloscope should be similar to the discriminator response curve illustrated previously. Defects in the circuit will cause either the entire curve, or a portion of it to be distorted to flattened.

If the entire response curve is distorted, the trouble may be caused by either improper alignment or by a defect in transformer T1. First check to be certain that both the primary and secondary tank circuits are properly tuned to the center frequency. If the discriminator is properly aligned, the trouble is most probably caused by a defect in transformer T1.

If only the upper portion of the response curve is distorted, the trouble may be caused by a defect in diode V1, capacitor C4, Resistor RI, or transformer T1. Use a capacitor checker to check capacitor C4 for

value and leakage, and use an ohmmeter to check resistor RI for a change of value. If these checks fail to locate the trouble, transformer T1 is probably defective.

Conversely, if only the lower portion of the response curve is distorted, the trouble may be caused by a defect in diode V2, capacitor C5, resistor R2, or transformer T1. Check capacitor C5 for value and leakage, and use an ohmmeter to check resistor R2 for a change of value. If these checks fail to locate the trouble, transformer T1 is problbly defective.



Discriminator Response Curve

FOSTER-SEELEY DISCRIMINATOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

Characteristics.

Same characteristics as electron tube version.

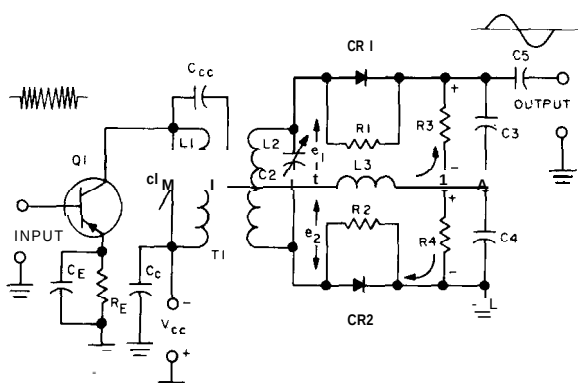
Circuit Analysis.

General. The Foster-Seeley discriminator (also known as the phase-shift discriminator) uses a double-tuned r-f transformer to convert the instantaneous frequency variations of the received f-m signal into instantaneous amplitude variations. The amplitude variations are then rectified and filtered to provide a dc output voltage which varies in amplitude and polarity as the input signal varies in frequency. The output voltage is zero when the input frequency is equal to the ***center frequency*** (unmodulated carrier frequency). When the input frequency rises above the center frequency the output increases in one direction (for example, becomes more positive), and when the input frequency drops below the center frequency, the output increases in the other direction (for example, becomes more negative).

Since the output of the Foster-Seeley discriminator is dependent ont only on the input frequency, but also to a certain extent upon the input amplitude, it is necessary to use one or two limiter stages before detection. When properly limited, and the input frequency is varied from a lower frequency through the resonance point of the discriminator, and is then raised higher in frequency, the typical discriminator response curve shown in the following illustration is obtained.

The usable portion of the typical "S" shaped response curve is from point A to point B in the illustration. Between these points, the curve is linear and the instantaneous output voltage is directly proportional to the instantaneous frequency deviation.

Circuit Operation, The following circuit schematic illustrates a typical Foster-Seeley semiconductor discriminator.



Foster-Seeley Discriminator Circuit (including limiter stage)

The collector portion of the preceding i-f (limiter) amplifier Q1 is shown on the schematic with conventional emitter resistor R_E and bypass capacitor C_E. The collector circuit tank consisting of Cl and L1 is the primary tank of i-f input transformer T1, while L2 and C2 form the secondary tank circuit; both tanks are tuned to the center frequency. Choke L3 forms the dc return for diode rectifiers CR I and CR2. While CR1 and CR2 are shown bypassed by equalizing resistors RI and R2, they are not always used (they are usually used when the diode back resistances are different). Resistors R3 and R4 are the load resistors bypassed by C3 and C4, respectively, for r-f, capacitor C5 is the output coupling capacitor.

The center tap on coil L2 is capacitively coupled through coupling capacitor CCC to the primary. And the full voltage exists across choke L3. At resonance (the center frequency) equal voltages e_1 and e_2 are produced across both halves of L2, thus equal vokages are applied to the anodes of CR1 and CR2. Assuming these voltages are positive, conduction occurs and current flow through diode load resistors R3 and R4 produce equal and opposing voltages across filter capacitors C3 and C4. Since the output is taken from C5 to ground, the equal and oppositely polarized signals cancel and produce no output at the center frequency. However, as the frequency is raised above the center frequency, the phase relationships in the halves of the tank circuit cause a voltage change so that e_1 becomes larger than e_2. Since it is larger than the voltage across R4, the voltage of R3 predominates, creating a positive output voltage.

Conversely, when the input signal frequency drops below the center frequency and is lower, voltage e_2 is larger than e_1 and the voltage across R4 predominates, creating a negative output. As long as the input frequency variations remain within the limits of peak separation marked A and B on the discriminator curve, a linear frequency versus amplitude relationship is maintained. That is the higher the frequency the larger the positive output voltage becomes, and the lower the frequency the larger the negative output becomes. (If desired, the discriminator transformer can be wound and connected to produce opposite polarities from that described above.) In any event, the output voltage is always developed across both R3 and R4, and it is always the algebraic sum of these. Capacitors C3 and C4 are used to store the instantaneous voltages and develop an average output which varies at audio frequencies. This output, in turn, is coupled to the audio amplifying stages by coupling capacitor C5 (any coupling method may be used). Thus, while the input consists of a constantly varying f-m signal of steady amplitude, the output is an audio frequency which varies linearly both in frequency and amplitude in accordance with the frequency swing of the input signal.

Failure Analysis.

No Output. A defect in the primary or secondary windings of T1, in the RFC, or in tank tuning capacitors C 1, C2, or C3, as well as defective diodes can cause a no-output condition. It is also possible for coupling capacitors CCC or C5 to be open, or for bypass capacitors Cc, as well as C3 or C4 to be shorted and bypass the signal to ground. Use an ohmmeter to check the primary and secondary of T1 and the RFC for continuity, and for shorts to ground. If these checks fail to locate the trouble, use an in-circuit capacitance checker to measure the values of cl, cc, ccc, C3, and C4. Note also, that both diodes must fail to cause no-output, since if only one fails there still will be an output. When possible, use an oscilloscope to observe the waveform at the input and follow the signal through the circuit noting where the signal disappears to locate the source of the trouble.

Low or Distorted Output. A defect in nearly any component in the discriminator circuit may cause the output to be low or distorted. Use a R-F Sweep Generator and an oscilloscope to isolate the trouble. Connect the sweep generator to the input and check the output with the scope on Q1 and at the anode of diode CR1 or CR2. Lack of signal at Q] indicates defective transistor or part in the transistor stage of Q1. A signal on Q1 but not at the diode anodes indicates CCC is either open or shorted to ground. If the input signal does not change in amplitude as the input frequency varies, the trouble is most likely in the discriminator circuit. To determine if the discriminator is at fault, ground the base of limiter stage Q1 and connect the r-f sweep input to the discriminator input, with the oscilloscope connected to the discriminator output. Adjust the sweep generator to produce an output which varies both below and above the discriminator center frequency and observe if the pattern on the oscilloscope is that of the typical “S” curve shown in the first illustration of this discussion. Defects in the circuit will cause either the entire curve or a portion of it to be distorted, or flattened.

If the entire response curve is distorted the trouble may be caused by either improper alignment or by a defect in transformer T1. First check to be certain that both the primary and secondary tank circuits are tuned to the proper center frequency. If the discriminator is aligned properly, the trouble is most likely in the transformer.

If only the upper portion of the response curve is distorted, the trouble may be caused by a defect in diode CR1, capacitor C3, resistor R3 or transformer T1. Use an in-circuit capacitance checker to check capacitor C3 for value and leakage, and use an ohmmeter to check resistor R3 for a change of value.

Conversely, if only the bottom portion of the discriminator response curve is distorted, the trouble may be caused by diode CR2, capacitor C4, resistor R4, or transformer T1. If the trouble persists use an in-circuit capacitance checker to check C4 for value and leakage, and use an ohmmeter to check resistor R4 for a change of value. If these checks fail to restore the output to normal, transformer T1 is most likely defective.

RATIO DETECTOR (ELECTRON TUBE)

Application.

The ratio detector is used in FM receivers to demodulate the received r-f signal, and in automatic volume control (AVC) circuits to transform frequency changes into dc control voltage changes.

Characteristics.

Converts instantaneous frequency variations into instantaneous dc voltage variations.

Employs a double tuned transformer and two diodes.

Has very low inherent distortion.

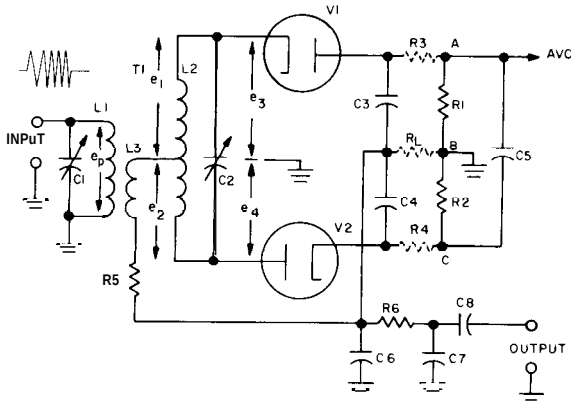
Output not affected by input amplitude variations.

Circuit Analysis.

General. The ratio detector uses a double tuned transformer, connected so that the instantaneous frequency variations of the FM input signal are converted into instantaneous amplitude variations. These amplitude variations are rectified to provide a dc output voltage which varies in amplitude and polarity as the input signal varies in frequency. The output is zero when the input frequency is equal to ***the center frequency*** (unmodulated carrier frequency). When the input frequency rises above the center frequency, the output voltage increases irr one direction (for example, becomes more positive).

When the input frequency drops below the center frequency, the output voltage increases in the other direction (for example becomes more negative). The specific polarity of the output voltages obtained for an increase or decrease in input frequency is determined by the design of the circuit and may vary in different circuits.

Circuit Operation. The accompanying schematic diagram illustrates a typical ratio detector.

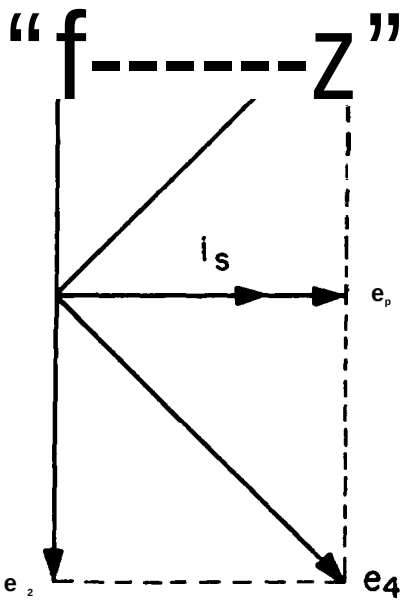


Ratio Detector

The input tank circuit, made up of capacitor Cl and the primary winding of transformer T 1, is tuned to the center frequency (fr) of the received r-f signal. Capacitor C2 and secondary winding L2 of transformer T1 form a tank circuit also tuned to the center frequency. Tertiary winding L3 provides additional inductive coupling which reduces the loading effect of the secondary circuit of the detector on the primary circuit of the detector. Diodes V 1 and V2 rectify the signal from the secondary tank circuit. Capacitor C5, in conjunction with resistors RI and R2, determines the operating level of the detector, while capacitors C3 and C4 determine the amplitude and polarity of the output. Capacitors C6 and C7, together with R6, form a filtering network at the output. Resistor R5 modifies the peak diode currents. Resistors R3 and R4 (shown in dotted lines on the schematic) were used in the original design of

the circuit to compensate for the changing reactance of the diodes for different amplitude input signals. In practical circuits, however, they are combined with RI and R2, and achieve the same result. The output of the detector is taken from the common connection between C3 and C4 to the common connection between RI and R2 which is also ground. Resistor R_L represents the load.

Operation can be best explained with vector diagrams which show the various phase relationships between the voltages and currents in the circuits. The following vector diagram illustrates the circuit phase relationships when the input frequency (f) is equal to the center frequency (fr).

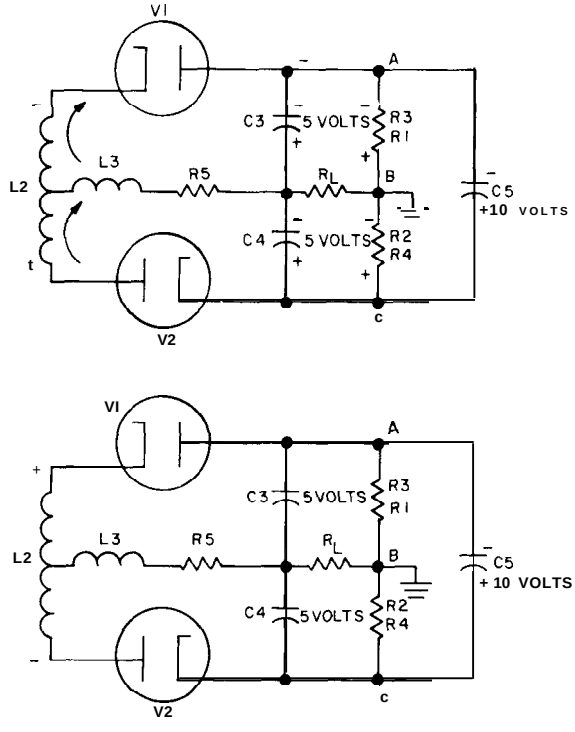


Vector Diagram at Resonance

The input voltage applied to the primary tank circuit is shown as vector e_p on the diagram. Since L3 is effectively connected in parallel with the primary tank circuit, voltage e_p appears across it. When voltage e_p is applied to the primary winding of transformer T1, a voltage is induced in the secondary winding which causes current to flow around the secondary tank circuit. When the input frequency is at the center frequency, the tank is at resonance and acts resistive. Therefore, tank current is in phase with the primary voltage e_p, as shown in the vector diagram. The current flowing in the tank causes voltage drops to be produced across each half of the balanced secondary winding of transformer T1, which are of equal magnitude and opposite polarity with respect to the center top of the winding. Since the winding is predominately inductive, the voltage drop across it is 90° out of phase with the current through it. Because of the center tap arrangement, the voltages to ground at each end of the secondary are 180° out of phase, and are shown as e_1 and e_2 on the vector diagram.

The voltage applied to the cathode of VI consists of the vector sum of voltages e_p and e_1 shown as e_3 on the diagram. Likewise, the voltage applied to plate of V2 consists of the vector sum of voltages e_p and e_2 shown as e_4 on the diagram. Since at resonance there is no phase shift, voltages e_3 and e_4 are equal as shown by the same length vectors.

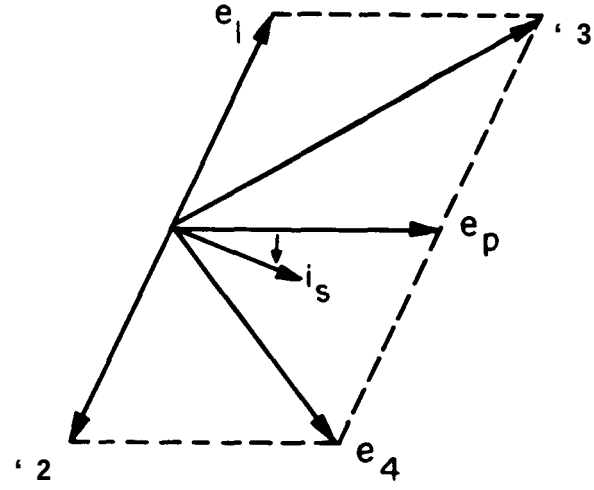
Consider now the manner in which the tubes operate with the discriminator voltages discussed above. When a positive input signal is applied to L1, a voltage of opposite polarity is induced into secondary L2. As shown in the following simplified schematic, the cathode of V1 is negative with respect to its plate, while the plate of V2 is positive with respect to its cathode. Since both voltages are of equal magnitude at resonance, both tubes conduct equally. Hence, current flow through Vl is in one direction, while current flow through V2 is in the opposite direction. This direction of current flow causes a negative polarity at point A and a positive polarity at point B, and through R_L applies a positive charge to C3. In a similar manner current flow through V2 produces a negative polarity at point B and a positive polarity at C. Hence, Capacitor C4 is charged negatively. Since the polarities are additive, capacitor C5 across the output charges to the series value of twice this voltage. In the example shown it is assumed that equal but opposite voltages of 5 volts exist across C3 and C4. Therefore, the total charge across C5 is 10 volts. Since the voltages across C3 and C4 are equal in amplitude and of opposite polarity the output across load R_L is the algebraic sum or zero.



Current Flow and Polarities at Resonance

When the input signal reverses polarity, the secondary voltage across L2 also reverses polarity. The cathode of VI is now positive with respect to its plate, and the plate of V2 is negative with respect to its cathode. Under these conditions neither tube conducts, and there is no output. Meanwhile, C5 retains most of its charge because of the large time constant supplied by R1 and R2, and discharges very slightly.

When an input frequency higher than the center frequency is applied to the detector circuit, a phase shift occurs and the current and voltage phase relationships change as shown in the following vector diagram.

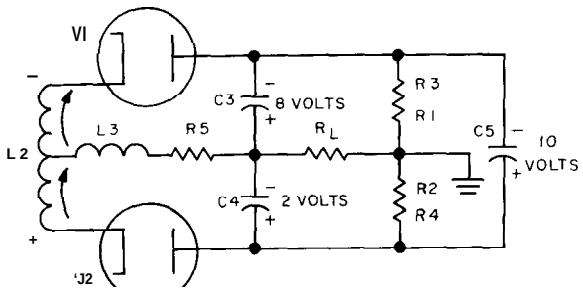


Vector Diagram for Higher Input Frequency

When a tuned circuit operates at a higher frequency than resonance, the inductive reactance of the cbil increases, while the capacitive reactance of the tuning capacitor decreases. Therefore, above resonance, the tank is predominately inductive and acts like an inductor. Hence the secondary current i_s lags the primary voltage e_p. Although secondary voltage e_1 and e_2 are still 180 degrees out of phase, they are also 90 degrees out of phase with the current which produces them (i_s). Thus the change to a lagging secondary current rotates the vector in a clockwise direction. Referring to the vector diagram it can be seen that e_1 is brought nearer in phase with e_p, while e_2 is shifted further out of phase with e_p. Thus the vector sum of e_p and e_1 is larger than that of e_p and e_2. Thesefore, above the center frequency, e_3, which is applied to the cathode of V 1 becomes greater than e_4, the voltage applied to the plate of V2.

Let us now examine the manner in which the tubes operate with the discriminator voltages developed above resonance as discussed above. When a

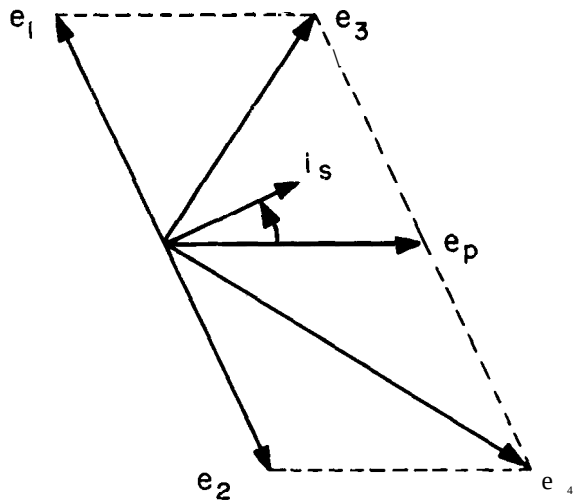
positive input signal is applied to L1, the same polarity as in the previous example discussed above exists, namely, V1 cathode is negative and V2 plate is positive and both tubes conduct. However, e_3 is not greater than e_4. Therefore, diode V1 conducts more than diode V2, and C3 charges to a higher voltage than at resonance, as shown in the following simplified illustration.



Current Flow and Polarities Above Resonance

Thus we assume in the figure an 8 volt charge on C3 and only a two volt charge on C4. Since C3 is positive with respect to C4, the output is a 6 volt positive signal. Meanwhile, capacitor C5 still remains charged to the sum of these voltages, or 10 volts, as originally stated. When the input signal reverses polarity, the polarity of the secondary also reverses, biasing both diodes in the opposite direction and preventing conduction. During the nonconducting period, C5 discharges very little because of its long time constant.

When an input frequency lower than the center frequency is applied to the detector circuit, a phase shift also occurs, and the current and voltage phase relationships change as shown in the following vector diagram.

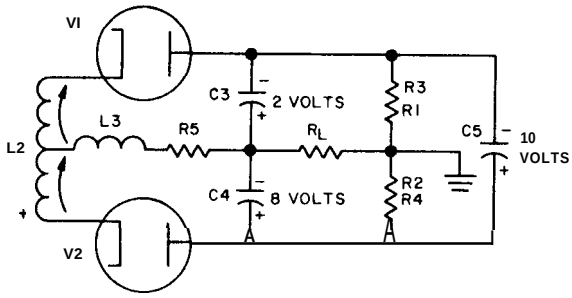


Vector Diagram for Lower Input Frequency

When a series tuned circuit operates at a lower frequency than resonance, the capacitive reactance of the tuning capacitor increases, while the inductive reactance of the coil decreases. Therefore, below resonance, the tank is predominately capacitive and acts like a capacitor. Hence, secondary current i_s ***leads*** the primary voltage e_p. Although secondary voltages e_1 and e_2 are still 180 degrees out of phase, they are also 90 degrees out of phase with the current which produces them. Thus the change to a leading secondary current rotates the vector in a counterclockwise direction. From the vector diagram it can be seen that e_2 is now brought nearer in phase with e_p, while e_1 in shifted further out of phase with e_p. Thus the vector sum of e_p and e_2 is larger than that of e_p and e_1. Therefore, below center frequency, e_4, which is applied to the plate of V2, becomes greater than e_3, the voltage applied to V1.

4

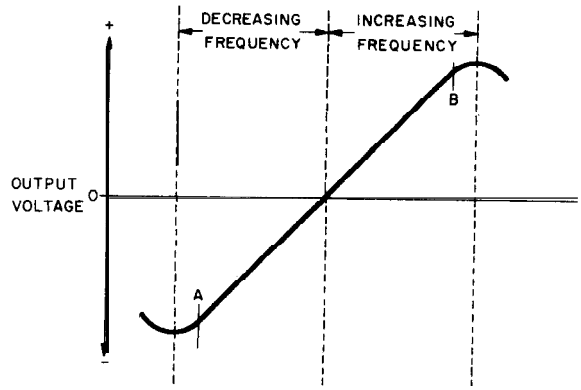
The following simplified schematic shows the polarities and voltages developed for the lower than resonance condition. Once again VI and V2 are conducting, but this time V2 is conducting more than V1, and hence, capacitor C4 is charged to the larger voltage 8 volts while C3 is only charged to 2 volts. The output voltage across the load in this case is a negative 6 volts because C4 is negatively charged with respect to C3. Again the charge across capacitor C5 consists of the sum of the voltages across C3 and C4, 01 10 volts as originally developed.



Current Flow and Polarities Below Resonance

When the input signal reverses its polarity, the signal across the secondary also reverses its polarity. The cathode of V1 is now positive with respect to its plate, and the plate of V2 is negative with respect to its cathode. Under these conditions, neither tube conducts, but the time constant of C3 and C4 maintains the current through the load in a negative direction until the next cycle of input.

When the input signal is varied from a lower than center frequency, through center frequency, and is raised to a frequency higher than the center frequency, the typicrd "S" shaped discriminator response curve shown in the following illustration is obtained. The usable portion of the typical "S" shaped response curve is from point A to point B in the illustration. Between these points, the curve is linear and the instantaneous output voltage is directly proportional to the instantaneous frequency deviation.



Ratio Detector Response Curve

The output of the ratio detector adjusts itself automatically to the average r-f amplitude of the input signal. Through the action of resistors R1 and R2, together with capacitor C5, audio output variations which would occur due to r-f amplitude variations in the input (such as noise) are eliminated. As previously mentioned, C5 charges to the sum of e_3 and e_4. The average sum of e_3 and e_4 depends upon the average r-f amplitude of e_p. Any amplitude variations at the input of the detector tends to change the voltages across R1 and R2, but because of the long time constant of C5, across the resistors, these voltages are held constant. Before the capacitor can charge or discharge to the higher or lower amplitude variation the impulse disappears, and the difference in charge on C5 is so slight that it is not discernible in the output. Because the voltage across C5 remains relatively stable and changes only with the amplitude of the center frequency, and since it is negative with respect to ground it is usually used for automatic volume control (AVC) applications.

Capacitors C6 and C7 together with resistor R6 form a low pass filter which attenuates the high audio frequencies and passes the lower frequencies. This is known as a de-emphasis network, which compensates for the pre-emphasis with which the high frequencies are transmitted and returns the audio frequency

balance to normal. When pre-emphasis is not employed these parts are not needed.

Failure Analysis.

No Output. A defective discriminator transformer, Tl, shorted tuning capacitor Cl or C2, an open output resistor R6, and open coupling capacitor C8, or shorted filter capacitors (C6 or C7) will produce a no output condition. Check the continuity of the windings of T1 with an ohmmeter. Check capacitors Cl, C2, C6 and C7 for shorts, and capacitor C8 for an open with an ohmmeter, and measure the resistance of R6. If above checks fail to restore the output, check all capacitors with an in-circuit capacitor checker. Note that one defective diode will produce a partial loss of output, and that both diodes must fail to cause a complete loss of output.

Low or Distorted **Output.** A defect in nearly any component in the detector circuit may cause the output to be either low or distorted. Therefore, it is good practice to use an r-f sweep generator and an oscilloscope to isolate the trouble. Ground the grid of the last I-F tube, connect the r-f sweep generator to the detector input, and connect the oscilloscope to the detector output. With the sweep generator set to produce an output which varies above and below the center frequency, the pattern observed on the oscilloscope should be similar to the discriminator response curve illustrated previously. Defects in the circuit will cause either the entire curve, or a portion of it to be distorted or flattened.

If the entire response curve is distorted, the trouble may be caused by either improper alignment or by a defect in the transformer T1. First check to be certain that both primary and secondary tank circuits are properly tuned to the center frequency. If the detector is properly aligned, check capacitors Cl and C2 with an in-circuit capacitor checker. Check RI and R2 with an ohmmeter for their proper values, and capacitor C5 for value and leakage with an in-circuit capacitor checker. If the trouble is still not located, the trouble is most likely caused by a defect in transformer T1.

If only the upper portion of the response curve is distorted, the trouble may be caused by a defect in diode V1, capacitor C3, or transformer T1. If the diode VI checks good, use an in-circuit capacitor checker to check C3 for value and leakage. If these checks fail to locate the trouble, transformer T1 is probably defective.

Conversely, if only the lower portion of the response curve is distorted, the trouble may be caused by a defect in diode V2, capacitor C4, or transformer T1. Use an in-circuit capacitor checker to check C4 for value and leadage. If these checks fail to locate the trouble, transformer T1 is probably defective.

RATIO DETECTOR (SEMICONDUCTOR)

Application.

Same application as electron tube version.

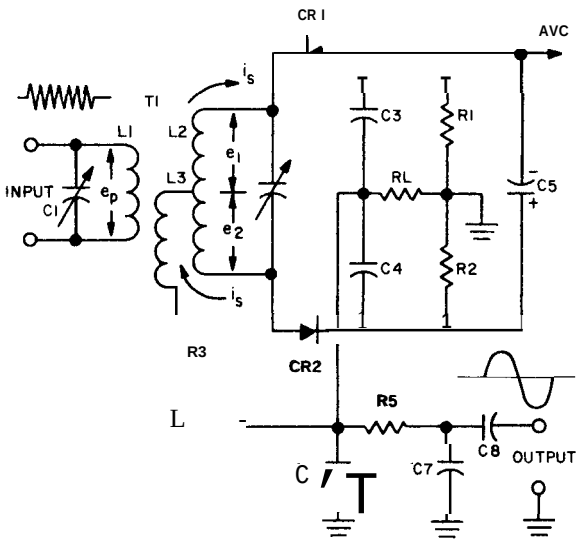
Characteristics.

Same characteristics as electron tube version.

Circuit Analysis.

General. The semiconductor ratio detector, like the electron tube ratio detector previously discussed the this Handbook, uses a double tuned transformer (discriminator) connected so that the instantaneous frequency variations of the FM input signal are converted into instantaneous amplitude variations. These amplitude variations are rectified by the diodes to provide a dc output voltage which varies in amplitude and polarity as the input signal varies in frequency. The output is zero when the input is equal to the ***center frequency*** (unmodulated carrier" frequency). When the input frequency rises above the center frequency, the output "voltage increases in one direction (for example, becomes more negative). The specific polarity of the output voltages obtained for an increase or decrease in input frequency is determined by the design of the circuits and may vary from circuit to circuit.

Circuit Operation. The accompanying schematic diagram illustrates a typical semiconductor ratio detector.

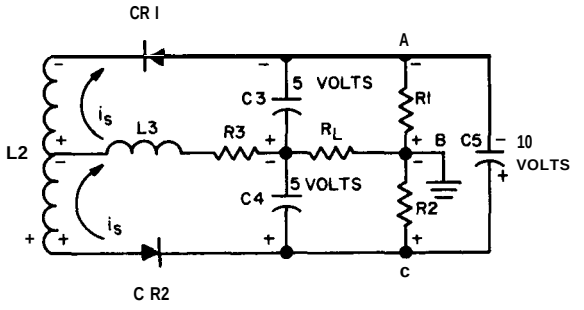


Ratio Detector

The input tank circuit comprised of Cl and primary winding L1 or T1 is tuned to the center frequency of the received f-m signal. Secondary winding L2 and capacitor C2 also form a tank circuit tuned to the center frequency. Tertiary winding L3 provides additional inductive coupling which reduces the loading effect of the secondary on the primary circuit of the detector. Solid state diodes CR1 and CR2 rectify the signal from the secondary tank. Capacitor C5, in conjunction with resistors R1 and R2 determines the operating level of the detector, while capacitors C3 and C4 determine the amplitude and polarity of the output. Resistor R3 modifies the peak diode current and furnishes a dc return path to ground. The output of the detector is taken from the common connection between C3 and C4 to ground, which is also the common connection of R1 and R2. Resistor R_L is the load resistor. A low-pass filter is formed by R5 together with C6 and C7 to provide high frequency reemphasis. Capacitor C8 is the output coupling capacitor.

When input voltage e_p is applied to the primary, it also appears across L3 since it is effectively connected in parallel with the primary tank circuit by inductive coupling. When voltage e_p is applied to the primary winding of transformer T1, a voltage is also inducted in the secondary winding and causes current to flow around the secondary tank circuit. When the input frequency is at the center frequency, the tank is at resonance, is resistive, and acts like a resistor. Therefore, tank current is in phase with primary voltage e_p. The current flowing in the tank circuit causes equal voltage drops to be produced across each half of the balanced secondary winding of Tl, which are of equal magnitude and of opposite polarity with respect to the center tap of the winding. Since the winding is predominately inductive, the voltage drop across it is 90 degrees out of phase with the current through it. At the same time, because of the center tap arrangement, the voltages to ground at each end of the secondary are 180 degrees out of phase and are shown as e_1 and e_2 on the schematic.

The voltage applied to the cathode of CR1 consists of the vector sum of e_1 and e_p. Likewise, the voltage applied to the anode of CR2 consists of the vector sum of voltages e_2 and e_p. Since at resomnce there is no phase shift, both voltages are equal. Consider now the manner in which the diodes operate with the discriminator voltage discussed above. When a positive input signal is applied to Ll, a voltage of opposite polarity is induced into secondary L2. As shown in the accompanying simplified schematic, the cathode of CR1 is negative with respect to its anode and is forward biased, while the anode of CR2 is positive with respect to its cathode and is likewise, forward biased. Since both voltages are of equal magnitude at resonance, both diodes conduct equally. Hence current flow through CR1 is in one direction, while the current through CR2 is in the opposite direction. This direction of current flow causes a negative polarity at point A and a positive polarity at point B. Through R_L a positive charge is applied to C3. In a similar manner current flow through CR2 produces a negative polarity at point B and a positive polarity at C. Hence Capacitor C4 is charged negatively. Since the polarities are additive, capacitor C5 across the output charges to the series value of twice this voltage.



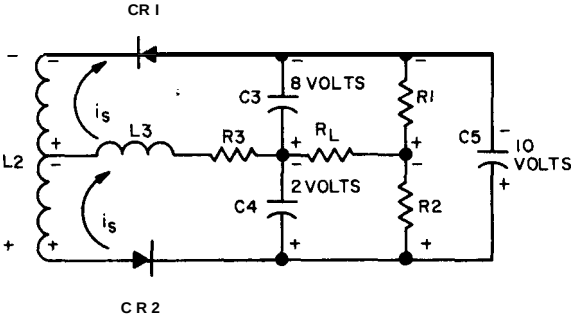
Simplified Schematic

In the example shown, it is assumed that equal but opposite voltages of 5 volts exist across C3 and C4. Therefore, the total charge across C5 is 10 volts. Since the voltage across C3 and C4 are equal in amplitude (5 volts) and of opposite polarity, the output across load resistor R_L is the algebraic sum or zero.

When the input signal reverses polarity, the secondary voltage across L2 also reverses polarity. The cathode of CR1 is ***now*** positive with respect to its anode, and the anode of CR2 is negative with respect to its cathode. Under these reverse-bias conditions neither diode conducts, and there is also no output. Meanwhile C5 retains most of its charge because of the long time constant offered by RI and R2 and discharges very slightly.

When a tuned circuit operates at a higher frequency than resonance, the inductive reactance of the coil increases, while the capacitive reactance of the tuning capacitor decreases. Therefore, above resonance the tank is predominately inductive and acts like an inductor. Hence the secondary current (i_s) *lags* the primary voltage e_p. Therefore, when an input frequency higher than the center frequency is applied to the detector circuit, a phase shift occurs. Although secondary voltages e_1 and e_2 are still 180 degrees out of phase, they are also 90 degrees out of phase with the current (i_s) which produces them. Thus the change to a lagging secondary current rotates the vector in a clockwise direction and e_1 is brought nearer in phase with primary voltage e_p, while e_2 is shifted further out of phase with e_p. Thus the vector sum of e_p and e_1 is now larger than that of e_p and e_2. Therefore, above the center frequency the voltage applied to the cathode of CR1 becomes greater than the voltage applied to the anode of CR2.

Consider not the manner in which the diodes operate with the discriminator voltages developed above resonance, as discussed above. When a positive input is applied to L1 the same polarity as in the previous example discussed above exists, namely CRI cathode is negative and CR2 anode is positive, and both diodes conduct. However, e_1 is now greater than e_2. Therefore, diode CR1 conducts more than diode CR2, and C3 charges to a higher voltage than at resonance, as shown in the following simplified illustration.

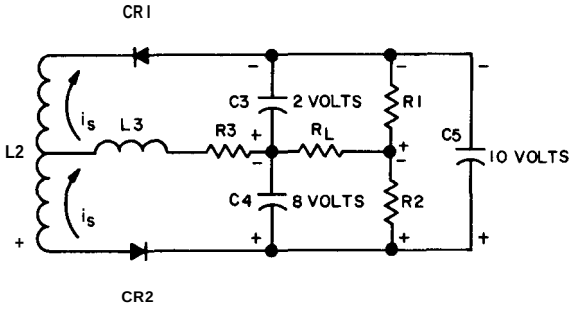


Current Flow and Polarities above Resonanea

Thus, we assume in the figure an 8-volt charge on C3 and only a 2-volt charge on C4. Since C3 is positive with respect to C4, the output is a 6-volt positive signal. Meanwhile, capacitor C5 still remains charged to the sum of these voltages or 10 volts, as originally stated. When the input signal reverses polarity, the polarity of the secondary also reverses, biasing both diodes in the opposite direction, and preventing conduction. During the nonconducting period, C5 discharges very little because of the long time constant.

When a tuned circuit operates at a lower frequency than resonance, the capacitive reactance of the tuning capacitor increases, while the inductive reactance of the tank coil decreases. Therefore, below resonance, the tank is predominately capacitive and acts Iike a capacitor. When an input frequency lower than

the center frequency is applied to the detector circuit, a phase shift also occurs and secondary current i_s *leads* the primary voltage e_p. Although secondary voltages e_1 and e_2 are still 180 degrees out of phase they are also 90 degrees out of phase with the current which produces them. Thus the change to a leading secondary current rotates the vector in a counterclockwise direction, and e_2 is now brought nearer in phase with e_p while e_1 is shifted further out of phase with e_p. Thus the vector sum of e_p and e_2 is now larger than that of e_p and e_1. Therefore, below the center frequency the voltage applied to the anode of CR2 becomes greater than the voltage applied to the cathode of CRI as shown in the following simplified schematic.



Current Flow and Polarities Below Resonance

Once again CR1 and CR2 are conducting, but this time CR2 is conducting more than CR1, hence, capacitor C4 is charged to the larger voltage of 8 volts, while C3 is only charged to 2 volts. The output voltage across the load in this case is a negative 6 volts because C4 is charged negatively with respect to C3. Again the charge across capacitor C5 consists of the sum of the voltages across C3 and C4, or 10 volts as originally developed.

When the input signal reverses its polarity, the signal across the secondary also reverses its polarity. The cathode of CR1 is now positive with respect to its anode and the anode of CR2 is negative with respect to its cathode. Under these conditions, neither diode conducts, but the time constant of C5 together with RI and R1 maintains the current through the load in a negative direction until the next cycle of input, and C5 discharges but slightly.

The output of the ratio detector adjusts itself automatically to the average amplitude of the input signal. Through the action of resistors RI and R2 together with capacitor C5, audio output variations which would occur due to r-f amplitude variations in the input (such as noise) are eliminated. Since C5 charges to the sum of the voltages developed across R1 and R2, any amplitude variations at the input of the detector tends to change the voltages across R1 and R2, but because of the long time constant of C5 across these resistors, these voltages are held to a minimum. Before C5 can charge or discharge to the higher or lower amplitude variation the impulse disappears, and the difference in charge across C5 is so slight that it is not discernible in the output. Because the voltage across C5 remains relatively stable and changes only with the amplitude of the center frequency, and since it is negative with respect to ground, it is usually used for automatic volume control (AVC) applications.

Capacitors C6 and C7 together with resistor R5 form a low pass filter which attenuates the high audio frequencies and passes the lower frequencies. This is known as a de-emphasis network, which compensates for the preemphasis with which the high frequencies are transmitted, and returns the audio frequency balance to normal. When pre-emphasis is not employed these parts are not needed.

Failure Analysis.

No Output. A defective discriminator transformer, T1, shorted tuning capacitor Cl and C2, an open output resistor R5, an open coupling capacitor C8, or shorted filter capacitors (C6 or C7) will produce a no-output condition. Check the continuity of the windings of T1 with an ohmmeter. Check capacitors Cl, C2, C6 and C7 for shorts and capacitor C8 for an open with an ohmmeter, and measure the resistance of R5. If any of these checks fail to restore the output check all capacitors for value with an in-circuit capacitance checker. Note that while one defective diode will produce a partial loss of output, both diodes must fail to cause a complete loss of output,

Low or Distorted Output. A defect in nearly any component of the detector will cause the output to be either low or distorted. Therefore, it is good practive to use an r-f sweep generator and an oscilloscope to locate the trouble. Ground the grid of the

last I-F stage and connect the r-f sweep generator to the detector input. With the sweep generator set to produce an output which varies above and below the center frequency, the pattern observed on the oscilloscope should be similar the discriminator response curve illustrated previously. Defects in the response curve will cause either the entire curve or a portion of it to be distored or flattened.

If the entire curve is distorted, the trouble maybe caused by improper alignment or by a defect in transformer T1. First check to be certain that both primary and secondary circuits are tuned properly to the center frequency. If the detector is properly aligned, check capacitors C1 and C2 with an in-circuit capacitance checker. Check R1 and R2 for their proper value with an ohmmeter, and capacitor C5 for value and leakage with an in-circuit capacitance checker. If the trouble is still not located, it is most likely caused by a defect in transformer T1.

If only the upper portion of the response curve is distorted, the trouble may be caused by a defect in diode CR1, capacitor C3, or transformer T1.

Conversely, if only the lower portion of the response curve is distorted, the trouble may be caused by a defect in diode CR2, capacitor C4, or transformer T1.

TRAVIS DISCRIMINATOR (ELECTRON TUBE)

Application.

The Travis discriminator is used as a detector in FM receivers and for automatic frequency control (AFC) circuits.

Characteristics.

Converts instantaneous frequency variations into instantaneous dc voltage variations.

Employs a triple-tuned transformer.

Has low inherent distortion.

Circuit is difficult to align.

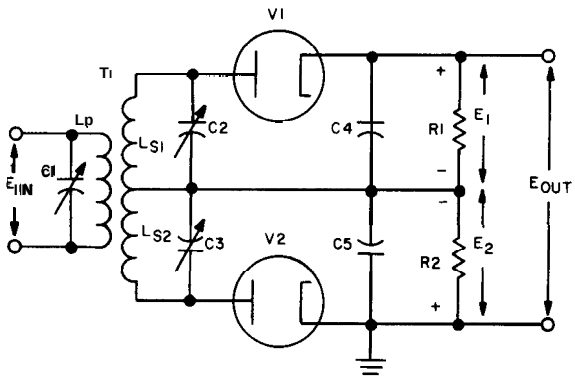
Must be preceded by a limiter since the output is affected by input amplitude variations.

Circuit Analysis.

General. The Travis discriminator uses two secondary tank circuits, with each tank turned so slightly different resonant frequencies to convert the FM input signal frequency variations into amplitude variations. The r-f amplitude variations are then rectified and filtered to produce a dc output voltage which varies in accordance with the variations of the input frequency. When the input frequency is equal to the ***center frequency*** (unmodulated carrier frequency), the discriminator output voltage is zero. As the input frequency rises above the center frequency, the output voltage increases in one direction, for example, increases in the positive direction, and as the input frequency drops below the center frequency, the output voltage increases in the other direction (for example, increases in the negative direction). Thus, the instantaneous discriminator output voltage is dependent on the instantaneous input frequency deviation (shift) from the center frequency. The specific polarity of output voltage obtained for an increase or a decrease in input frequency is determined by the design of the circuit and may vary in different circuits.

The Travis discriminator output is dependent not only on variations in the input frequency, but also to a certain extent, on variations in the input amplitude. Since variations in the amplitude of the FM signal are caused by unwanted noise or fading, they must be prevented from reaching the discriminator or the circuit will reproduce the unwanted noise as well as the desired intelligence. To prevent this, the discriminator is usually preceded by a limiter such as those explained in the Special Circuits Section of this Handbook. The limiter produces an r-f output signal of constant amplitude regardless of input amplitude variations, and thus effectively eliminates any AM noise from the FM signal.

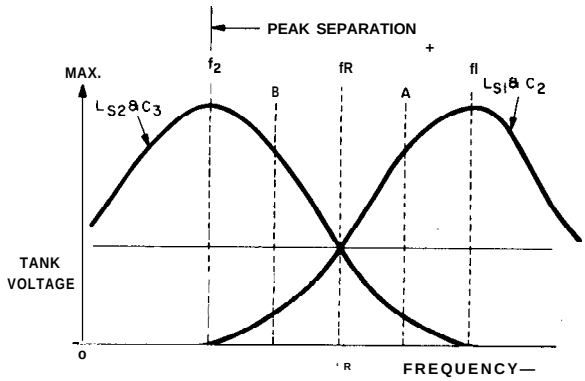
Circuit Operation. The accompanying schematic diagram illustrates a simple Travis discriminator.



Travis Discriminator

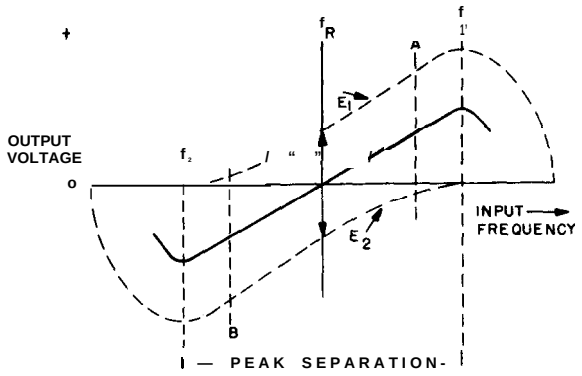
Capacitor Cl and the primary winding (L_p) of transformer T1 form a resonant tank circuit which is tuned to the center frequency. The upper half of the secondary winding (L_{s1}) of transformer T1 and capacitor C2 form a resonant tank circuit which is tuned above the center frequency by an amount slightly greater than the maximum input frequency deviation. The lower half of the secondary winding (L_{s2}) of transformer T1 and capacitor C3 form a resonant tank circuit which is tuned below the center frequency by the same amount that the upper tank circuit is tuned above the center frequency. The r-f signals from the two tank circuits are rectified by diodes VI and V2, and a dc voltage is developed across load resistors R1 and R2. Capacitors C4 and C5 are filter capacitors which remove the r-f ripple component from the detected signals developed across resistors R1 and R2, and holds these voltages relatively constant. The total output voltage is taken across the sen"es combination of resistors R1 and R2 (that is, from the cathode of diode V1 to ground).

When an input signal with a frequency equal to the center frequency is applied to the primary tank circuit (L_p and Cl), a voltage is induced into the secondary winding of transformer T1 which develops r-f voltages of equal amplitudes in secondary tank circuits L_{s1} and C2, and L_{s2} and C2, as shown in the accompanying illustration of the tank circuit response.



Tank Circuit Response Curve

Since the two secondary tank circuits are tuned to resonant frequencies (f_1 and f_2) equidistant from the center frequency, both tank circuits are tuned off-resonance by equal amounts and equal r-f voltages are produced. On the positive half of the input cycle the anode of V1 is positive and current flows through resistor R1, developing a dc output voltage with polarity as marked on the schematic. Simultaneously, the anode of diode V2 is also positive and the d-c output voltage produced across R2 by current flow is equal and opposite that of RI. Therefore, the total output voltage taken across the two resistors in series (from cathode of V1 to ground) is zero. The condition is shown at the center frequency (f_R) on the accompanying discriminator response curve illustration.



Discriminator Response Curva

Voltage E_1 is developed across load resistor R1 (with respect to ground), and voitage E_2 is developed across load resistor R2. As shown in the illustration, voltage E_1 is equal in magnitude and opposite in polarity to voltage E_2 at the center frequency. Thus, at the center frequency, the output voltage (E_{out}) is zero.

When an input frequency higher than the center frequency is applied to the primary tank circuit of the discriminator, *a* voltage is induced into the secondary winding of transformer T1 which is nearer to the resonant frequency of the upper tank, and therefore, a larger voltage is applied to V1 anode. Consequently, VI conducts heavvier and the iarger current flow through RI produces a larger dc output voltage, El, charging C4 to a higher value. In a similar manner, the voltage developed across the lower tank circuit as shown by response curve B is further away from the lower-tank resonant frequency and the positive anode voltage on V2 is lower than that of V1. Hence, the small current flow through resistor R2 develops a smaller output voltage, E2, and C5 is charged to a lower value. The net output voltage, E_{out} across the two resistors is positive when the input frequency is higher than the center frequency, since El is always positive and greater than E2. When a still higher frequency is applied the primary tank, the same action occurs except that El becomes much larger and E2 becomes much smaller. Likewise, when the input frequency is lower and nearer the lower tank frequency the opposite condition prevails. That is El becomes smaller, while E2 becomes larger. Consequently, the net output voltage, E_{out}, across the two resistors is negative when the input frequency is lower than the center frequency, since E2 is always negative and larger than El,

Thus, the output voltage of the Travis discriminator varies in magnitude and polarity as the input frequency varies above the below the center frequency. As mentioned previously, the discriminator output is dependent not only on the input frequency, but also to a certain extent on the input amplitude. If the input signal amplitude drops below the limiting level of the preceding limiter stage, the signal and any variations in the signal amplitude will appear at the discriminator. Since the discriminator diodes are essentially half-wave rectifiers, they will detect the amplitude variations in much the same manner as an AM detector, producing noise in the discriminator output. Thus, for proper operation, the input signal to the limiter must aIways remain above the limiting level of the stage. Another disadvantage of the Travis discriminator is that it is difficult to align because each of the three tank circuits must be tuned to a slightly different resonant frequency. Because it is sensitive to amplitude variations, and because it is difficult to align, the Travis discriminator is not often used in modern FM circuits.

Failure Analysis.

No Output. Loss of input signal, the failure of capacitor Cl, transformer T1, or both diodes can cause a no-output condition. (Note that if only one diode fails, the output will be distorted rather than completely absent.) If the diodes are not at fault, either transformer T1 is defective or capacitor Cl is shorted.

Low or Distorted Output. The failure of nearly any component in the Travis discriminator may cause the output to be low or distorted. Therefore, it is good practice to use an r-f sweep generator and an oscilloscope to locate the specific portion of the circuit that is faulty. First, use the oscilloscope to observe the input to the discriminator to be certain that the trouble is not due to distorted input signrd. If the correct discriminator input signal is present, ground the grid of the limiter stage preceding the discriminator, connect the r-f sweep generator to the discriminator input, and connect the oscilloscope to the discriminator output. With the sweep generator

adjusted to produce an output signal which varies above and below the center frequency, a characteristic "S" shaped discriminator response curve will be obtained if the circuit is operating properly and aligned correctly. Defects in the circuit or alignment, however, will cause a portion of the response curve to be distorted.

If only the upper (positive) portion of the response curve is distorted, the trouble may be caused by a defect in diode VI, resistor RI, capacitors C2 or C4, transformer T1 or misalignment of tank C_2, L_s. Check resistor R1 for proper value with an ohmmeter, and check capacitor C4 for proper value, leakage, or a short with an in-circuit capacitance tester. If these checks fail to locate the defective component, the transformer assembly (consisting of T1 and Cl, C2, and C3) is either misaligned or defective. Check the alignment.

When only the lower (negative) portion of the response curve is distorted, it may be caused by a defect in diode V2, resistor R2, capacitors C3 or C5, transformer Tl, or misalignment of tank C3, L_{s2}. Check resistor R2 for proper value with an ohmmeter, and check capacitor C5 for proper value with an ohmmeter, and check capacitor C5 for proper value, leakage, or a short, with an in-circuit capacitance tester. If these checks fail to locate the defective component, the transformer assembly (Tl, Cl, C2, and C3) is either misaligned or defective. Check the alignment.

Distortion or flattening of the entire response curve is usually caused by improper alignment of the discriminator, although it may also be caused by low diode emission.

GATED-BEAM DETECTOR

Application.

The gated-beam detector is used in FM receivers to demodulate the received r-f signal.

Characteristics.

Converts instantaneous frequency variations into instantaneous dc voltage variations.

Employs three tuned tank circuits and a special beam-power tube.

Has low inherent distortion.

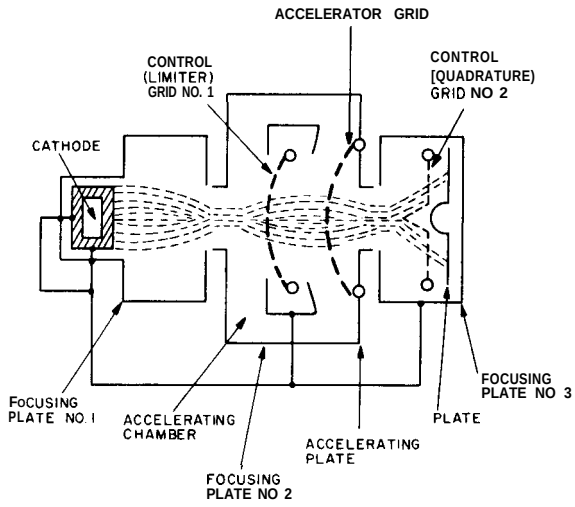
Output is independent of input amplitude variations.

Provides both limiting and discriminator action in a single tube.

Circuit Analysis.

General. The gated-beam detector uses a gated-beam tube to limit, detect, and amplify the received f-m r-f signal. The output is a dc voltage which varies in amplitude and polarity as the input varies in frequency. This output voltage is zero when the input frequency is equal to the center frequency (unmodulated carrier frequency). When the input frequency rises above the center frequency, the output voltage increases in a positive direction, and when the input frequency drops below the center frequency, the output increases in a negative direction.

Circuit Operation. Before attempting to explain the circuit operation of the gated beam detector, a brief review of the tube used in the circuit is essential. The following illustration shows a cross-sectional diagram of a typical gated-beam tube.



Gated-Beam Tube Cross-Section

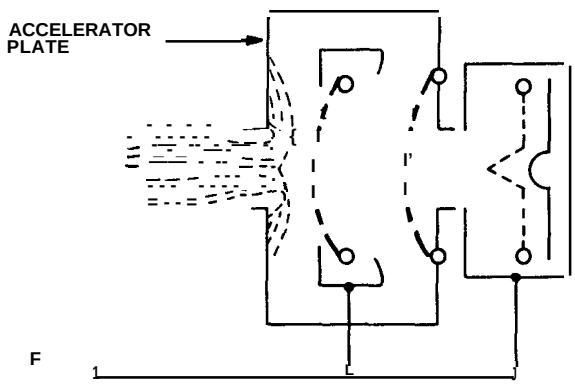
There are two major differences between the gated-beam tube and an ordinary pentode. First, the flow of electrons from the cathode to the plate is maintained in a concentrated beam formed by the elements of the tube, and secondly, cathode current

flows at all times, even during the period of time during which no plate current flows.

The shield around the cathode, known as focusing plate No. 1, is internally connected to the cathode, and as the electrons leave the cathode they pass through a narrow opening in the shield, which is at cathode potential and repels electrons. Thus a narrow stream of electrons is formed.

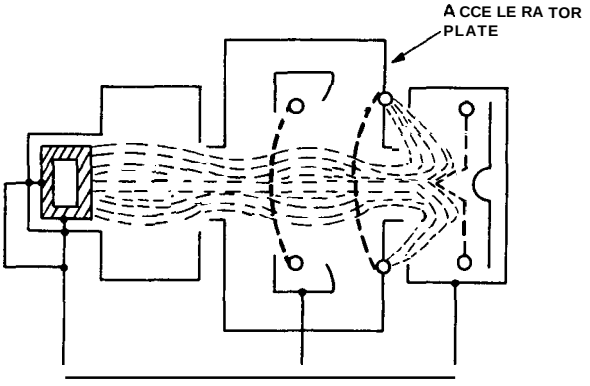
As the electron stream enters the accelerating chamber, which is at a high positive potential, it tends to spread, due to the attraction of the positive field. Ordinarily, the stream would continue to spread, but as it approaches the No. 1 control grid, it is prevented from spreading further by the repelling action of a second focusing plate, also connected to the cathode. Once the electrons pass through the first control grid, they are attracted towards the accelerator grid, which is at the same potential as the accelerator plate, and again the electron stream tends to spread. However, before the spreading becomes excessive, the stream enters the field of focusing plate No. 3 which is also at cathode potential, and further spreading is checked. The focusing plate is provided with a narrow opening, which concentrates the beam into a narrow stream again as it passes through this orifice. The electron stream then passes through a second control grid (referred to as the quadrature grid) and is attracted to the potential positive plate.

If a signal is applied to the first control grid, and it is sufficiently negative to prevent the electron stream from passing through it, the electrons approaching this grid rapidly build up a dense space charge in front of the grid. Because electrons repel each other, the accumulated space charge aids the control grid in quickly cutting off plate current flow, and accounts for the sharp cut-off tube characteristic. (This control grid is also referred to as the limiter grid for this reason.) The electrons cannot return to the cathode because of the narrow opening in the focusing plate, and they are attracted to the wall of the accelerator chamber instead, thus maintaining cathode current flow, as shown in the following illustration.



First Control (Limiter) Grid at Cut-off

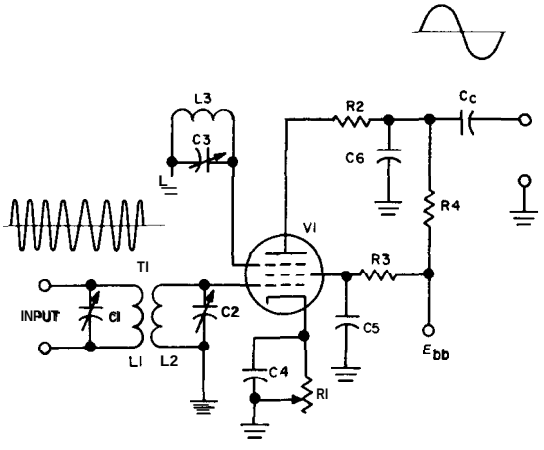
In a similar manner, when a signal of sufficient strength and of proper polarity to repel the electron stream is applied to the quadrature grid (No. 2 control grid), with the limiter grid above cut-off, plate current will not flow. Cathode current flow continues, however, because the electron stream is attracted to the accelerator wall instead, as illustrated in the following figure.



Second Control (Quadrature) Grid at Cut-off

To summarize tube operation, both the limiter grid and the quadrature grid must be sufficiently positive at the same time to permit passage of the electron stream to the plate.

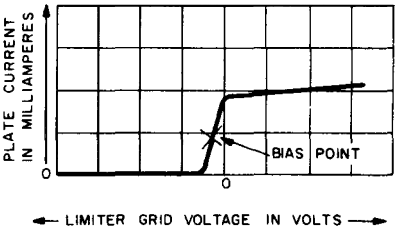
The following circuit schematic illustrates the gated beam tube connected as a typical gated-beam detector.



Typical Gated-Baam Detaetor

The input tank circuit, consisting of LI, the primary of i-f transformer T1, and capacitor Cl, is tuned to the center frequency of the incoming f-m signal. L2, the secondary of the transformer TI, and capacitor C2, also. comprise another tank circuit, which is also tuned to the center frequency. The first grid of the tube and the cathode, perform the function of a limiter stage, with resistor RI and capacitor C4 in the cathode circuit to provide a method of adjusting the limiter bias. The accelerator grid is connected to voltage-dropping resistor R3 which establishes the proper voltage on the accelerator grid, andC5 bypasses it to ground. Capacitor C3, together with L3, form another tank circuit also tuned to the center frequency, and is connected to the second control grid. Resistor R2, (usually of a small value) is placed in the plate lead to increase output linearity. Resistor R4 is the plate load, and together with capacitor C6 forms an integrating network which produces the sine-wave output. The output is taken from across C6, and applied to the audio stages through coupling capacitor Cc.

The limiting capabilities of the gated beam detector are much better than that of a conventional pentode, because of the sharp control characteristic, as shown in the following graph.

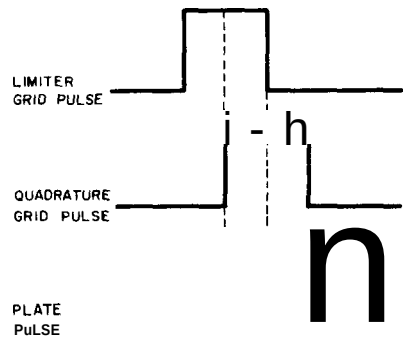


Limiter Grid Tube Control Curve

Cathode resistor R1 is adjusted to bias the limiter at the center of the steepest part of the control-characteristic curve. With no signal applied to the limiter grid, the tube conducts. When the electron stream arrives at the quadrature grid, some electrons are absorbed by this grid, and the resulting current flow charges C3 of the quadrature tank circuit. When C3 is charged sufficiently negative, the grid current stops and this negative charge momentarily maintains the quadrature grid at cut-off, Tank inductor L3, however, tries to keep the current moving in the same direction, but when its field collapses it causes a

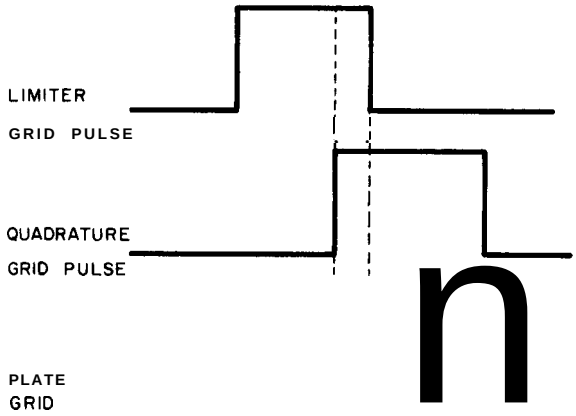
reverse flow of current which discharges C3. When C3 discharges sufficiently, the grid again becomes positive and begins drawing grid current, and the cycle repeats. Since the tank is tuned to the center frequency of the received signal, it oscillates at the tuned frequency. The voltage across C3 lags the current which produces it, and the result is a series of pulses appearing on the quadrature grid at the center frequency, but lagging the limiter grid voltage by 90 degrees. Because the quadrature grid has the same control characteristics as the limiter grid, these pulses place the tube alternately at cut-off and at saturation on alternate half cycles of oscillation.

When a signrd appears on the limiter grid at the center frequency and increases slightly in a positive direction, the tube is effectively driven into saturation. That is, as the electron stream passes through the limiter and accelerator grids, and arrives at the quadrature grid, the quadrature grid is out-of-phase and is at cut-off, and the electron stream is attracted to the accelerator wall. However, some 90 degrees later, the quadrature grid shifts in a positive direction because of the favorable oscillation of the quadrature tank, and this time the electron stream is permitted to pass through the quadrature grid to the plate. Before the quadrature grid phase changes, the signal applied to the limiter grid drives the tube quickly into cut-off, and plate current again ceases. The resulting signal appearing on the plate, therefore, is a square shaped pulse, which starts with the delayed opening of the quadrature grid, and ends with the closing of the limiter grid, as shown in the following "At Center Frequency" illustration.



Relationship of Pulses At Center Frequency

If the signal on the limiter grid shifts to a frequency higher than the center frequency, the pulse appears on the limiter grid at an earlier time than at the center frequency, and therefore, also arrives at the quadrature grid at an earlier time. Since the pulses on the quadrature grid are still occurring at the center frequency (because of tank circuit oscillation), and the limiter pulse arrives earlier, the resulting pulse relationships are as shown in the "Above Center Frequency" waveform illustration.



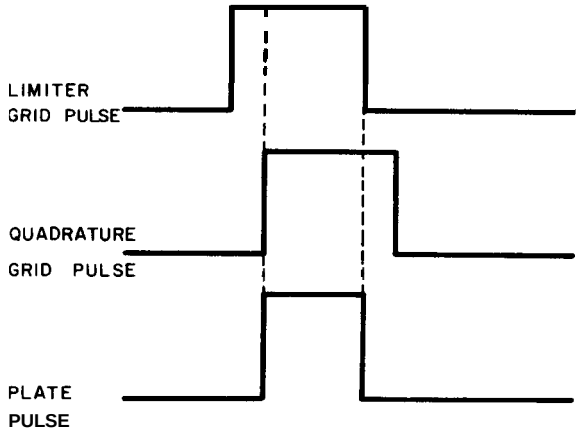
Relationship of Pulses above Center Frequency

Since plate current starts with the delayed opening of the quadrature grid, and ends with the closing of the limiter grid, the plate pulse is now narrower than it was at the center frequency.

Conversely, if the signal on the limiter grid shifts to a frequency below the center frequency, the pulse arrives on the limiter grid at a later time, and thus arrives at the quadrature grid at a later time. It is therefore nearer in phase with the pulses on the quadrature grid, since these quadrature pulses are still occurring at the center frequency, and the resulting pulse relationships are as shown in the "Below Center Frequency" waveform illustration.

Under the three circumstances discussed above, the peak amplitude of the plate current remains the same (it is effectively at saturation and limited), while the variations in the frequency of the input pulses are represented at the plate only by the length of time for which plate current flows. A higher input frequency produces a shorter duration of plate current, and a lower input frequency produces a longer duration of plate current.

These plate pulses, however, are occurring at an r-f rate, and therefore will not be reproduced by the following audio stages. However, since the width of the plate pulses constantly vary in accordance with the f-m modulation, the plate pulses also vary at an audio rate. Therefore, the average plate current varies at audio frequencies, and a useable audio output is obtained by an integrating network consisting of C6 and R4. Since the charge on C6 varies at the same rate as the average plate current, taking the output from capacitor C6, provides an audio output, and at the same time, it changes the squared pulse into a useable sine-wave to minimize distortion.



Relationship of Pulses Below Center Frequency

The advantage of the Gated Beam Detector lies in its extreme simplicity. It employs only one tube, yet provides a very effective limiter with a linear detector. It requires relatively few components, and is very easily adjusted. Operation, however, is limited to the frequencies below 30 MHz. Since at the higher frequencies, the shunting effect of the interelectrode capacitance between the limiter and quadrature grids is sufficient to produce an out-of-phase voltage across the quadrature grid, which subtracts from the quadrature voltage and reduces the output. This effect is minimized in some circuits by the addition of a screen grid, to the tube or by careful shielding, but neither method completely eliminates the out-of-phase effect, and for this reason, the gated-beam circuit is usually used ordy in low frequency applications.

Failure Analysis.

No output. A defect in nearly any component in the circuit could cause a no-output condition to exist. Check the plate supply voltage at the tube socket, if

plate voltage is not present, check resistors R2 and R4 and capacitor C6. If plate and grid voltages are normal, the tube is probably defective.

Check for a signal on the limiter grid with an oscilloscope. If no signal is present, check for a signal on the primary of the transformer. If still no signal appears, the trouble is somewhere in the preceding stages, and the detector is probably not faulty. If there is a signal on the primary of the transformer, check the tuning capacitors with an in-circuit capacitor checker. If they are found to be good, the trouble is probably a defective transformer. Check cathode resistor R1 for proper value and adjustment, and capacitor C4 also, using an in-circuit capacitor checker. With the oscilloscope, check for a signal on the quadrature grid. If a signal is present, make sure it is at the center frequency. If no signal is present, check C3 with an in-circuit capacitor checker, and L3 with an ohmmeter. Check R3 for proper value, and C5 for a short to ground.

Low or Distorted Output. It is unlikely that a low output condition will exist, but if it does, R2, R4, or C6 is most likely at fault. Check R2 and R4 for proper value, and C6 with an in-circuit capacitor checker.

If the output is distorted, make the checks just mentioned above for a low output condition, and if the distortion still occurs, make certain that the three tanks are aligned properly, and contain no defective components. Also check R1 for proper value and adjustment, using a voltohmmeter and also check capacitor C4 with an incircuit capacitor checker.

PART 10-3. VIDEO

VIDEO DETECTORS

General.

A video detector is very similar to the standard AM detector, with the exception of the requirement for handling a broader range of frequencies. Since it is located between the IF and the video amplifier stages, it must be able to handle the same wide range of frequencies as the IF and video amplifier stages without distortion. The IF frequencies used in radar applications vary from about 30 Hz to 8 MHz, and in television, from about 20 MHz to 4.5 Hz. This requirement necessitates the use of high-frequency compensating circuits in the detector output, which consist of both series and hunt peaking circuits. When using electron tube diodes, a diode with low plate-to-cathode capacitance should be seIected. When using semiconductor diodes, it is necessary to keep the input impedance level on the high side to maintain the rectification efficiency of the diode at a high level. A transistor, however, can serve efficiently as a video detector into a relatively low value of impedance. The high base impedance provides the necessary high impedance input, while the output at medium or moderately low impedance matches the following video amplifier stage.

BASIC VIDEO OETECTOR (ELECTRON TUBE)

Application.

The video detector is used to change the received amplitude modulated video signal into a dc voltage.

Characteristics.

Employs a basic AM diode detector.

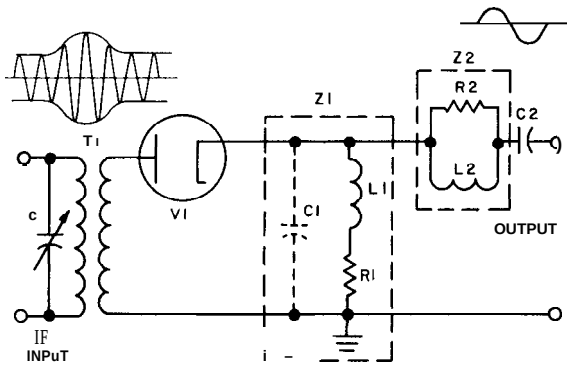
Has a wider bandwidth than the conventional AM detector.

Employs compensating networks for frequency compensation and to improve linearity.

Circuit Analysis.

General. The operation of the basic video detector is identical to the operation of the AM diode detector previously discussed in this section of the Handbook. The only difference lies in the addition of compensating circuits for the added frequency response requirements. Discussion of the operation of the detector in stripping off the modulation from the carrier is covered completely in the previous discussion of the diode detector. The reader should refer to the discussion of the Diode Detector in this section of the Handbook for proper background before proceeding with the discussion of the video detector.

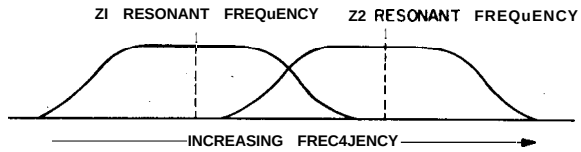
Circuit Operation. The schematic diagram of a typical video detector employing series and shunt peaking is shown in the following illustration.



Basic Video Detector (Electron Tube)

The anode of diode VI is connected to the untuned secondary of IF transformer, T1, with the primary tuned by capacitor C. Inductance Ll, in series with resistor RI, together with capacitor Cl, forms a shunt peaking circuit, referred to as impedance network Z1. Inductance L2, together with R2, forms a series peaking circuit, referred to as impedance network Z2. Capacitor C2 is the output coupling capacitor. Resistor R1 broadens the bandwidth of Z1, and R2 broadens the bandwidth of Z2.

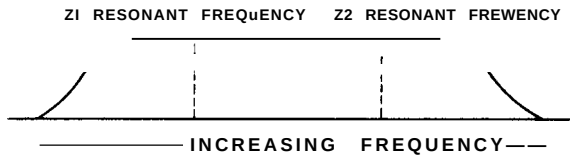
Peaking circuits Z1 and Z2 are utilized to improve the output linearity, and provide a wide band-pass characteristic. The circuit operates in the following manner. A frequency increase causes the capacitive reactance of the stray capacitance to decrease, and since this stray capacitance (represented by Cl) shunts the output, the output voltage tends to decrease at high video frequencies. Z1 is a parallel-tuned circuit resonated to the high frequency at which the output first tends to decrease, by the stray and distributed wiring and circuit capacitance represented by Cl. Since the impedance of the parallel tuned (shunt peaked) circuit is maximum at resonance, the output remains linear beyond the high frequency drop-off point (without compensation). The bandwidth of this tuned (shunt peaked) circuit is widened because the Q of the circuit is decreased by the presence of series resistor RI. As the output frequency is increased still further, it passes beyond the resonant peak of Z1, and as the impedance of Z1 now decreases, the output again tends to decrease. **Z2,** however, forms another broadly-tuned circuit, and is series-resonated at a point above the resonant frequency of Z1. These circuits are so tuned that some overlap of the tuned circuit response curves occurs, as shown in the following illustration.



Combined Response Curve of Z1 and Z2

Since the impedance of a series tuned circuit is minimum at resonance, and because Z2 is in series with the load, the output once again is extended. Actually L2 is series peaked using the stray capacitance to ground, and is also broadened by shunt resistor R2.

The resultant overall response curve for the video detector is shown as follows.



Overall Response Curve for Video Detector

Failure Analysis.

No Output. A defect in transformer T1, a defective tube, or an open C2 will cause a no-output condition. Check the continuity of the windings of T1 with an ohmmeter. Check C2 for an open with an ohmmeter. If a no-output condition still exists, check the value of the capacitor with an in-circuit capacitor checker.

Low or Distorted Output. A defective diode is about the only component in the circuit that would cause a low output condition to exist. While a low output is also possible because the values of L1 or L2 may change and change the response curve, this possibility is rather remote. Do not neglect the

possibility of either RI or R2 changing value sufficiently to affect the response,

If the output is distorted only at the lower frequencies, the defect is probably in one of the components of Z1. Check the value of L1. Check L1 for continuity and RI for proper value with an ohmmeter.

If the output is distorted only at the higher frequencies, series peaking circuit Z2 is probably defective. Check C2 with an in-circuit capacitor checker. Check L2 for continuity and R2 for proper vahre.

BASIC VIDEO OETECTOR (SEMI CONDUCTOR)

Application.

The basic video detector is used in semiconductor receivers of the superheterodyne type to provide a high gain video output.

Characteristics.

Uses either fixed or self-bias.

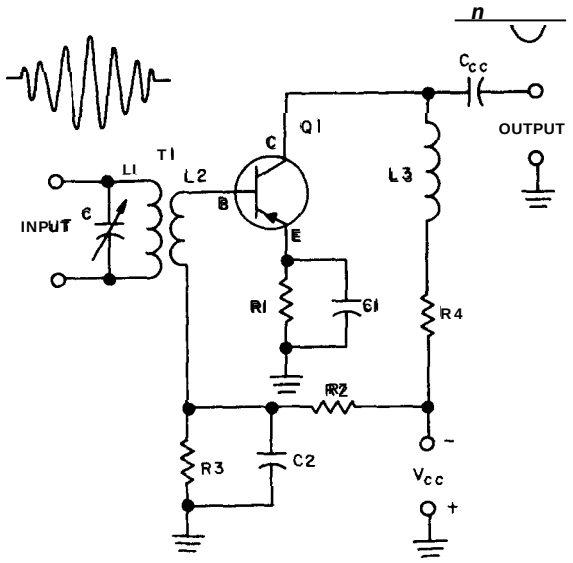
Is equivalent of a diode and one stage of transistor amplification.

Uses video peaking circuits to provide good high frequency responses.

Circuit Analysis.

General. The operation of the basic video detector is identical to the operation of the AM diode detector previously discussed in Part A of this Handbook. The only difference lies in the use of the base-emitter junction of the transistor as a diode in place of a separate diode. Compensating circuits are added in the collector circuit to ensure better high frequency response. The reader should refer to the discussion of the Diode Detector, in Part A of this section of the Handbook, for proper background before preceding with the discussion of the semiconductor basic video detector.

Circuit Operation. The schematic of a typical transistor video detector using shunt peaking is shown in the following illustration.



Basic Video Detector (Semi Conductor)

The base of transistor Q1 is connected to the untuned secondary of i-f transformer T1, with the primary tuned by capacitor C. Resistors R2 and R3 from a base bias voltage divider from the negative supply to ground, with the voltage drop across R3 supplying the base bias to Q1 through the secondary winding L2 of TI. R3 is bypassed by C2 to prevent a degenerative voltage from being developed across R3 with the instantaneous bias swings, thus allowing voltage divider R2 and R3 to provide a steady forward bias to the base of Q1. Resistor RI is a conventional emitter swamping resistor used to stabilize the transistor against thermal changes and, Iikewise, is bypassed by Cl to prevent degeneration in the emitter circuit and negative feedback effects. Inductor L3 is a shunt peaking inductance with R4 supplying resistance to widen the response. L3 also acts as the detector output load resistor across which

the output voltage is developed and applied through coupling capacitor Ccc to the following stage, or direct to the CRT if sufficient drive exists.

When an input signal is applied to T1, the i-f frequency is selected by tuned circuit Ll and C, and this i-f together with any modulation component is inductively coupled through secondary L2 which is left untuned for a broad response, and the signal is applied to the base of Q1. The emitter-base junction of QI acts as a rectifier and instaneously changes the bias in accordance with the low frequency variations of the modulation envelope. Any remaining i-f is bypassed through capacitors Cl and C2 to ground and has no effect on circuit operation. As the audio envelope of the received signal changes the bias on Ql, the collector current is varied likewise, and the collector current fluctuates in accordance with the modulation. The audio frequency variations are bypassed across emitter resistor R1 by capacitor Cl so that only the long time temperature variations can produce a voltage change across RI. However, the flow of collector current through L3 and R4 produces a change of collector voltage on the collector side of the choke. A positive modulation swing causes a decrease of forward conduction and raises the instantaneous collector voltage. Likewise, a negative audio excursion causes an increased forward bias and conduction, and the collector voltage of Q1 reduces. Since only a small change in base current causes a large change in collector current, amplification of the detected signal is obtained in the collector circuit of Q1 and appears as a larger output voltage across L3 and R4. By resonating L3 with the stray capacitance in the circuit, the normal drop off in amplitude of higher frequencies is compensated for and the high frequency range is extended. Resistor R4 keeps L3 loaded down so that the overall frequency response of the detector is broadened. As the output voltage is developed across L3 it also is applied through Ccc to the output. Where the output voltage is sufficient the CRT may be driven directly. Where the voltage is not sufficient, an additional voltage amplification driving amplifier stage is added to increase the overall drive, as required.

Failure Analysis.

No Output. An open input transformer, an open base circuit, emitter circuit, or collector circuit, as well as a defective transistor or open coupling capacitor can cause a no-output condition. Check the collector, base, and emitter bias with a high resistance voltmeter. Voltage at the collector indicates that L3 and R4 are not open, while emitter voltage indicates that RI is not open or shorted. Likewise, base bias indicates that voltage divider R2 and R3 is operating, and that secondary L2 or T1 has continuity. With these voltages obtained and no output, either winding LI of T1 is open or shorted, or Ccc is open. Check C and CCC with an in-circuit capacitance checker, and also check the continuity of T1 primary LI with an ohmmeter. If base bias is zero R3 is shorted, also check C2 for capacity with an in-circuit capacitance checker. If the emitter voltage is also zero R1 is shorted cy Cl, however, the transistor will still function and produce an output which will vary with temperature. If there is no collector voltage, check the supply voltage to make certain it is not at fault, check the value of R4 with an ohmmeter and check L3 for continuity.

Low Output. High base bias, low collector voltage, or a defective transistor can cause a no-output condition. If bias voltage divider resistor R3 changes to a higher value of resistance, or if R2 becomes lower in value, the net effect is to make the total base bias higher, check these resistors with an ohmmeter. If R4 becomes higher in resistance, the collector voltage will also drop and reduce the output. Check R4 with an ohmmeter. If a high bias is measured across emitter reisitor RI, capacitor Cl is open, check Cl for value with an in-circuit capacitance checker. Do not neglect the possibility that the input tank controlled by capacitor C may be detuned from the desired i-f input frequency. If not shorted, tuning C will peak the response. If the response does not peak as C is tuned around the input frequency, check capacitor C for a short or open on a capacitance meter.

PART 10-4. BALANCED

BALANCED DETECTORS

General.

Balanced detectors usually employ two tubes or transistors in a balanced circuit arrangement with two

inputs applied and with a single output. One input, usually the carrier or reference oscillator, is so balanced that no output is produces unless the second input is applied. The balanced detector circuit is practically identical to a balanced modulator, and both operate similarly, except that the inputs and outputs are reversed. There are as many balanced detector circuit arrangements as there are balanced modulator circuits. Usually each circuit has some advantage over another and each type is selected for its particular use and because of the availability and cost of the components. The simpler and more commonly used circuits such as the lattice type, ring type, balanced-bridge type, and basic diode type all employ diodes, whereas the more complicated types provide larger outputs, improved sensitivity, and lower noise, using triodes and pentagrid tubes. Each of these circuits will be explained in more detail later in this section of the Handbook. While the diode type of circuits may appear at first glance to act as conventional rectifiers, they act as non-linear impedance across which the inserted carrier is combined with the input signal to produce the proper audio beat output, and rectification noise is eliminated.

The balanced detector may be used to convert an r-f input to an i-f output, an i-f input to an audio output, or an audio input to an audio output. While the majority of circuits are used for single-sideband detection, the ring and lattice types are usually not used in receivers, but are particularly popular in multiplex telephone circuits where their bilateral characteristic makes them particularly desirable for this type of work. The basic balanced diode detector is frequently used in color TV receivers to obtain the hue and saturation components of the color signal.

BASIC DIODE BALANCED DETECTOR (ELECTRON TUBE)

Application.

The basic diode type of balanced detector is frequently used in 'single-sideband and color television receivers.

Characteristics.

Has balanced inputs and outputs.

Requires a local (reference) oscillator input at a fixed frequency.

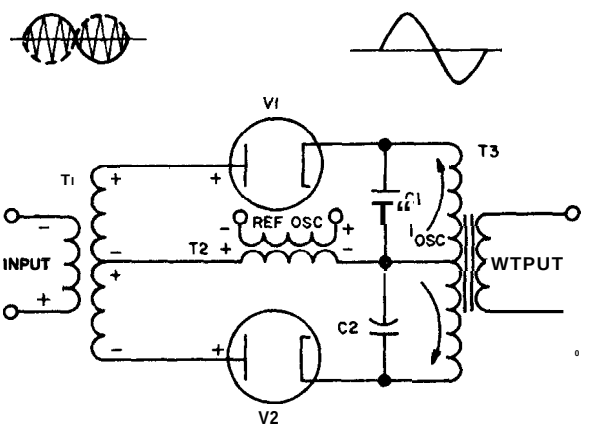
Oscillator signal is applied in-phase and input signal is applied in push-pull.

May use either electron tube or semiconductor diodes.

Circuit Analysis.

General. The basic balanced diode detector is similar in appearance and operation to an FM or phase detector except that the input and output is always a balanced arrangement. The reference oscillator signal which usually simulates the carrier signal is applied inphase to both diodes (same polarity is supplied to each pair of anodes) and is balanced out in the output circuit. Thus, with no input signal there is no output. The input signal is applied in push-pull to the diodes and the in-phase component of the input signal adds to the reference oscillator signal and unbalances the detector at the difference frequency. In a similar manner, the out-of-phase components reduce the amplitude of the signal at the other diode. When the difference frequency is an audio frequency an audio output is produced.

Circuit Oparation. A typical balanced diode type of detector is shown in the following schematic. Transformer T1 is the push-pull input transformer. Oscillator transformer T2 is connected in-phase (same polarity) with both diodes VI and V2, and T3 is the output transformer. Capacitors Cl and C2 are r-f bypass capacitors connected across the primary of output transformer T3.



Balanced Diode Detector

The reference oscillator (carrier) is applied to the center tap of T1 so that the anodes of both diodes are both of the same polarity (in-phase) as far as the oscillator signal is concerned. Thus, if no input signal is applied, the oscillator signal causes equal conduction in both diodes during the positive portion of its operating cycle.. Equrd currents are passed through the primary of output transformer T3 in opposite directions from the center tap to the cathode of the diodes. Hence, the induced voltages are of opposite polarity and cancel out so that no output voltage is induced into the secondary winding. As long as no input signal is applied, the oscillator signal will always automatically cancel in the secondary of T3.

When the sideband signal input is applied to Tl, one end of the secondary winding will be positive while the other end is negative, considering one half-cycle of operation. Thus, VI will normally conduct while V2 remains non-conducting. On the opposite half-cycle of operation, the anode of V1 will be negative while the anode of V2 is positive. Hence on this half-cycle V2 will conduct while V1 remains non-conducting. Since the reference oscillator signal is connected in-phase, on one half-cycle of input signal both the oscillator and input signal will add to increase conduction through V1, while the input signal opposes the oscillator signal through the other half of the winding so that the anode of V2 is at zero or at a slight negative potential (considering both to be of equal amplitude). Since the input signal and the carrier oscillator differ in frequency by the audio modulation frequency, they will beat against each other and produce the difference frequency in the output transformer. The sum frequency created by the beating of the two signals is a high radio frequency which is bypassed across the primary of T3 by either Cl or C2, so that only the difference frequency can pass through the primary and induce an audio output in the secondary of T3.

During the negative half cycle of oscillate signal, the in-phase comection of T2 will place a negative potential on the anodes of VI and V2 so that neither V1 nor V2 can conduct. Thus, in the absence of an input signal, again there is no output. When an input signal is applied, the in-phase component will place a negative potential on the anode of V1, while the out-of-phase component will reduce the negative oscillator potential on the anode of V2 to zero; still no conduction will occur. Thus, during the negative portion of the oscillator signal, no output will occur.

The alternate pulses of current flowing through the primary of T3, when a diode is conducting, will induce a secondary voltage in T3 of the same frequency; any i-f or r-f component will be shunted around the primary winding through Cl or C2 so that only the detected audio appears in the output. Output transformer T3 may be replaced by resistors shunted by Cl and C2 and connected in series in some circuit variations. Operation is the same, with the capacitors being charged by the voltage drop across the resistors and, since they are connected in series, the output is the difference between the two voltages. When connected to an audio coupling capacitor this dc output varying at audio frequency rates will produce an audio output also. Whether the diodes operate alternately or simultaneously depends upon the phase and value of the signal applied to the anodes. With in-phase signals of the same polarity and amplitude both diodes operate, and equal and opposite output voltages cancel out in the secondary of T3 to produce no output (assuming perfect balance). With out-of-phase signals (push-pull input), one anode will be positive and conduct while the other is negative, and remain back-biased and non-conducting. Whether the diodes conduct on alternate half-cycles depends upon whether the input signal is stronger than the reference oscillator. The output may be push-pull or single-ended as desired, without affecting operating.

Failure **Analysis,**

No Output. Loss of reference oscillator signal, no input signal, a defective output transformer, or defective diodes can produce a loss of output. Check for the presence of an output from T2. If an output exists, check T1 similarly for a signal input. If there is no output from T2, check the primary and secondary windings for continuity. If continuity exists in the windings of T2, the oscillator circuit is probably defective. If an output exists at T2 but there is no signal input, check the primary and secondary windings of T1 for continuity. If continuity exists, the r-f or i-f input circuits are probably at fault. If an input exists at T1 and a reference oscillator signal exists at T2, but there is still no output, both diodes VI and V2 may be defective. In addition, check Cl and C2 for value and for a shorted capacitor, and check T3 primary and secondary for continuity. If continuity exists in T3 and neither Cl nor C2 is shorted, there is still a possibility that T3 primary or secondary may

be shorted. Measure the resistance of the windings of T3; a resistance of a few ohms or less indicates a probable short-circuited winding between the primary and secondary. The possibility of a short in T] or T2 also exists, but since these transformers usually have a very low resistance, it is usually difficult to determine if they are defective by resistance readings alone. Because of the few parts in this circuit, a quick resistance check of all parts will usually reveaI the defective item except for the transformers which a voltage check will determine more clearly. If the shunting resistance of T3 on capacitors Cl and C2 is low, it may not be possible to make a capacitance check without first disconnecting one terminal of the capacitors from the circuit.

Low Output. A low output may be caused by defective diodes, partially shorted transformer windings on T1, T2, or T3, or leaky capacitors Cl and C2. The output of the reference oscillator should also be checked for normal amplitude. If the amplitude is normal, diodes VI and V2 are probably defective. Check the values of Cl and C2 and check them also for excessive leakage. If the low output persists, check transformers Tl, T2, and T3 for partial shorts (shorted turns), shorts, and leakage to ground. To do this, it will be necessary to make separate dc resistance checks of the windings, and to check the winding inductance on an inductance bridge. Also check leakage to ground and transformation ratio (turns ratio). Since precise measurements are necessary and require laboratory-type equipment, it is doubtful that all these tests can be performed aboard ship. Do not neglect the possibility that an excessively low input and oscillator signal can cause a low output. Usually the oscillator output is kept at about ten times the input signal to create a strong beat signal and reduce the actual ratification of the input signal to such a small value that ratification distortion effects are eliminated.

Distortion. Since faithful reproduction in a balanced detector depends upon the operation of the reference (carrier) oscillator at the exact frequency of the suppressed carrier, and that distortion components are not introduced by overdrive at the transmitter, it is often erroneously assumed that the detector is at fault, whereas adjustment of the transmitter or receiver is actually required. When distortion is encountered carefully tune the receiver to the proper sideband as shown by the strongest S-meter reading, and adjust the reference oscillator ***fine*** tuning for the clearest signal. At the same time, adjust the r-f gain control for the clearest signal and the audio gain for proper volume. Place the upper-lower sideband switch in the position which provides the most intelligible signal. If distortion exists at the clearest tuning point, check by tuning in other sideband signals. If they are undistorted, the transmitter is being driven too hard. If all signals are distorted, the tubes are probably defective. Check each part separately until the distortion is located.

BASIC TRANSISTOR BALANCED DETECTOR

Application.

The basic transistor type of balanced detector is frequently used .in single-sideband and color TV receivers.

Characteristics.

Has balanced inputs and outputs.

Requires a local (reference) oscillator input together with an r-f sideband input.

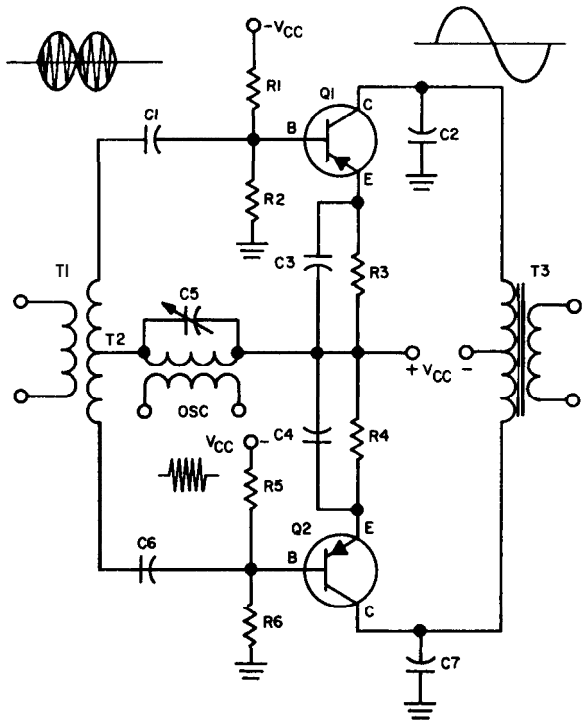
Oscillator signal is applied in-phase, and the input signal is applied in push-pull.

Uses fixed bias but may also use self bias.

Circuit Analysis.

General. The basic transistor detector is similar in appearance and operation to an FM or phase detector, except that the input and output is always a balanced arrangement and transistors are used instead of diodes. The reference oscillator signal which usually simulates the carrier signal is applied in-phase to both transistors and is balanced out in the push-pull output circuit. Hence, with no input signal there is no output. The sideband input signal is applied in push-pull to the transistors, and the in-phase component of the input signal adds to the reference oscillator signal and unbalances the detector at the difference frequency. In a similar manner, the out-of-phase components reduce the amplitude of the signal at the other transistor. When the difference frequency is an audio output frequency, an audio output is produces.

Circuit Operation. A typical balanced transistor type of detector is shown in the following schematic.



Transistor Balanced Detector

Transformer T1 is the push-pull r-f input transformer. Oscillator transformer T2 is connected in parallel with the bases of both transistors Q1 and Q2, isolated for dc through coupling capacitors C 1 and C6. The secondary winding of T2 is tuned to resonance by C5. Resistors RI and R2 form the base voltage bias divider for Q1, while R5 and R6 are the base bias dividers for Q2. Hence a forward bias is applied to the transistors. Resistors R3 and R4 are emitter swamping resistors bypassed by C3 and C4 to provide temperature compensation for the transistors, and prevent possibility of thermal runaway. (See the introduction to the Amplifier Section of this Handbook for a complete discussion of common-emitter bias and stabilization.)

The reference oscillator (carrier) is applied to the center tap of T1 so that the bases of both transistors are fed in-phase (of the same polarity) as far as the oscillator signal is concerned. Thus if no input signal is applied, the oscillator signal causes equal conduction in both transistors during the positive portion of the operating cycle. Since equal collector currents flow in opposite directions through the primary of output transformer T3, no voltage is induced in the secondary and there is no output developed across the secondary of T3. As Iond as no r-f input signal is applied, the oscillator signal will always cancel out automatically in the secondary of T3. Capacitors C2 and C7 also bypass to ground any r-f components in the collector circuit so that no oscillator output can be produced if no input signal is applied. Likewise, with only an r-f input applied but no reference oscillator signal the collector is bypassed to ground so that no output can be produced by the sideband r-f input alone.

When the sideband input signal is applied to T1, one end of the secondary winding will be positive while the other end is negative, considering one half cycle of operation. Thus, Q1 will normally conduct heavily while Q2 remains lightly conducting. On the opposite half cycle of operation, the base of Q1 will conduct lightly while Q2 conducts heavily. Since the reference oscillator signal is connected in-phase, on one half cycle of input signal both the oscillator and sideband input signal will add to increase conduction through Q1, while the input signal opposes the oscillator signal through the other half of the winding, so that the base of Q2 is at zero bias or at a slight positive potential (considering both of equal amplitude). Since the input signal and the difference frequency can pass through the primary winding of T3 and induce an audio output in the secondary of T3.

During the positive half cycle of oscillator input signal, the in-phase connection of T2 will place a positive potential on the base of Q1 and Q2 so that neither Q1 nor Q2 will conduct. Thus, in the absence of an input signal, again there is no output. When an input signal is applied, the in-phase components will place a positive reverse bias potential on the base of Q1, while the out-of-phase component will reduce the reverse bias but Q2 will not conduct, since the oscillator amplitude is greater than the sideband signal. Thus during the positive half cycle of the oscillator signal no output will occur.

The alternate pulses of current flowing through the primary of T3, when the transistor is conducting, will induce a secondary voltage in T3 of the same

frequency, and any i-f or r-f component in the collector circuit will be shunted to ground, so that only the detected audio appears in the output. Output transformer T3 may be replaced by resistors shunted by C2 and C7 and connected in series in some circuit variations. Operation is the same in this instance, with the capacitors being charged by the voltage drop across the resistors, and, since they are connected in series, the output is the difference between the two voltages. When connected to an audio coupling capacitor this dc output varying at audio frequency rates will produce an audio output also. Whether or not the transistors operate alternately or simultaneously depends on the phase and value of the signal applied to the bases. With in-phase signals of of same polarity and amplitude, both transistors operate, and equal and opposite output voltages cancel out in the secondary of T3 to produce no output (considering perfect balance). With out-of-phase signals (push-pull input) one base will be negative and conduct while the other is positive and remains backbiased and non-conducting. Whether or not the transistors conduct on alternate half cycles also depends upon whether or not the input signal is stronger than the reference oscillator. The output may be push-pull or single-ended as desired, without affecting operation.

Failure Analysis.

No Output. Loss of reference oscillator signal, no input signal, a defective output transformer, or defective transistors can produce a loss of output. Check for the presence of an output from T2. If an output exists check T1, similarly, for a signal input. If there is no output from T2 check the primary and secondary windings for continuity. If continuity exists in the windings of T2, the oscillator circuit is probably defective. If no output exists at T2 and there is no signal input, check the primary and secondary windings of T] for continuity. If continuity exists, the r-f or i-f input circuits are probably at fault. If an input exists at T1 and a reference oscillator signal exists at T2, but there still is no output, both transistors are probably defective. Also check C2 and C7 for value and for a short. Check T3 primary and secondary for continuity. If continuity exists in T3 and neither C2 nor C7 is shorted there is still a possibility that T3 primary or secondary may be shorted. Measure the resistance of the windings of T3; a resistance of a few' ohms or less indicates a probable short-circuited winding. The possibility of a short in T1 or T2 also exists. Because of the few parts in this circuit a quick resistance check of all parts will usually reveal the defective item: If the shunting resistance of T3 on capacitors C7 and C2 is low, it may not be possible to make a capacitance check without first disconnecting one terminal of the capacitors from the circuit.

Low Output. A low output may be caused by defective transistors, partially shorted windings on T1, T2, or T3, or by leaky capacitors C2 and C7. The output of the reference oscillator should also be checked for normal amplitude. If normal, transistors Q1 and Q2 may be at fault. Check the values of C2 and C7 with a capacitance checker, and also check them for excessive leakage. If the low output persists, check transformers T1, and T2, and T3 for partial shorts (shorted turns), shorts and leakage to ground. To do this, it will be necessary to make separate dc resistance checks of the windings with an ohmmeter; check the winding inductance on an inductance bridge; and also check leakage to ground and transformation ratio (turns ratio). Since precise measurements are necessary and require laboratory type of equipment, it is doubtful that all these tests may be performed aboard ship. Do not neglect the possibility that excessively low sideband input and r-f oscillator signals can cause a low output. Usually the oscillator output is kept at about ten times the input signal to create a strong beat signal, and reduce the actual rectification of the input signal to such a small value that rectification distortion effects are eliminated.

Distortion. Since faithful reproduction in a balance detector depends upon the reference oscillator operating at the exact frequency of the suppressed carrier, and also that distortion components are not introduced by overdrive at the transmitter, it is often erroneously assumed that the detector is at fault when adjustment of the transmitter or receiver are what is actually required. When distortion is encountered, carefully tune the receiver to the proper sideband as shown by the strongest “S” meter reading and adjust the reference oscillator fine tuning control (C4) for clearest signal, at the same time adjust the r-f gain control for clearest signal, and the audio gain for proper volume. Place thee upper-lower sideband

switch in the position which provides the most intelligible signal, If distortion exists at the clearest tuning point, check by tuning in other sideband signals. If they are undistorted, the transmitter is being driven too hard. If all signals are distorted, the transistors may be defective. Check each part separately until the distortion is located.

LATTICE TYPE DIODE BALANCED DETECTOR (SEMICONDUCTOR)

Application.

The lattice-type diode detector is used for single sideband reception, and for double sideband suppressed carrier detection, particularly in carrier telephone multiplex circuits.

Characteristics.

May use either electron tubes or crystal diodes.

Has push-pull input and balanced output.

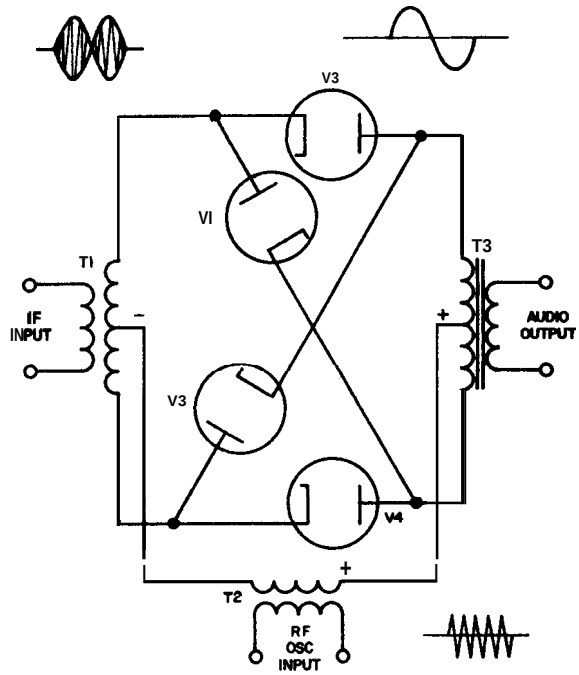
Requires reference oscillator input, and signal input.

Uses only transformers and diodes.

Circuit Analysis.

General. The lattice-type detector is sometimes called a shunt-quad demodulator. The output of a reference oscillator, which simulates the carrier signal, is applied in series with the center taps of the input and output transformers to provide a signal of the same polarity to each pair of diodes. When no sideband input is applied, this in-phase signal causes two of the diodes to conduct simultaneously and produce a circulating current traveling in opposite directions through one-half of the input and output transformer primaries. The magnetic flux induced in each half of the same winding in each transformer opposes the other, and the voltage induced in their secondaries cancel, so that no output is produced from either transformer because of the carrier signal. Thus, with no input signal applied, there is no output from the circuit. When an input signal is applied, it alternately adds to and subtracts from the oscillator signal, thus unbalancing the circuit. Each diode conducts alternately on opposite half cycles, producing an audio output in the secondary of the output transformer.

Circuit Operation. The schematic of a typical lattice-type balanced diode detector is shown in the accompanying illustration.



Lattice-Type Diode Balanced Detector

Transformer Tl is the i-for subcarrier input transformer, while T2 is the reference (carrier) oscillator transformer which is connected in-phase between T1 and T3. T3 is the audio output transformer. Diodes V1 and V3 form one group of rectifiers and diodes V2 and V4 form the other set of rectifiers. The rectifiers conduct simultaneously for in-phase signrds and alternately for push-pull signals.

Consider first the condition where no input signal is applied except the reference oscillator signal. Assuming an instantaneous polarity such that the center tap of T3 is positive and that of T1 is negative, the plates of V2 and V4 have a positive voltage applied and both diodes are forward-biased and conduct. Electron flow is from the negative terminrd of T2 through the upper half of T1 to the cathode and plate

of V2, back through the top half of the primary winding of T3 to the positive terminai of T2. Similarly, current flows through the bottom half of the winding of T1 from the negative terminal of T2 to the cathode and plate of V4, and back through the bottom half of the primary of T3 (in the opposite direction) to the positive terminal of T2. With equal voltages applied to the plates of the diodes equal currents flow. Therefore, the flux generated by the flow of current through the top half of T] is opposite to the flux created by current flow through the bottom half of Tl, and no output is induced in the primary. In a similar manner, the opposing plate current flow through the upper and lower halves of T3 produces opposite and canceling magnetic fields around the primary of T3 so there is no output from the secondary. Thus, the effect of an output from the reference oscillator is cancelled in both the input and output transformers because the circuit is completely balanced. Hence, with no input signal there will be no output, even though the reference oscillator voltage is applied. During the first half cycle of operation, the plates of diodes V1 and V3 are back-biased and do not conduct. On the opposite half-cycle, the polarity of the reference oscillator is such that the plates of diodes V2 and V4 are back-biased and do not conduct, while diodes V1 and V3 are forward-biased and conduct. With still no input and the r-f oscillator input of the opposite polarity, current flow is in the opposite direction through the bottom half of T3 and the top half of T2 for diode Vl, and through the upper half of T3 and the lower half of T1 for diode V3. Although current flows in the opposite direction to that for V2 and V4, the current flow through the upper and lower halves of both transformers is still in opposition. Hence, once again opposing fluxes are created in the transformer primary which cancel at the output so that no signal output is produced at the primary of T1 or the secondary of T3. Thus, regardless of oscillator polarity, there is never any output when only the in-phase signal from the reference oscillator is applied.

Since the reference oscillator amplitude is stronger than that of the incoming signal, the polarity of the reference oscillator determines which set of diodes conduct. At the instant diodes V2 and V4 are conducting, the push-pull input signrd connection will supply an in-phase signal to V2 and an out-of-phase signal to V4. Thus, conduction through diode V2 will be increased while the current through V4 is decreased. The reduced current through one half of the primary winding of output transformer T3 and the increased current through the other half of the winding add to produce a single polarity output in the secondary.

On the opposite half cycle of the reference oscillator signal, the plates of V1 and V3 will be driven positive and conduct while V2 and V4 are back-biased. Since the reference oscillator is almost the same frequency (except for the audio difference signal) as the input sideband signal, the polarity of T1 will also reverse and an in-phase signal will be sup plied to V3 and an out-of-phase signal to V1. Thus, conduction through diode V1 will be decreased while that through V3 will be increased. The reduced current through one half of the primary winding of output transformer T3 and the increased current through the other half of the winding add to produce a single polarity output in the secondary. This time, the polarity is opposite to that produced by V2 and V4 so that the negative half of the audio cycle is produced.

When the sideband input signal is mixed with the reference oscillator in the diode, sum and difference beat frequencies are produced. The high inductive reactance and leakage capacitance between turns of audio output transformer T3 effectively bypass the sum (high frequency) signal so that it does not appear in the output. Meanwhile, the audio frequency (difference) signal produces a voltage drop across the primary of T3 and induces a voltage into the secondary. This is the desired audio output voltage.

When this type of detector is used in multiplex telephony, the sideband input beating against the audio subcarrier also produces sum and difference frequencies. However, the sum frequency is still a high audio frequency (15 to 20 kHz or higher) and does not appear in the output because its amplitude is very low and it is inaudible. Thus, oniy the desired low frequency audio (difference) signals are produced.

Failure Analysis.

No Output.If there is no reference oscillator signal, or if transformers T1, T2, or T3 are defective, or the diodes are defective, no output will be produced. Likewise, if there is an oscillator signal but no input signal, no output will be obtained, Check for input and output signals. If an oscillator signal appears on

the primary of T2 but not on the secondary, T2 is open or shorted. Similarly, if there is an input on the primary of T1 but not on the secondary, T1 is open or shorted. If there is an input signal and a reference signal present but there is no output signal, either the diodes, or transformer T3 is defective. Note that it is necessary for all diodes to be defective to prevent an output, since each pair of diodes controls only one hrdf of the cycle. Usually a quick resistance analysis will locate the open or shorted component except for the transformers, in which case a voltage check should be made.

Low Output. With a normal input signrd and a normal oscillator signal, a low output can only be caused by low diode emission or by partially shorted transformers. Check the transformers and diodes. In this instance it is possible for only two of the diodes to be defective.

Distorted Output. Defective diodes, a low oscillator output, shorted transformer turns, or excessive leakage to ground or the core can produce distortion. It is also important that the oscillator frequency be correctly tuned. If an adjustment of the oscillator tuning does not improve the condition, the diodes or transformers are defective. There also remains the possibility that the transmitter is being overdriven and causing distortion. Try receiving other signals and if the distortion clears up the transmitter is being overdriven and causing distortion.

RING–TYPE DIODE DETECTOR (ELECTRON TUBE)

Application.

The ring-type diode detector is used for double-side-band suppressed carrier and single-sideband detection, particularly in multiplex telephone carrier equipment.

Characteristics.

May use either tube or crystal diodes.

Has a push-pull input and a balanced output.

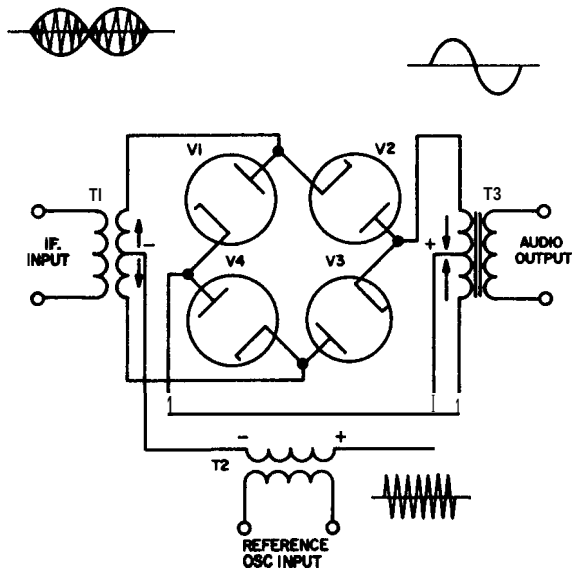
Requires both a reference oscillator input, and a signal input.

Uses only transformers and diodes.

Circuit Analysis.

General. The ring-type detector is basically a lattice-type detector which resembles a bridge circuit. A simulated carrier signal from a reference oscillator is applied between the center taps of the input and output transformers to provide an in-phase signal to each pair of diodes. With equal conduction between opposite diodes and equal but, opposite-direction, currents flowing in the two halves of the same transformer, the fields cancel, and no output is obtained as long as only the simulated carrier signal is applied, When an input signal is applied simultaneously with the simulated carrier, it alternately adds to, and subtracts from, the oscillator signal. Thus, each diode conducts alternately on opposite half-cycles, and an audio output is produced.

Circuit Operation. The schematic of a typical ring-type detector is shown in the accompanying illustration.



Ring-Type Detector

Transformer TI is the r-f of subcarrier input transformer, and T2 is the reference (carrier) oscillator transformer which is connected in-phase between T1 and T3. Transformer T3 is the audio output transformer. Diodes VI and V3 form one pair of rectifiers, and diodes V2 and V4 form the other pair. The diodes conduct simultaneously for in-phase signals and alternately for push-pull signals.

Consider first the condition where no input signal is applied except the reference oscillator signal. Also, assume that the instantaneous polarity is such that the center tap of T3 is positive, while that of T1 is negative. Therefore, the plates of V2 and V4 have a positive voltage applied, and the diodes conduct. Electron flow is from the negative terminal of T2 through the lower half of T1 and cathode to plate of diode V4, and back through the lower half of T3 primary winding to the positive terminal of T2. Similarly, current flows through the top half of the secondary winding of T1 and cathode to plate of V2, and back through the top half of the primary winding of T3 to the positive terminal of T2. With equal plate voltages applied to the diodes, equal currents flow through the transformers. Since the current flows in opposite directions through each half of the transformer winding, equal and opposite fields are generated around the windings. Because the opposing fields cancel each other, no oscillator signal is produced in the primary winding of T1 or in the secondary winding of T3. Thus, the possibility of an output resulting from the application of the reference oscillator is eliminated because the circuit is completely balanced. Hence, with no input signal, there will be no output, even though the reference oscillator voltage is applied. During the first half-cycle of operation, the plates of diodes V1 and V3 have a negative potential applied and do not conduct. On the opposite half-cycle, the polarity of the reference oscillator changes so that the plates of diodes V2 and V4 are supplied with a negative voltage and do not conduct, while the plates of diodes V1 and V3 are supplied with a positive voltage and do conduct. This time, current flow through the circuit is in the opposite direction through the top half of T3 and cathode to plate of V3, back through the lower half of T1 to the positive terminal of T2. For diode V1, current flow is through the top half of T1 and the lower half of T3. Although current flows in the opposite direction to that for V2 and V4, the current flowing through the upper and lower halves of each transformer is still in opposition. Hence, once again opposing fields are created around the windings and cancel, so that no signal output is produced in the primary of T1 or the secondary of T3. Thus, regardless of the oscillator polarity there is never any output when only in-phase signals from the reference oscillator are applied.

Since the reference oscillator amplitude is stronger than that of the incoming sideband signals, the polarity of the reference oscillator on the diodes controls conduction. At the instant that diodes V2 and V4 are conducting, assume that the push-pull input signal supplies an in-phase signal to V4 and an out-of-phase signal to V2. Thus, conduction through diode V4 is increased, while the current through V2 is decreased. The increased current through one-half of the primary winding of output transformer T3, and the reduced current through the other half of the winding produce aiding fields around the transformer, and induce an output voltage in the secondary winding.

During the opposite half-cycle of reference oscillator signal, the plates of V1 and V3 are driven positive and conduct, while those of V2 and V4 are supplied with a negative plate voltage and do not conduct. Since the reference oscillator frequency is almost the same as the sideband signal (except for the audio difference signal), the polarity of T 1 input also reverses. An in-phase signal is now applied to V1, and an out-of-phase signal to V3. The reduced current through one half of the primary winding of output transformer T3, and the increased current through the other half of the winding produce aiding fields around the transformer, which induce an output voltage in the secondary. This time, the output polarity is opposite to that produced by V2 and V4 because of the change in the direction of current flow, and the negative half of the audio cycle is produced.

When the sideband input signal is mixed with the reference oscillator in the diode, sum and difference (beat) frequencies are produced. The high inductive reactance and leakage capacitance between turns of audio output transformer T3 effectively bypasses the high frequency (sum) signal so that it does not appear in the output. Meanwhile, the audio frequency (difference) signal produces a voltage drop across the primary of T3 and induces a voltage into the secondary. This is the desired detected audio voltage.

When this type of detector is used in multiplex telephony, the sideband input beating against the audio subcarrier also produces sum and difference frequencies. However, the sum frequency is still a

very high audio frequency (15 to 20 kHz or higher) and does not appear in the output because its amplitude is low and it is inaudible. Thus, only the desired low frequency audio (difference) signals are produced.

Failure Analysis.

No Output. If there is no reference oscillator signal, or if transformers T1, T2, or T3 are defective, or the diodes (V1, V2, V3 and V4) are defective, no output will be produced. Likewise, if there is an oscillator signal but no input signal, no output will be obtained. Check for the presence of input and output signals. If an oscillator signal appears on the primary of T2 but not on the secondary, T2 is either open or shorted. Check the transformer resistance and continuity. Similarly, if there is an input on the primary of T1 but not on the secondary, check the primary and secondary resistance and continuity of T1. If there is an input signal and a reference signal present, but there is no output signal, the diodes are probably defective. Also check output transformer T3 for continuity and resistance. Note that is is necessary for all diodes to be defective to prevent an output, since each pair of diodes only controls one half of the cycle. Usually a quick resistance analysis will locate" the open or short-circuited component.

Low Output. With a normal input signal and normal oscillator signal, a low output can only be caused by low diode emission, or partially shorted or leaky transformers. Check the transformers for the proper winding resistance, and check all diodes. It is rdso advisable to check the input and reference oscillator signals on an oscilloscope for peak amplitude. Usually, the oscillator is about ten times the strenght of the input signal. If the input signal is too small in amplitude and cannot be increased by adjustment of the receiver r-f gain control, the receiver circuits are probably at fault. If the reference oscillator output is low, check the oscillator for possible trouble such as low plate voltage, high bias, or defective parts.

Distortad Output. Defective diodes, a low oscillator output, too strong a sideband input signal, shorted transformer turns, or excessive leakage to ground or to the core can produce distortion. It is also important that the oscillator frequency be correct. If an adjustment of the oscillator tuning does not improve the signal, try reducing the setting of the r-f gain control. If the distortion persists, the diodes, or the transformers are probably at fault. The possibility also remains that the transmitter is being overdrive. Try receiving other signals; if the distortion clears up, the transmitter is at fault.

BALANCED BRIDGE DETECTOR (ELECTRON TUBE)

Application.

The balanced bridge detector is used for double-sideband suppressed carrier and single sideband detection particularly in multiplex telephone carrier equipment.

Characteristics.

May use either electron tube or crystal diodes.

Has a balanced input and a balanced output.

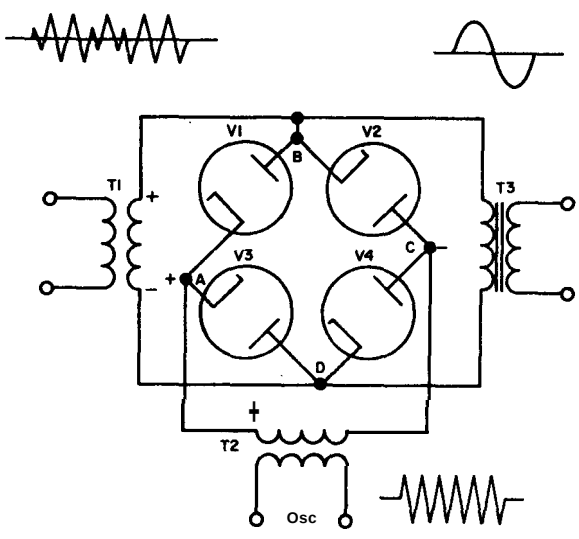
Requires both a reference oscillator input and a signal input to produce an output.

Uses only transformers and diodes.

Circuit Analysis.

General. A simulated carrier signal from a reference oscillator is applied between the midpoints of the balanced bridge rectifier. One one half cycle of r-f carrier operation the bridge diodes are back-biased, and the brdanced bridge is effectively opened so that there is no path for the r-f carrier through the output transformer. During the next half cycle of carrier signal the bridge diodes are forward-biased, and effectively shunt the carrier signal around the output transformer. Thus, in the absence of a molulated input signal, no output can occur. When an input signal is applied together with the simulated carrier, it alternately adds to and subtracts from the oscillator signal, and the bridge is unbalanced. Consequently, each diode conducts alternately on opposite half cycles and current flows through the output transformer first in one direction and then in the opposite direction, and an audio output is produced.

Circuit Oparation. The schematic of a typical balanced bridge type detector is shown in the accompanying illustration.



Baianced-Bridge Detector

As shown in the schematic, T1 is the i-f input transformer (the line input transformer for telephone carrier equipment). T3 is the audio output transformer and T2 is the simulated r-f carrier (oscillator) transformer. Four identical tube diodes are used, with VI and V4 conducting simultaneously as one set of rectifiers, and V2 and V3 as the other set of rectifiers.

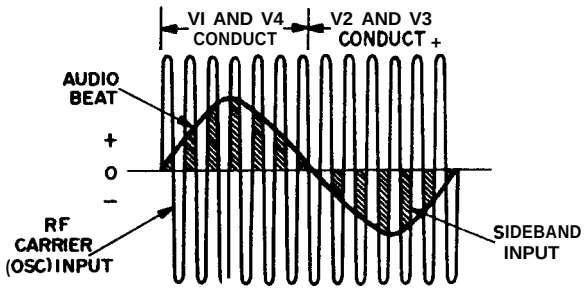
Let us first consider operation of the r-f carrier oscillator with no input signal applied to T1. Considering the half cycle of operation where a positive potential is applied to point A of the bridge and a negative potential to point C of the bridge it is evident that all four diodes are back-biased and will not conduct. Therefore, the bridge is effectively open and there is no output. During the next half of the oscillator cycle, point A is made negative and point C positive. Therefore all diodes are forward biased and conduct, effectively shunting both T1 and T3, and again there is no output. For these two conditions the bridge is balanced, and with no sideband input signal present on T1 there can be no output from T3.

When a signal appears on the secondary of T1, the bridge is unbalanced and two of the diodes are forward-biased while the other two diodes remain reverse biased and do not conduct. Assume that the i-f input signal produces a positive voltage on the top of T1 secondary and a negative voltage at the bottom. Diode V1 thus has a positive voltage applied to the anode from the input signal, and when the simulated oscillator signal is negative at point A, the cathode of V1 is also negative and V1 conducts. At the same time a negative input signal is applied to the cathode of V4, while a positive oscillator voltage is applied to the anode, and V4, likewise, conducts. During this half cycle of operation V3 has a negative voltage applied to the cathode from the oscillator at point A, but the plate has a larger negative voltage applied from the input signal. Hence, V3 does not conduct. In a similar manner, V2 has a positive oscillator voltage applied to the anode and a larger positive signal voltage applied to the cathode. Hence, V2 also does not conduct.

When the input signal changes polarity, diodes V2 and V3 are forward-biased and conduct. However, diodes V1 and V4 are now back-biased and cease to conduct, assuming that the carrier (oscillator) polarity has not changed. When the bridge is unbalanced and either set of diodes conduct, a path for the flow of current exists through the conducting diodes and the secondary of T1, in series with the oscillator secondary winding of T2. Depending upon which set of diodes conduct, the flow is first in one direction and then in the opposite direction during the next half cycle. The current flow through these paths is controlled by the amplitude of the signals applied and the respective reactance offered by the transformer windings. At the same time, the changing sideband input frequencies and the constant carrier (oscillator) signal are mixed, and sum and difference beat frequencies are produced. At any one instant, the difference frequency is the audio frequency, while the sum frequency is a higher radio frequency. Since transformer T3 is an audio transformer, it offers a high reactance (impedance) to the flow of radio frequency currents, and because of its appreciable capacity between turns offers a low (shunting) leakage reactance. Therefore, the r-f signals are effectively bypassed around T3 so there is no output for these frequencies. On the other hand, the audio beat signal current flows through the primary of T3 and induces an audio output voltage in the secondary.

The folIowing waveform illustration shows pictorially how the bridge detector develops the audio output. The r-f carrier (oscillator) input is shown as a

constant amplitude signal consisting of alternate positive and negative half cycles. It is assumed that the sideband input signal consists of an r-f signal one Hz more than the carrier frequency. Thus if we assume the oscillator operating at one million Hz, the sideband input signal occurs at a frequency of one million and one Hz and is the upper sideband (assuming signal sideband operation). When these two frequencies flow through the diodes they are mixed, and beat together producing a two million and one Hz sum frequency and a one Hz audio difference frequency.



Detector Waveforms

The one Hz audio frequency produces one positive and one negative half Hz; during this interval one million positive oscillator half Hz and one million negative oscillator half Hz occur and are shown in the illustration as seven half Hz for convenience and ease of drawing. Thus we see that V1 and V4 conduct during the positive input excursion of the single audio cycle while V2 and V3 conduct during its negative excursion. During each audio conduction period the amplitude first increases and then decreases to produce the audio sine wave originally introduced in the modulation process.

Idealized waveforms were used in the illustration and discussion of circuit operation. In actual operation the complex waveforms of speech (or music) are reproduced with a minimum of distortion. In the bridge detector the sideband signal is the larger and controlling signal, whereas in the bridge modulator the audio is the controlling signal and the oscillator signal is kept larger in amplitude to minimize distortion.

Failure Analysis.

No Output. A no-output condition can result from lack of sideband input or loss of carrier (oscillator) input, as well as from defective diodes or transformers. An open transformer primary or seconary winding on Tl, T2, or T3 can prevent an output, Check the primary and secondary windings for continuity with an ohmmeter. There is also the possibility of a shorted winding which can be located by checking the primary and secondary windings with an oscilloscope. While a defective diode may cause loss of one half of the signal, it is necessary for all four diodes to be defective to prevent any output.

Low Output. Low oscillator or input signals, or low emission in the diodes can produce a reduced output. Check the oscillator and input signal amplitude on an oscilloscope (use an r-f probe for high frequency signals). There is also the possibility that a partially shorted winding can reduce the signal. Use an oscilloscope and check that the waveform and amplitude in the secondary of each transformer is equal to or greater than the primary signal.

High or Distorted Output. A higher than normal output is rather unlikely and would be a direct result of greater than normal input and oscillator signal amplitudes. Check the preceding circuits for improper inputs and plate voltages. Distortion will usually occur because of higher or lower than normal inputs or outputs (carrier and sideband signals). Normally the oscillator and sideband signals are of different amplitudes to produce a good beat signal. When the signal amplitudes become equal, or have less than a 3 to 1 ratio, over-modulation distortion occurs. There is also the possibility of spurious beat signals causing unwanted signals or noise. Usually observation with an oscilloscope will indicate if any unwanted signals are present. If present, it will be necessary to determine the source, which is usually external (strong local signals) and either trap out the unwanted signal or minimize the pickup with either a low pass or a high pass band filter.

TRIO DE, PUSH-PULL OUTPUT BALANCED DETECTOR (ELECTRON TUBE)

Application.

The triode push-pull output type of balanced detector is commonly employed in single sideband

receivers used in fixed-station transoceanic telephony rather than in modern communications receivers, which generally use the product type detector.

Characteristics.

Uses a triode tube for increased gain and better brdancing.

Has a balanced input and a balanced output.

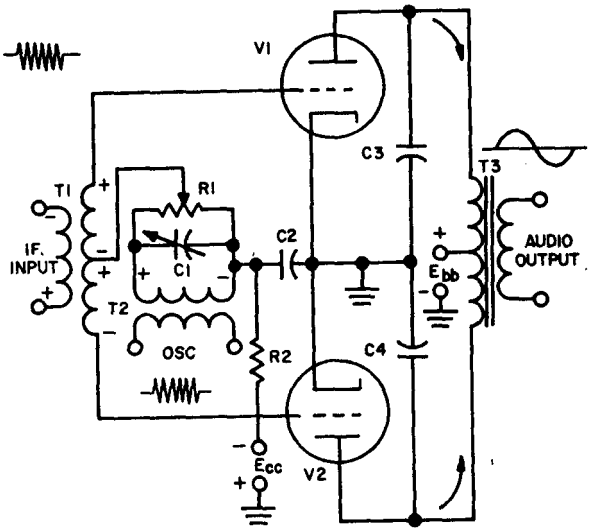
Requires a reference oscillator input and a sideband input to produce an audio output.

Can use either fixed or self bias.

Circuit Analysis.

General. The simulated carrier (r-f oscillator) signal is applied to the triode grids in parallel, and in the absence of a sideband input cancels out in the output transformer. Thus with no sideband input and only an oscillator input there is no output. When a sideband signal is applied to the grids it alternately adds in series with the simulated carrier (oscillator) signal on the in-phase half cycles, and causes the plate current of one tube to increase while that of the other tube decreases. The carrier and input signals beat together. The difference frequency appears in the primary of the output transformer producing an audio output, while the sum frequency is bypassed to ground. When the polarity of the input signal changes during the next half cycle, the polarity of the oulput changes and the other half cycle of the audio output is produced. The amplitude of the oscillator input is made adjustable to obtain a minimum of distortion.

Circuit **Operation.** The schematic of a typical triode push-pull output type of balanced detector is shown in the accompanying illustration.



Triocle Push-Pull Output Balanced Detector

The i-f input transformer, T1, is center tapped to provide a push-pull sideband input to the grids of V] and V2. The center tap is returned to the variable arm of potentiometer R1, which is connected across the secondary of oscillator transformer T2. Variable capacitor Cl is used to tune the secondary of T2 to resonance. Potentiometer R1 provides the proper amplitude of the oscillator signal applied to VI and V2. To provide a good beat frequency ratio, the oscillator amplitude is usually adjusted for about ten times the input amplitude from the i-f stage. Fixed

bias is applied from a separate negative supply through decoupling resistor R2, by-passed by C2 to ground. The rotor of Cl is placed at r-f ground potential by C2. The cathodes of VI and V2 are grounded. The plates of VI and V2 are connected in push-pull through audio output transformer T3, with the plate supply connected to the center tap on the transformer. Capacitors C3 and C4 are r-f bypass capacitors which allow only the audio signal to flow through T3 primary.

When the carrier (oscillator) output alone is applied to VI and V2 grids, it is effectively applied in parallel by connecting the secondary of T2 between both grids and ground. Thus when VI grid is driven positive a current flows from the cathode of V1 to the plate and through T3 to the center tap and power supply. Simultaneously, the grid of V2 is also driven positive, and an equal flow of current occurs from the cathode of V2 to T3 center tap and the supply in the direction opposite that of V1. Both currents of equal magnitude flowing in opposite directions through the primary of T3 cause opposing fields which cancel, so that no output is produced from the secondary winding of T3. Hence, no output is produced when the oscillator signal alone is applied to VI and V2. When the sideband input is applied to T1 primary it induces equal and opposite voltages in the center-tapped secondary so that the grid of VI is driven positive, while the grid of V2 is driven negative. These two secondary voltages add algebraically to the oscillator signal from T2. If at any instant the oscillator signal is operating on the positive half cycle, the voltage at the grid of V1 is the sum of the oscillator and sideband signal and causes the plate current of V1 to increase. At the same time the grid of V2 is driven negative and subtracts from the oscillator signal. Since the oscillator signal is adjusted for about ten times the amplitude of the input signal, the plate current of V2 is reduced. The magnetic field caused by the decrease of V2 conduction, is the same field polarity as that caused by the increase of V1 conduction. Thus, the two fields add to induce an output voltage in the secondary of T3.

The induced secondary voltage is an audio frequency since the oscillator and sideband signals beat together in the plate circuit, and produce sum and difference frequencies. The sum frequencies are bypassed to ground by C3 and C4 since they are at a higher radio frequency than the oscillator. While the difference frequency is at a low (audio) frequency and is offered a low reactance path through the primary of T3. Thus, only the audio component of the input signal is passed through T3 to produce the detected or demodulated audio output of the stage.

On the opposite half of the input signal cycle the opposite condition occurs. That is, VI is driven negative, while V2 is driven positive, and the negative half of the audio output cycle is developed in the primary of T3, and induced into the secondary as the audio output, When R1 is adjusted for the proper amplitude, the oscillator push-push input is balanced properly to produce a strong audio beat in the plate circuit, providing a minimum of noise and a relatively undistorted audio output signal.

Failure Analysis.

No Output. I_Qss of sideband input signal or loss of the oscillator (simulated carrier) signal when the opposite signal is present (or loss of both signals) will prevent any output. A defective tube or loss of plate voltage, open or shorted transformers T1, T2, or T3, too high a bias, or defective bypass capacitors C2, C3, or C4 can also prevent an output. With the plate voltage off, check the transformer primary and secondary windings with an ohmmeter, and check the resistance from grid to ground, and plate to ground, of each tube. If C3 or C4 is shorted, the plate to ground resistance will be zero and no plate voltage will be measured on either tube. If C2 is defective the bias voltage supply will be grounded and the entire bias supply voltage dropped across R2. Both tubes will draw a steady, heavy, plate current, there will be no output and the plate will most probably glow red. If RI is open or T2 is defective there will be no output. In the case of R1 open, no grid voltage will be measured from grid to ground with a voltmeter. In the case of a defective T2, no beat signrd will be present to provide an output and no r-f (oscillator) voltage will be present at the grid. If T1 is open no bias will be measured from grid to ground of V1 or V2, and either there will be no output, a weak output, or a badly distorted output. If tuning capacitor Cl is shorted there will be no oscillator output and no audio output from T3. If the secondary of T3 is open there will be no output, and continuity cannot be measured with an ohmmeter. There is also a possibility that the plate supply may be open because of a blown fuse in the power supply. Check for supply

voltage to ground at the center tap of T3, if not present the trouble is in the power supply. If R2 is shorted and an extremely high bias exists at the grids of V1 and V2 they can be held at cutoff and there will be no output. Also, do not neglect to check the bias supply for the proper voltage since it may be at fault.

Reduced or Low Output. Improper plate or bias voltage, or a defective tube can cause a reduction of output. Measure the bias and plate voltages to ground with a voltmeter. If the voltages are lower than normal, check the values of RI and R2 with an ohmmeter (with bias voltage disconnected). Check capacitor C2 for leakage using an in-circuit capacitance checker. If the plate voltage is low check the resistance of the primary winding of T3 (with plate voltage off), and check C3 and C4 for leakage to ground with a capacitance checker. There is also the possibility that R1 may be misadjusted, and the output can be brought back to normal by resetting RI. Also check the input and output with an oscilloscope. The signals in the secondary of T1 should be greater in amplitude than in the primary. Likewise the output voltage should be greater than the primary audio voltage. If the signal at the primary of T1 is lower than normal with the receiver gain control at maximum, the receiver is at fault. Check the preceding stages of the receiver.

Distorted Output. If the simulated carrier (oscillator) is not set at the correct frequency there will be distortion. If the frequency is sufficiently low it is possible that the lower sideband is being received rather than the upper. This can be recognized by the inverted speech. As the simulated carrier is reduced in frequency by tuning Cl the speech should develop more low frequencies; if the frequencies increase instead, the lower sideband is being received and the carrier frequency should be increased until the distortion disappears. If the ratio between the input and the oscillator signal amplitudes is less than 10:1. readjust RI for the proper amplitude until the distortion disappears. If the bias on V1 and V2 is improper the output may be larger than normal but greatly distorted. Check the bias with a voltmeter and check the bias supply for normal output voltage. Also check R2 for proper tolerance value.

TRIODE, PARALLEL OUTPUT BALANCED DETECTOR (ELECTRON TUBE)

Application.

The triode parallel output type of balanced detector is commonly employed in single sideband receivers used in fixed station transoceanic telephony, where the full output of a push-pull type detector is not required.

Characteristics.

Uses triode tubes for increased gain and improved balancing.

Has a balanced input and a push-push (parallel) output.

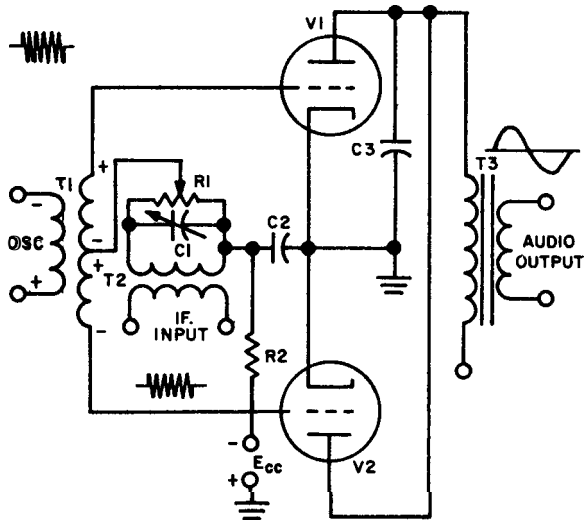
Requires a reference oscillator input, together with a sideband input, to produce an output.

Uses either fixed or self bias.

Circuit Analysis.

General. The simulated carrier (r-f oscillator) signal is applied to the triode grids in push-pull and cancels out in the plate circuit. Thus, with an oscillator input, but no sideband input there is no output, since any r-f not cancelled is bypassed to ground. When a sideband signal is applied to the grids it alternately adds to and subtracts from the simulated carrier signal. The plate current of one tube increases while the plate current of the other tube decreases. Thus the net change of current flow through the output transformer primary is zero for the r-f signals. Since opposing fields are produced in each half of the transformer primary, and the plate circuit is bypassed to ground for r-f, no output can occur. Simultaneously, the signals beat together and produce an audio frequency plate current flow which is not bypassed to ground. The audio voltage changes in the primary of the output transformer produce an audio output in the secondary. When the polarity changes from cycle to cycle, so does the audio signal and both the positive and negative half cycles are produced. The amplitude of the oscillator input is made adjustable to reduce distortion.

Circuit Operation. The schematic of a typical triode parallel output type of balanced detector is shown in the following illustration.



Triode Balanced Detector with Parallel Plates

Oscillator transformer T1 has a center-tapped push-pull secondary. Fixed bias is applied to the grids of V1 and V2 through i-f input transformer T2 tuned by variable capacitor Cl. R-f decoupling is provided by feeding the bias voltage through decoupling resistor R2, and C2 bypasses any r-f to ground, effectively placing the rotor of Cl at r-f ground potential. Potentiometer R1 acts as an adjustable voltage divider across the input tank to permit adjusting for the proper amplitude ratio between the oscillator and sideband signals. The plates of VI and V2 are parallel connected and bypassed to ground for r-f by C3. Transformer T3 is an audio output transformer from whose secondary the audio output signal is taken.

Assuming that the r-f oscillator alone is operating with no sideboard input signal, the grids of VI and V2 are driven in opposite directions by the push-pull connected secondary of T1. Thus, if VI is driven in a positive direction, V2 is driven in a negative direction. Since the amplitude of the oscillator signal is the same at both grids, with the plates connected in parrdlel an increase of plate current on one tube is balanced out by an equal decrease of plate current on the other tube. Hence, the net change of current flowing through the primary of output transformer T3 is effectively zero. In addition any r-f component appearing in the plate circuit is offered a low impedance path to ground by bypass capacitor C3 and no output is developed by T3.

When a sideband input signal appears on the secondary of T1 it is applied in parallel to both tube grids and alternately adds to and subtracts from the oscillator signal. Thus, during one half cycle VI is conducting heavily and V2 is conducting lightly. On the next half cycle of oscillator, or signal input, the opposite polarity prevails at the grids and V2 conducts more than V1. Since the signal component is applied equally to both grids the increase in plate current flow through one tube is counteracted by the decrease of plate current in the other tube. Once again, the net change for any current flowing through output transformer T3 is effectively zero and no output is produced. To ensure that no r-f output exists, bypass capacitor C3 is used to shunt the plate circuit to ground for r-f signals. Thus, neither the sideband input signal or the simulated carrier (oscillator) signal can appear in the output of T3. However, when both signals are applied to the tube grids, they beat together and produce sum and difference frequencies. Since the sum frequency is a bigh radio frequency it is bypassed to ground C3 and has no effect on the output. On the other hand, the difference signal is the low frequency audio signal which was orignally changed to a sideband signal in the transmitter modulator. Since the capacity of C3 is very small it offers a high impedance to the audio component, while the path through the primary of audio output transformer T3 offers a low impedance. As a result, the audio frequency changes in plate current pass through the primary of T3 and induce an audio output voltage in the secondary.

Potentiometer R1 is used to adjust the relative amplitude of the sideband input signal so that with a given oscillator input amplitude, the sideband signal may be adjusted to be one tenth of this value (a 10:1 ratio produces optimum beat frequency performance). Also, capacitor Cl is used to tune the secondary of T2 for maximum input signal response. In some circuit variations Cl is placed across the oscillator transformer primary together with Rl, and adjusts the oscillator amplitude instead of the input signal amplitude. Use of these adjustments permits a better balance to be obtained and reduces the effects of noise and spurious beats when properly adjusted.

Failure Analysis

No Output. Lack of an input signal, or no oscillator input, will prevent an output. Defective tubes, loss of plate voltage, improper bias voltage, or a shorted capacitor (C2 or C3) can also cause loss of output. First measure the bias and plate supply voltages. If either the bias or plate supply is at fault, the power supply fuse is blown or the trouble is in some portion of the power supply. With normal supply voltages check the grid voltage on tubes V1 and V2, and the plate voltage. With normal bias voltage at the supply terminal lack of bias on the grid of the tubes may be caused by RI, R2, or T2 secondary being open. Check the voltage at the junction of R2 and C2 to ground. If no voltage is present either R2 is open or C2 is shorted. Check the resistance of R2, and check C2 for a short. Zero resistance to ground across C2 indicates the capacitor is shorted. If bias voltage is present at R2 but not at the center tap of T1 secondary, potentiometer RI is open. Check the resistance of RI with the power off. If there is bias voltage at the center tap of T1 secondary, but not at either V1 or V2 grid, the secondary winding between the center tap and the tube grid indicating no voltage is open. Check the secondary winding for continuity. With normal plate supply voltage, but no voltage on the plate of V1 or V2, either the tubes are defective, capacitor C3 is shorted, or the primary of T3 is open or shorted. If T3 primary is open, no voltage can be measured from the top end of T3 primary to ground; if shorted, no voltage will be measured at either end of the winding. Check for continuity, with the power off, to verify that T3 is open, and measure the resistance to ground and across the winding. If the resistance to ground is less than 1-ohm, T3 is shorted to ground. Likewise, if the winding resistance is less than l-ohm, the winding is shorted and no output will be obtained from the secondary. If the winding is open there will be no continuity and the meter will read infinity. In the case of a low resistance to ground the possibility exists that the ground is due to C3 being shorted. Similarly, a short to ground in V1 or V2 will cause a similar indication, however, the short will disappear when the defective tube is removed.

Low Output. If the ratio of amplitude between the oscillator simulating the carrier and the sideband signal input is less than 10:1 the beat signal will most probably be reduced. Low emission in tube V1 or V2, or low plate voltage and improper bias voltage can also cause reduced output. It should also be kept in mind that a weak input signal which is below the normal threshold value of the receiver will also produce a low output, however, this is normal and can be caused by fading or other poor reception conditions. In the event of trouble it will usually be noted that all signals are weak. When due to external conditions, there will usually be signals of different strengths as the receiver is tuned over the operating spectrum. Where the receiver is equipped with a signal strength meter, comparison of known signals will usually indicate if operation is below normal. Assuming that a low output is suspected, check the plate and grid voltages. If these voltages are normal values as specified in the technical manual for the equipment, either one of the transformers T1, T2, or T3 may be defective, the oscillator stage may be at fault, or preceding receiver stages may not be performing properly. Check the amplitude of the input signal and that of the oscillator signal using a simulated test signal input. If the oscillator and input waveforms and amplitudes appear normal, or within specifications, the fault is probably in the plate circuit of the detector. If not normal, the trouble is in either the preceding stages or the oscillator stage, dependent upon which one is abnormal. If the oscillator signal is below normal either T2, Cl, or RI is at fault if the bias voltage is normal. If the bias voltage is abnormal either R1, R2, or C2 may be at fault. In either case check the resistors for within tolerance values and T2 for continuity. Check capacitor C2 for leakage. A lower than normal plate voltage and output can be caused by leakage in C3. A defective output transformer can be caused by leakage to ground in T3 or by shorted primary or secondary turns. If T3 is not at fault, the possibility exists that either or both tube sockets are defective or that leakage exists at some wiring tie point.

Distortion. Usually distortion is caused by overmodulation effects produced by the lack of sufficient oscillator amplitude or an excessively strong input signal. Check the oscillator stage and T2 for normal output. Readjust RI to see if the distortion can be changed or minimized, and in the case of a stronger than normal input signal check the preceding stages of the receiver for lack of AVC control or improper settings of the r-f gain control. Also check plate and bias voltages on V1 and V2. There is also the possibility that peaking of Cl or changing the oscillator

frequency slightly may restore normal operation. If these changes do not restore operation, each of the parts in the circuit should be checked for proper value and leakage, and the preceding stages of the receiver checked to make certain that the distortion is not being produced elsewhere.

PENTAGRID BALANCED DETECTDR

Application.

The pentagrid type of balanced detector is employed in single sideband receivers where improved sensitivity and better balancing is desired than is obtained with diodes or triodes.

Characteristics.

Uses pentagrid tubes to supply increased gain and improved balancing.

Has a push-pull input and a push-pull output.

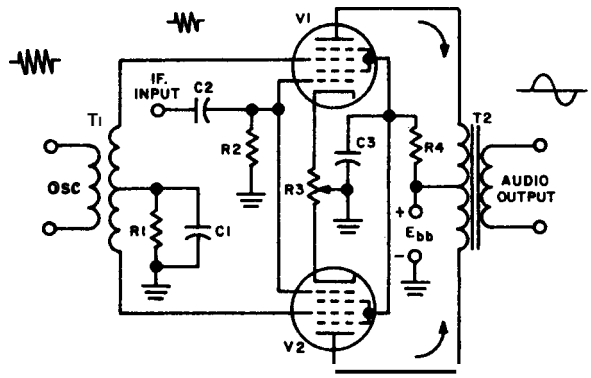
Requires both a reference oscillator input and a sideband input to produce an audio output.

Uses self bias and degeneration for improved operation.

Circuit Analysis.

General. The oscillator signal simulating an r-f carrier is applied through an input transformer with a center tapped secondary so that the input is applied in push-pull. The plates are also connected in push-pull through an audio output transformer. Thus the oscillator signal is cancelled in the plate circuit and does not appear in the output. The sideband input is resistance-capacitance coupled in parallel (push-push) to the tube grids. Because of the push-pull output, any r-f is cancelled in the plate circuit. Adjustable cathode bias permits setting for proper balance and cancellation. When both the oscillator and r-f signals are applied simultaneously, they beat together, and the difference voltage develops an audio output. The sum voltage is bypassed around the output transformer so that ordy an audio output is produced.

Circuit Operation. The schematic of a typical pentagrid balanced detector is shown in the accompanying illustration.



Pentagrid Balanced Detector

The oscillator input is applied through T1 which has a center tapped secondary, and the oscillator signal is applied to grid 3 or VI and V2 in push-pull. Resistor RI is the grid return resistor, bypassed for r-f by Cl. The sideband r-f input signal is applied through coupling capacitor C2 and grid resistor R2 to the control grids of V1 and V2. This connection applies the input signal in parallel (push-push), while the plates of both tubes are connected in push-pull through center tapped audio output transformer T3. The plate voltage is applied to the center tap of the primary winding of T3, and through voltage dropping and decoupling resistor R4 to the screens of both tubes. The screens are bypassed by C3 to place the screen grids at r-f and audio ground potential. Potentiometer R3 is connected between both cathodes with the variable arm connected to ground. Thus, the circuit may be accurately balanced by adjustment of the potentiometer, and complete cancellation of the r-f plate signal is obtained.

In the absence of an input signal, the simulated carrier input from the oscillator is applied to T1. Because of the center tap connection, which is grounded for r-f by Cl, the opposite ends of the

secondary winding are of opposite polarity. Thus when the grid of VI tends to increase plate current because of a positive input polarity, the grid of V2 is driven negative and reduces plate current flow. Normally, the fields in the primary halves of T2 would aid each other and produce a larger secondary output. However, transformer T2 is an audio transformer and offers an extremely high impedance path for r-f, and the distributed turn-capacitance offers a high leakage reactance which shunts the r-f around the transformer and to ground. Hence, there is no oscillator output from the secondary of T2. On the next half cycle of operation, the oscillator signal changes polarity and so do the grids of V1 and V2. Again, no output is obtained because of the high impedance and shunting capacitance of T2 primary winding. Since there is no effective change of plate current over the complete cycle of operation, the average plate current remains at the static value determined by the bias of grid 3. Grid bias is developed across RI by the flow of grid current, which charges C 1. Although grid current only flows on the positive half cycles, first VI grid conducts and then V2 grid conducts to produce a constant bias across c l .

When an input signal is applied to C2 an output is applied across R2 feeding both tube grids in parallel. Thus, if both grids are driven positive, plate current will increase and flow through the windings of T2 in opposite directions. Hence, equal magnetic fluxes are developed in the primary of T2 and cancel, so that no output appears in the secondary. On the negative half of the input cycle, plate current is reduced and again flows equally in opposite directions through the primary of T2, so that no output is produced. With R3 connected to ground, the cathode current of each tube can be adjusted for complete balance. Since R3 is not bypassed the cathode circuit becomes degenerative, and each signal instantaneously developes an opposing bias, which is applied to the cathode to reduce amplification to a low value. With the screen of V1 and V2 connected to the power supply through R4, a constant dc screen voltage is developed to determine the maximum plate swing available. Bypass capacitor C3 ensures that the screen voltage does not change with the signal and modulation to provide screen degeneration. Since the cathode current of both tubes flows through the screen and is controlled by the bias or signal voltages on number 1 and number 3 grids, it is clear that complete mixing of both signals occurs. Therefore, when both the oscillator and input signals are simultaneously applied they produce a beat in the plate circuit which develops both sum and difference frequencies. Since the sum frequency is a high r-f or i-f signal it is bypassed across the primary of T2 by the high capacitance per turn (leakage reactance) and no output is produced. The difference voltage beat, however, is a low audio frequency which is offered a low reactance path through the primary winding of T2. Thus, the audio beat signal produces a change in magnetic flux linking the primary and secondary windings of T2, and these moving lines of force cutting the secondary winding develops an output voltage in T2. Since the rate of change of flux is at an audio rate, an audio output signal is produced. Because the circuit is degenerative the full amplification of the electron tubes is not realized. Since the output is taken in push-pull, the ratio of one half of the primary turn winding to the secondary turns usually provides a step up of voltage. It is important to remember that an output can only be obtained when both signals are applied together to create the audio difference (beat) signaL

Failure Analysis.

No Output A loss of plate voltage, a lack of input (sideband) signal or simulated carrier (oscillator) signal, a defective tube, or open or shorted part can produce a loss of output. If T1 or T2 are defective the grid circuit of V1 and V2 can be open or shorted to ground. This will be indicated by a lack of bias developed across RI as measured with a high resistance voltmeter. If sideband input signal coupling capacitor **C2** is open no signal will appear on the grids of V1 and V2. Check for a signal on the grids of the tube and, if not present, check the input side of **C2.** If a signal appears on the input side but not on the grid side, check C2 for capacitance. If Cl is shorted to ground no oscillator signal will appear on grid 3. Check Cl resistance to ground or use a capacitance checker. If a signal appears on number 1 grid and an oscillator signal appears on number 1 grid and an oscillator signal on number 3 grid and there is no output, either R4 is open, C3 is shorted, or T2 is defective, or the tubes are at fault. Check for proper screen voltage on V1 and V2. If screen voltage is missing check R4 for a resistance value within tolerance (with plate and screen voltages off). Check C3 for a short, and also check the resistance of cathode

potentiometer R3. If plate supply voltage is present at the center tap of T2 primary winding but does not appear at the plates of VI and V2, the primary of T2 is open or shorted to ground. If plate voltage appears satisfactory but there is still no output, either the tubes are defective or the secondary winding of T2 is open or shorted.

Low Output Improper bias, plate, or screen voltage may cause a low output. A defective tube or partially open transformer T1 or T2 can also produce a low output. Check the bias, screen, and plate voltages. If normal bias is obtained across R3, or from the cathodes of VI and V2 to ground, and R3 can be adjusted for balanced voltages the tubes are probably satisfactory. If low screen voltage is indicated, R4 may have increased in resistance or C3 can be partially shorted. Check R3 for resistance and check C3 for capacitance. It is also possible that a high resistance primary on T3 can produce 1oss of, or low plate voltage. Check the resistance of T2 primary. If the bias, plate, and screen voltages appear within normal tolerance values, tubes VI and V2 may be at fault. Also, the oscillator amplitude may be low or the input (sideband) signal may be too weak. Check the operation of the oscillator and check for normal oscillator amplitude. If the oscillator circuit is satisfactory input transformer T1 may be defective. Check T1 primary and secondary for resistance, continuity, and turns ratio. A normal primary input, but low secondary output, indicates either T2 is defective, or Cl or RI is low. Check Cl for a partial short and RI for normal value. If the oscillator input is normal and the previous checks have been made, a low output may be produced by low input (sideband) signal. This can be caused by lack of proper amplification in the preceding receiver stages, or because coupling capacitor C2 is open, or grid return R2 is open. If R2 is open the circuit will most probably block on strong input signals. Check C2 for capacitance and leakage, and measure the resistance of R2.

Distorted Output. If the ratio of the oscillator signal to the input signal is too small, an improper beat will be developed and the output will be distorted. With an assumed normal oscillator this condition can be quickly checked by adjusting the receiver r-f gain control, and noting if the distortion can be made to disappear. If not, either the bias is at fault or the circuit is not properly balanced. Try readjusting R3 to determine whether or not balance will restore normal operation. If the distortion remains, make a resistance check of the resistors, and a capacitance check of the capacitors in the circuit. There is also the possibility that the oscillator which simulates the carrier is set to the wrong frequency and that the lower side band is being received instead of the upper sideband or vice-versa. This condition is easily determined by noting if the audio is inverted as the oscillator is tuned slightly past its center frequency (the audio note increases in pitch as the oscillator frequency is reduced). There also exists another possibility of distortion which is caused by improper transmitter adjustment. This can be determined by requesting the sender to reduce his audio gain or reduce peak r-f output and noting if the signal improves. Any distortion caused by selective fading will quickly return to normal when the fade is completed. Hence occasional bursts of distortion can be due to selective fading which cannot be controlled by the technician.

SECTION 11
MIXING, HETERODYNING, AND AUTOMATIC CONTROL CIRCUITS

PART 11–1. MIXER CIRCUITS

AUOIO MIXERS

General.

Audio-frequency mixing is defined as the combining of two or more audio-frequency (20 to 20,000 Hz) signals from separate sources in any desired proportion at the input to an audio-amplifier system. The term ***audio mixer*** should not be confused with the term ***mixer*** used to designate the nonlinear circuit that heterodynes the r-f and local-oscillator signals in a superheterodyne receiver. Audio mixers are considered as "combining" circuits and are operated as linear circuits.

Audio mixing circuits are used in public-address, sound-distribution, and similar audio systems to combine two or more input-channel signals for further amplification in the main channel of an audio-amplifier system. It is necessary to control the individual input-channel signal levels before mixing occurs. Also, if frequency compensation of the individual input signals is required, the frequency compensation must be accomplished before the signals are applied to the mixer input. It is desirable to have the individual signals to each mixer input as nearly equal to one another as possible so that similar control settings of the mixer circuit will produce similar output signal levels. This is especially true where the mixer circuit (channel) controls are front-panel controls which are easily accessible to the operator and require frequent operation or adjustment.

When a low-amplitude signal is to be mixed with a signal of greater amplitude, an audio-amplifier stage, called a ***preamplifier,*** is used to increase the amplitude of the smaller signal so that it is approximately equal to the amplitude of the larger signal; then the two input signals will be of approximately the same amplitude (level). before mixing occurs. In some instances, if the smaller of the two signals is at a satisfactory level for application to the mixer circuit, the signal with the larger amplitude is simply attenuated to a level which is equal to that of the smaller signal.

Audio mixer circuits can be classified as either electron- tube type of resistance-network type. Mixers may be further classified as high- or low-impedance, constant- or nonconstant-impedance, and high- or low-level mixers. The audio mixer circuits briefly described in this section are representative of typical electron-tube audio mixers.

COMMON PLATE-LOAO AUDIO MIXER

Application.

The common plate-load audio mixer circuit is used to combine two (or more) input audio signals by amplifying the signals and combining them in a common load impedance. The mixer circuit is generally used in public-address and sound-distribution systems to provide for the control and mixing of several input channels.

Characteristics.

Operates Class A with cathode bias.

Combines two individual input signals; each input signal is amplified, inverted, and combined in a common plate-load impedance with relatively low distortion.

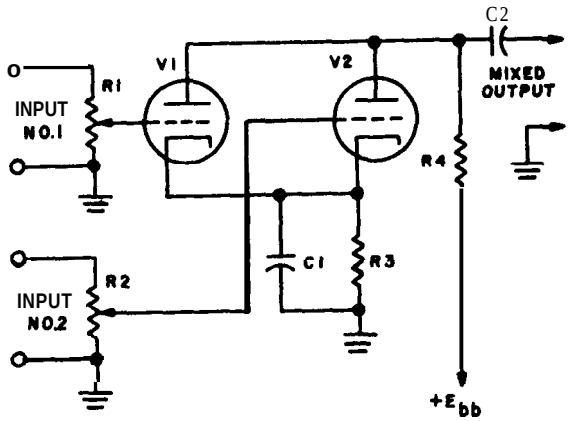
Additional circuits can be connected in parallel to provide for additional input channels.

Circuit Analysis.

General. The common plate-load audio mixer combines two input signals. The circuit is fundamentally two Class A audio amplifiers in parallel with a common plate-load resistance. The combined output signal is taken from across the plate-load resistance. More than two input signals can be mixed by applying each signal to a separate amplifier tube; each tube in turn, operates into the common plate-load resistance.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a common plate-load audio mixer circuit. Electron tubes V1 and V2 are identical-type triode tubes; although two separate triodes are shown, a twin-triode is commonly used in this circuit. Potentiometer (variable resistors) RI and R2 are the grid resistors for V1 and V2, respectively. Also, R1 and R2 are used to terminate a preamplifier, crystal pickup, or other high-impedance signal source, and control the level of

signal applied to each grid of the mixer circuit. Resistor R3 is the common cathode-bias resistor for V1 and V2; capacitor Cl is the cathode bypass capacitor. Resistor R4 is the common plate-load resistor for both V1 and V2; capacitor C2 is the output coupling capacitor.



Common Plate-Load Audio Mixer

In this mixer circuit, the two input circuits are isolated from one another, so that the setting of one control (Rl or R2) will have no effect upon the other. The two inputs are relatively high impedance; potentiometers R1 and R2 generally range from 500K to several megohms. in practice, no great attempt is made to achieve an exact match of impedances at the input to the mixer circuit. However, the values of R1 and R2 are usually made sufficiently high to act as a load or terminating impedance for a preamplifier stage, a crystal pickup, or a high-impedance, high-output microphone. If the signal source is a low impedance, an input matching transformer is required to obtain impedance transformation from the low-impedance source to the relatively high-impedance input of the mixer circuit.

The operation of each tube in the common plate-load audio mixer is similar to the operation of the R-C coupled triode voltage amplifier, described in the Amplifier Section of this Handbook, for individual input signals. For example, assume a condition where an audio signal is applied to Input No. 1 but no signal is applied to Input No. 2. In this instance, assuming that potentiometer RI is adjusted for a suitable input level to the grid of VI, the output signal developed across the plate-load resistor, R4, is 180 degrees out of phase with the input signal and is a reproduction of the input signal as it would be for any R-C coupled voltage amplifier. When audio signals are applied to both inputs of the mixer circuit, the combined signals appear across the plate-load resistor, R4, and are coupled through capacitor C2 to the grid circuit of the following audio amplifier stage. If the grid circuit of the following stage uses a potentiometer as the grid resistance (R-C coupling), then this potentiometer functions as a master gain control for the amplifier, since it controls the amplitude of the mixed audio signals applied to the grid of the following stage.

The mixer circuit illustrated is very satisfactory for two input channels. It uses two tubes sharing a common plate-load resistor. When more thao two inputs are desired, as for example three or four inputs, various circuit combinations incorporating three or four tubes may be used; however, there is a limitation to the number of tubes which can share a common plate-load resistance without suffering considerable loss of gain and introducing some distortion. Therefore, common plate-load mixers are generally limited to two or possibly three tubes. (Where more input channels are desired, modification of the basic circuit is necessary to provide a degree of plate-load isolation.) Since the plate resistances of the two tubes (V1 and V2) are in parallel, each tube works into a load impedance which is always less than its own plate resistance. Under such conditions of operation, the output voltage obtainable from the circuit is seriously limited.

Since one tube operates into a load consisting of the other tube's plate resistance effectively in parallel with the load impedance (R4), it is obvious that the gain of the two tubes as shown in the schematic will be less than the gain of a single voltage-amplifier tube because the load impedance for either tube is always less than its own plate resistance (r_p). Therefore, the gain of each tube will always be less than one-half the gain obtained from a normal voltage amplifier. If the normal voltage amplifier is considered to be a constant-voltage generator, as shown in part A of the following illustration, the a-c component of plate current (i_p) is:

$$i_p \frac{-\quad -\mu e_s}{r_p + Z_L}$$

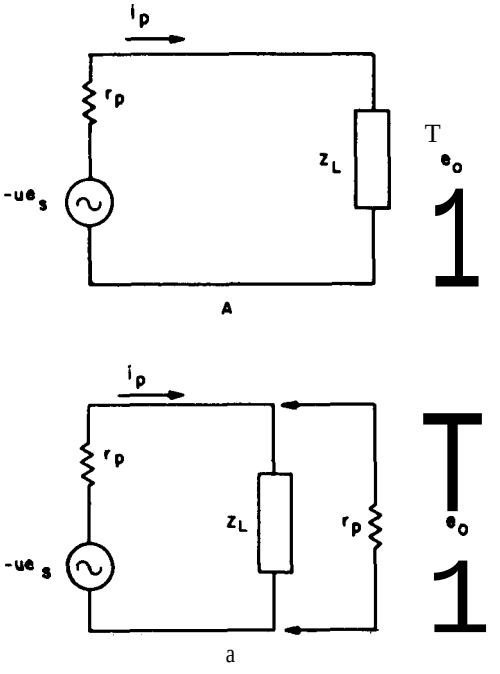
and the ac component of output voltage (e_n) that appears across the load impedance, Z_L, is:

$$e_o = i_p Z_L$$

By substitution then:

$$e_o = \frac{-\mu e_s}{r_p + Z_L} Z_L$$

$$= \frac{-\mu e_s Z_L}{r_p + Z_L}$$



Simplified Amplifier Circuit

It is apparent that the output voltage (e_o) of a normal voltage amplifier is not μ times the applied signal (e_s), because some voltage is lost in the internal resistance (r_p) of the tube and is not developed across the load impedance, Z_L: In part B of the illustration, the plate resistance (r_p) of a second tube is shown in parallel with the load impedance, as would be the case for a two-tube mixer circuit. The load impedance for this condition can now be expressed as:

$$\frac{r_{p2} Z_L}{r_p + Z_L}$$

where: Z_L = load impedance

r_{p2} = plate resistance of second tube

However, since identical tubes (Vl and V2) are used in the mixer circuit, the plate resistance of each tube can be considered to be equal to that of the other; therefore, r_{p2} is equal to r_p. The ac component of output voltage (e_o) for the two-tube mixer can now be expressed as:

$$e_o = \frac{-\mu e_s Z_L}{r_p + Z_L}$$

Substituting $\frac{r_p Z_L}{r_p + Z_L}$ for Z_L:

$$e_o = -\mu e_s \frac{r_p Z_L}{r_p + Z_L}$$

$$r_p \frac{r_p Z_L}{r_p + Z_L}$$

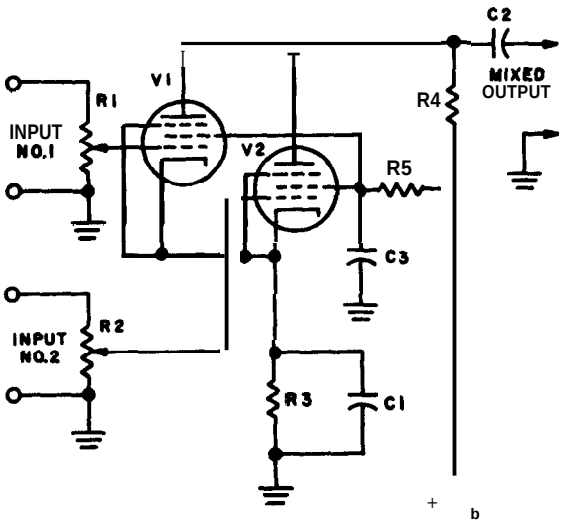
$$= \frac{-\mu e_s Z_L r_p}{Z_L r_p + r_p^2 + Z_L r_p}$$

$$= \frac{-\mu e_s Z_L r_p}{r_p^2 + 2 Z_L r_p}$$

$$e_o = \frac{-\mu e_s Z_L}{r_p + 2 Z_L}$$

From this expression it can be seen that, for two triodes in parallel, the output voltage (e_o) will always be less than one-half that obtained with a normal voltage amplifier. Similarly, for a three-tube mixer the gain will be less than one-third the gain obtained from a normal voltage amplifier; for a four-tube mixer it will be less than one-fourth.

Improved performance can be obtained by using pentode instead of triode tubes. The accompanying circuit schematic illustrates two pentode electron tubes in a common plate-load audio mixer circuit. Electron tubes VI and V2 are identical-type, sharp-cutoff pentodes. The circuit is fundamentally the same as that previously described for triode tubes except for the addition of the screen-dropping resistor, R5, and the screen bypass capacitor, C3. The circuit operation is the same as that described for the triode mixer circuit.



Pentodes Using Common Pkrte-Load

When pentodes are used in the common plate-load mixer circuit, the loss of gain due to the shunting of the load impedance by other tubes is slight and, for all practical purposes, may be neglected. The plate resistance of a pentode as a resistance-coupled amplifier is extremely high compared to that of a triode, so that nearly the full gain of the pentode can be realized in this circuit.

Failure Analysis.

No Output. The common plate-load audio mixer circuit is similar in many respects to a resistance-coupled voltage amplifier circuit insofar as failures are concerned. Failure of the plate-voltage supply will disrupt operation of the circuit, as will an open circuit in the cathode. The filament and plate voltages should be measured, as well as the dc voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether the plate load resistor (R4) or cathode resistor (R3) is open. Each input should be checked with an oscilloscope to determine whether signals are applied to the input of the circuit and whether they are of the proper amplitude. An open output coupling capacitor (C2) will prevent signals from reaching the stage following the mixer.

If the mixer circuit uses pentode tubes, the voltage applied to the screen grid should be measured, to determine whether it is within tolerance and whether the screen bypass capacitor (C3) is shorted. A shorted screen bypass capacitor will remove screen voltage from the tubes and may cause the screen-dropping resistor, R5, to burn out. When normal output is obtained from one channel but not from the other, the input to the faulty channel shouId be checked with an oscilloscope to determine whether the trouble is due to an open input potentiometer (Rl or R2) or failure of the input-signal source.

Low or Distorted Output. The applied plate voltage should be measured to determine whether it is within tolerance. Also the output coupling capacitor, C2, should be checked to determine whether it is leaking; leakage of this capacitor will drop the applied plate voltage and permit voltage-divider action to affect the operation of the following stage. Thus, if the input resistor of the following stage is returned to ground, the voltage at the plates of VI and V2 will be reduced, and the operation of the following stage will be upset by the change in voltage applied to its grid. An open cathode bypass capacitor Cl ***will*** cause the mixer circuit to be degenerative, and wiil also result in "cross-biasing" of the tubes so that the stage gain will be severely decreased. A shorted cathode bypass capacitor will result in a loss of bias and distortion of the output signal. Depending upon the configuration of the preceding stage (for example, a preamplifier stage, R-C coupled), it is possible that a dc voltage may be applied to the input potentiometer (RI or

R2) because of a leaky or shorted coupling capacitor. In this case, a dc voltage which is dependent upon the setting of the potentiometer will be applied to the grid, and the tube bias will be affected.

In the pentode audio mixer circuit, a leaky screen bypass capacitor (C3) or an increase in the value of the screen-dropping resistor (R5) will cause reduced gain because of the decreased screen voltage, while an open screen bypass will cause reduced gain because of degeneration within the stage.

SEPARATE PLATE-LOAD AUDIO MIXER

Application.

The separate plate-load audio mixer circuit is used to combine two (or more) input audio signals by amplifying the signals and combining them at the common input of a following stage. The mixer circuit is commonly used in public-address and sound distribution systems to provide for the control and mixing of several input channels.

Characteristics.

Operates Class A with cathode bias.

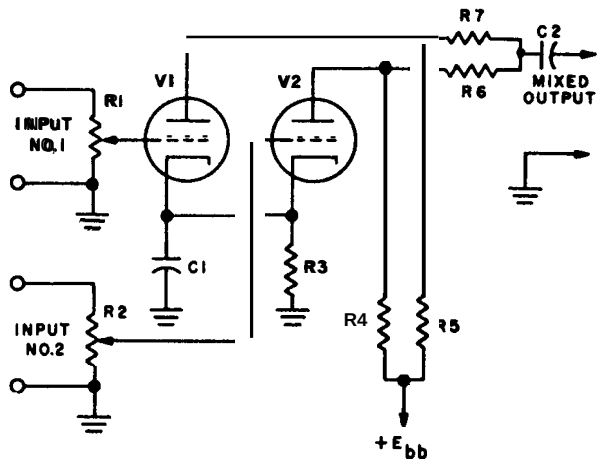
Combines two individual input signals; each input signal is amplified, inverted, and fed through an isolation resistance to the common input of a following stage.

Additional circuits can be connected in parallel to provide for additional input channels.

Circuit Analysis.

General. The separate plate-load audio mixer circuit combines two input signals. The circuit is fundamentally two separate Class A audio amplifiers with each output fed through an isolation resistor to a common input impedance of the following stage. More than two input signals can be mixed by applying each additional signal to a separate amplifier which has its own plate-load resistance, and feeding the amplifier output through an isolation resistance to a common input impedance of the following stage.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a separate plate-load audio mixer circuit. Electron tubes VI and V2 are identical-type triode tubes; two separate triodes are shown, but a twin-triode is commonly used in this circuit. Potentiometers (variable resistors) RI and R2 are the grid resistors for V1 and V2, respectively. Also, R1 and R2 are used to terminate a preamplifier, crystal pickup, or other high-impedance signal source, and control the level of signal applied to each grid of the mixer circuit. Resistor R3 is the common cathode-bias resistor for V1 and V2; capacitor Cl is the cathode bypass capacitor. Resistors R4 and R5 are the plate-load resistors for V2 and V1, respectively, resistors R6 and R7 are the output-isolation resistors. Capacitor C2 is the output coupling capacitor.



Separate Plate-Load Audio Mixer

In this mixer circuit, the two input circuits are isolated from one another, so that the setting of one control (RI or R2) will have no effect upon the other. The two inputs each have a relatively high impedance; potentiometers RI and R2 generally range in value from 500K to several megohms. In practice, no great attempt is made to achieve an exact match of impedances at the input to the mixer circuit. However, the values of R1 and R2 are usually made sufficiently high to act as a load or terminating impedance for a preamplifier stage, a crystal pickup, or a high-impedance, high-output microphone. If the signal source is a low impedance, an input matching transformer is required to obtain impedance transformation from the low-impedance source to the relatively high-impedance input of the mixer circuit.

The operation of each tube in the separate plate-load audio mixer is similar to the operation of the R-C coupled triode voltage amplifier, described in

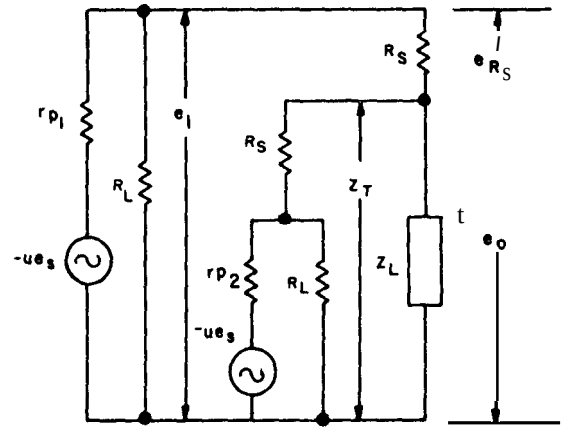
Section 6. When audio signals are applied to both inputs of the mixer circuit, the individual amplified signals appear across the respective plate-load resistors, R5 and R4. The individual signals are then applied through the series isolation resistors (R6 and R7) to the output coupling capacitor, C2, which couples the combined signals to the grid circuit of the following audio amplifier stage. If the grid circuit of the latter stage uses a potentiometer as the grid resistance, then this potentiometer functions as a master gain control for the amplifier, since it controls the amplitude of the mixer audio signals applied to the amplifier grid.

The mixer circuit illustrated is very satisfactory for two input channels. When more than two inputs are desired, as for example three or four inputs, an additional tube is connected to the circuit for each additional input desired, and its individual plate load resistance is coupled to the common output circuit by means of an isolation resistor to provide a degree of isolation between amplifier tubes. Thus, some of the inherent disadvantages of the basic common plate-load audio mixer are overcome. The isolation resistors (R6 and R7) are usually two to five times the value of the individual plate-load resistors (R4 and R5). As a result, each tube in the mixer circuit works into a complex load impedance which approaches a normal load for a voltage amplified stage; therefore, distortion due to nonlinearity is considerably reduced. Although the normal stage gain is obtained when the tube works into a normal load, the output signal voltage available at the input of the following stage is considerably reduced because of the loss introduced by the signal-voltage drop across the isolation resistor. However, the net result is that the higher output voltage from the mixer is available at the input of the following stage for a given percentage of distortion, as compared to the output voltage obtainable from other triode mixer circuits, such as the common plate-load audio mixer.

The voltage delivered to the input of the following stage by the mixer is always less than one half that obtainable with a normal voltage amplifier. In the following illustration, the complex load impedance into which one tube works is simplified to show the amplified-signal voltage division and the resulting useful signal output available across the load impedance, Z_L, corresponding to the inPu' of the s[uc-] ceeding stage. Since both tubes (V1 and V2) employed in the mixer are identical-type tubes, the plate resistances (r_p) can be considered to be equal. Also, the isolating resistors (R_s) are equal to each other, and the plate-load resistors (R_L) are equal to each other. The a-c component of output voltage (e_o) for the mixer using isolation resistors, expressed as a voltage relationship, is as follows:

$$e_o = e_1 - e_{Rs}$$

where: e_1 = voltage developed across R_L
e_{Rs} = voltage developed across isolating resistor R_s



$$Z_T = \frac{\left(\frac{r_p R_L}{r_p + R_L} + R_s\right) Z_L}{\left(\frac{r_p R_L}{r_p + R_L} + R_s\right) + Z_L}$$

Simplified Mixer Circuit

Since the resistance of R_s is greater than the impedance, Z_T, a greater signal voltage appears across R_s than across Z_T. Therefore, the output voltage (e_o) developed across Z_L must always be less than the voltage developed across the isolating resistor, R_s and less than one-half the voltage obtainable from a normal voltage amplifier. Depending upon the value of the load impedance, Z_L, the output voltage (e_o) may be as low as one-third the voltage obtainable from a normal voltage amplifier.

Pentodes can be used to advantage in this circuit because the plate resistance of a pentode is extremely high compared to that of a triode. The value of the isolation resistor need only be several times the value of the plate-load resistor and, since nearly the full

gain capability of the pentode can be realized, the output voltage available at the load impedance will be greater than one-half of the output voltage obtained from a normal amplifier.

Failure Analysis.

No Output. The separate plate-load audio mixer circuit is similar in many respects to a resistance-coupled voltage amplifier circuit insofar as failures are concerned. Failure of the plate-voltage supply will disrupt operation of the circuit, as will an open circuit in the cathode. With tubes known to be good installed in the circuit, the filament and plate voltages should be measured, as well as the dc voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether the individual plate-load resistors (R4 and R5) or cathode resistor (R3) is open. Each input should be checked with an oscilloscope to determine whether signals are applied to the input of the circuit. An open output coupling capacitor (C2) will prevent signals from reaching the stage following the mixer.

If the mixer circuit uses pentode tubes, the voltage applied to each screen grid should be measured, to determine whether it is within tolerance and whether the screen bypass capacitor is shorted. A shorted screen bypass capacitor will remove screen voltage from the tubes and may cause the screen-dropping resistor to burn out.

When normal output is obtained from one channel but not from the other, the input to the faulty channel should be checked with an oscilloscope to determine whether the trouble is due to an open input potentiometer (RI or R2) or failure of the input-signal source.

Low or Distorted Output. The applied plate voltage should be measured to determine whether it is within tolerance. Also the output coupling capacitor, C2, should be checked to determine whether it is leaking. A leaky (or shorted) output coupling capacitor will form a voltage divider comprised of both isolating resistors (R6 and R7) effectively in parallel, and this combination is in series with the input resistor of the following stage. Thus, the voltage at the plates of V1 and V2 will be reduced somewhat, and the operation of the following stage will be upset by the positive voltage applied to its grid. An open cathode bypass capacitor C 1 will cause the circuit to be degenerative, and will also result in "cross-biasing" of the tubes so that the stage gain will be decreased. A shorted cathode bypass capacitor will result in a loss of bias and distortion of the output signal. Depending upon the configuration of the preceding stage (for example, a preamplifier stage, R-C coupled), it is possible that a positive d-c voltage may be applied to the input potentiometer (Rl or R2) because of a leaky or shorted coupling capacitor. In this case, a positive d-c voltage, the amount of which is determined by the setting of the potentiometer, will be applied to the grid and affect the bias.

If plate-load resistor R4 (or R5) should open, the plate voltage applied to V2 (or Vl) will be considerably below normal, since the plate voltage will be applied to the tube through both isolating resistors in series with the plate-load resistor, R5 (or R4) of the other tube, VI (or V2). As a result, the signal output from the tube with the plate voltage below normal will be extremely low.

If the mixer circuit uses pentode tubes, a leaky screen bypass capacitor or an increase in the value of the screen-dropping resistor will cause reduced gain because of the decreased screen voltage, while an open screen bypass will cause reduced gain because of degeneration within the stage.

VIDEO MIXERS

General.

Video mixing is defined as the combining of two or more video signals. The video signals to be combined consist of various forms of pulse information and may include any number of the following: radar video, beacon video, range markers, range strobe, azimuth markers, IFF video, blanking gates or pulses, and other special forms of information.

The term ***video mixer*** should not be confused with the term ***mixer*** used to designate the circuit that heterodynes the r-f and local-oscillator signals in a superheterodyne receiver. Video mixers are considered as "adding" circuits and perform algebraic addition of pulse information; the pulses can be of either polarity and need not be in coincidence. In certain applications, video mixers are designed to combine signals of a given polarity only. Also, in many radar applications, video mixers are designed to combine time-coincidence pulses in a nonadditive manner; operation in this manner prevents excessive output amplitude and possible overloading in subsequent video amplifier stages, and thus prevents "blooming" of the indicator display.

The majority of electron-tube video mixing circuits presently in use are variations of two basic types: the common-cathode video mixer and the common-plate video mixer. Most video mixer requirements can be met by one or the other of these two circuits. The common-cathode video mixer does not invert the signal but acts in a manner similar to the cathode follower, whereas the common-plate video mixer does invert the signal. The common-cathode video mixer is degenerative, and the amplitude of the combined output of the two input signals in coincidence is less than that of the larger input signal. The common-plate video mixer normally has some gain; as a result, the amplitude of the combined output of the two input signals in coincidence is generally greater than the larger of the two input signals. Therefore, if the amplitude of the combined output signal from the common-plate mixer is excessive for the application, modifications to the basic circuit are necessary to reduce the adding effect. Otherwise, the output is likely to overload subsequent video amplifier stages when coincident signals are applied to the input.

A video mixer is normally required to handle pulse information having pulse widths of 0.5 to 500 microseconds and pulse repetition rates of 200 to 2000 pulses per second. Common-cathode video mixers are capable of handling very fast rise-time pulses because of the cathode-follower action of the circuit. Common-plate video mixers are purposely designed with high frequency compensation, to enable them to handle the rise time of the input video pulses.

COMMON-CATHODE VIDEO MIXER

Application.

The common-cathode video mixer circuit is used to combine two (or more) input video or pulse signals. Depending upon the circuit configuration, when input signals are in time-coincidence the output signal can be a limited-amplitude combination of the input signals or a nonadditive output signal which is representative of the larger input signal only.

Characteristics.

Input signals are of positive polarity; output signal is of positive polarity. Negative input signals can be combined (by the basic mixer circuit) only at very low levels.

Gain of video mixer (as a cathode follower) is approximately 0.75.

Degenerative circuit (cathode follIower) provides limited-amplitude additive mixing of time-coincident signal pulses because of common-cathode biasing arrangement. Modification of basic circuit to include fixed bias near cutoff provides nonadditive mixing of time-coincident signal pulses.

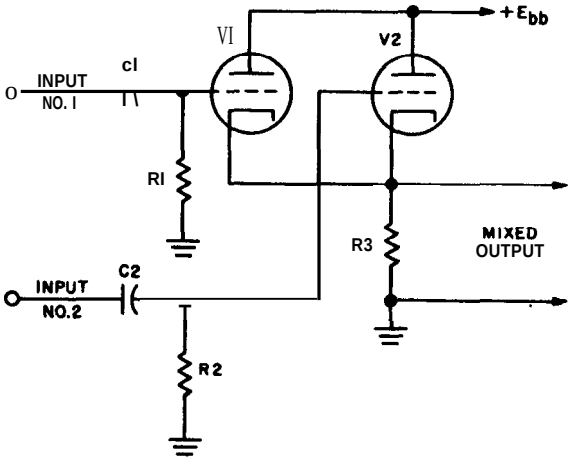
When more than two input signals are to be combined, additional common-cathode video-mixer circuits may be connected in parallel with little change in operating characteristics.

Output impedance is relatively low.

Circuit Analysis.

General. The basic common-cathode video mixer combines two positive video signals. The circuit is fundamentally two cathode followers in parallel with a common cathode resistance. The output polarity is positive, and the combined signal is taken from across the cathode resistance. Any number of positive input signals can be mixed by applying each signal to a separate cathode follower; each cathode follower, in turn, operates into the common cathode resistance. Whether or not any addition of signals occurs in the output depending upon the biasing of the cathode-follower stages.

Circuit Operation. The following circuit schematic illustrates two triode electron tubes in a common-cathode video mixer circuit. Electron tubes VI and V2 are identical-type triode tubes, although the accompanying schematic illustrates two separate triodes, a twin-triode is commonly used in this circuit. Capacitor Cl couples one input signal to the grid of V1; capacitor C2 couples the other input signal to the grid of V2. Resistors RI and R2 are the grid resistors for VI and V2, respectively. Resistor R3 is the common cathode-bias resistor for V1 and V2, and it is also the cathode load resistance for the video-mixer circuit across which the combined, or mixed, pulse output signal appears. The plate of each tube is tied directly to the supply voltage, $+E_{bb}$. The tolerance of component values in this circuit is not critical, and 10-percent-tolerance parts are normally used.



Basic Common-Cathode Video Mixer Circuit

When voltage is first applied to the circuit, the grids (of VI and V2) are at zero bias, and the combined plate current of both tubes passes through common-cathode resistor R3 to quickly establish the no-signal, or quiescent, bias. The electron tubes, V1 and V2, are assumed to be identical-type tubes, or a single-envelope twin-triode with identical characteristics; however, a small unbalance in tube characteristics will not greatly affect the circuit operation.

The operation of each tube in the common-cathode video mixer circuit is similar to the operation of the cathode follower, described in the Amplifier Section of this Handbook, when the input signals *are not* in time-coincidence. For example, assume a condition where a positive pulse is applied to the input of V1 but no signal is applied to the input of V2. In this instance, as the input signal to V1 increases in a positive direction, the plate current of V1 increases, causing an increased voltage drop across cathode-load resistor R3. As the input signal to VI falls, the plate current decreases to its former value, causing a decrease in the voltage drop across cathode-load resistor R3. Thus, the output-signal voltage developed across the cathode-load resistor is a reproduction of the original input signal applied to the grid of V1. Furthermore, since the input signal produces a change in the cathode bias, this bias voltage is in phase with the input signal and therefore reduces the amplitude of the grid-to-cathode voltage of VI, producing degeneration of the output voltage. (Cathode-follower gain is always less than one.) Note that as the plate current of V1 increases with signal the voltage developed across cathode-load resistor R3 also increases, and that this instantaneous voltage, in turn, changes the no-signal bias for the grid of V2. Thus, the instantaneous voltage increase developed across R3 by the signal applied to V1 effectively decreases the plate current of V2 and results in a decrease in the plate current of V2 through the common cathode-load resistor, R3. The net result is a decrease in the signal current through the cathode-load resistor because of the cathode-follower action of V1 and the degenerative action of V2. Therefore, the output-signal amplitude for one input signal is always less than the original input-signal amplitude.

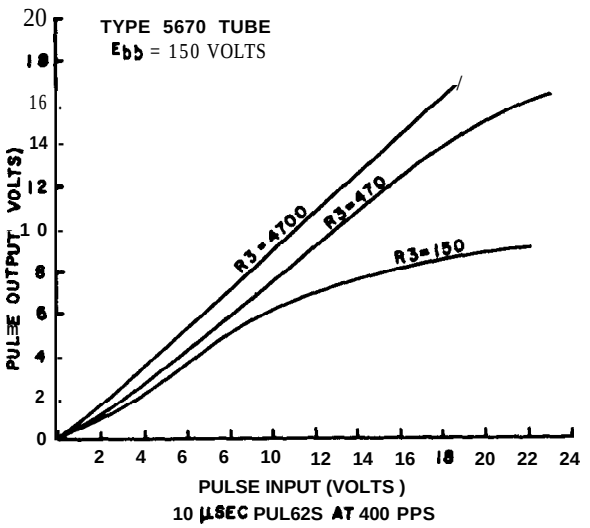
The operation of the common-cathode video mixer when two input signals ***are*** in time-coincidence produces some adding of signals to give a combined output which is always less than the amplitude of the larger of the two coincident input signals and greater than the output signal that results when only one input signal is present. The limited addition of time-coincident positive input signals results from the use of a common cathode-load resistance which causes "cross-biasing" of the two tubes. The extent of signal adding is primarily a function of the value of the cathode resistor, R3, and the level of the input signals. Where the value of the cathode resistor is such that the gain of each stage is considerably less than unity (relatively small value cathode resistor), the biasing action is not complete and some addition of signals will always occur. When the no-signal bias is large (relative large value cathode resistor), but not sufficient to completely cut off the plate current, the gain of the cathode follower is less for small positive signals than for the larger positive signals. This effect is caused by nonlinearity in the gain characteristic at low input levels. Also, the gain is reduced, resulting in the addition of the input signals. Since some additive effect can be tolerated, initial cutoff of plate current for each tube is not necessary, and grid bias is normally obtained by cathode-resistor action only.

If the output of the common-cathode video mixer is required to operate into a low-impedance coaxial cable which is terminated in a low impedance, the effective value of the cathode-load resistance is also a low value. When this is the case, the gain of the mixer is decreased because of the lower output impedance; therefore, less cross-biasing is produced by coincident signals appearing at the cathode-load resistance.

If the mixer is biased to cutoff, it combines coincident input signals of identical pulse width (duty cycle) in which a manner that only the input with the largest amplitude appears at the output; this manner of operation is called ***nonaddictive mixing,*** and is described later as a modification to the basic mixer circuit.

The following tabulation compares the performance of a typical common-cathode video mixer circuit for three values of cathode-load resistance, 4700, 470, and 150 ohms. Two input signals of different pulse widths were used to obtain the data given. Each individual input level was adjusted to provide the output voltage given in the table, and then the input signals were applied simultaneously to each respective input to obtain time-coincident signals. The effect in each case was to obtain a combined output which was greater than the output obtained from either signal alone.

Cathode-Load Resistor (ohms)	4700	470	150
Output Volts (for one input)	3.0	3.0	3.0
Output Volts (two inputs in coincidence)	3.6	3.9	4.3
Input No. 1 (volts):			
180-μsec pulse at 400 pps	4.1	4.9	8.0
Input No.2 (volts):			
10-μsec pulse at 400 pps	4.0	4.9	6.0



Gain Characteristic of Common-Cathode Mixer

The preceding graph illustrates the gain characteristic and linearity of a single cathode-follower stage in a typical common-cathode video mixer circuit for three values of cathode-load resistance. Note that the largest value of cathode-load resistance offers the largest gain and provides the greatest range of linearity; whereas, the smallest value of cathode-load resistance provides less gain and poor linearity. Furthermore, the ***additive factor*** for time-coincident input signals will increase for the lower values of cathode-load resistance because the stage gain decreases; as a result, less cross-biasing is produced by the combined output signals developed at the common cathode-load resistor.

As previously stated, the output of the common-cathode video mixer for signals in time coincidence is always less than the amplitude of the largest input signal and greater than the output obtained from either input signal alone. An indication of the amount of addition of two signals in time coincidence is given by the ***additive factor.*** The additive factor (in percent) is expressed as:

$$\text{Additive factor} = 100\,\frac{E_R - E_H}{E_L}$$

where E_R = resultant (combined output voltage for inputs in coincidence
E_H = output voltage for highest input level
E_L = output voltage for lowest input level

The effect of the value of cathode-load resistance (R3) upon the combined output pulse amplitude and the additive factor can be seen by comparing the results obtained when using different values of cathode-load resistance. In the first example, a 4700-ohm cathode-load resistor is used; in the second example, a 150-ohm cathode-load resistor is used.

a. The value of cathode-load resistor for a video mixer is 4700 ohms. Assume two positive input signals of 4.8 and 4.1 volts amplitude and corresponding output signals of 3.6 and 3.0 volts amplitude. When the input signals are in coincidence, the measured output-signal amplitude is 4.2 volts. Using the formula given above to determine the additive factor:

Given: $E_R = 4.2$
$E_H = 3.6$
$E_L = 3.0$

Therefore:

$$\text{Additive factor} = 100\,\frac{4.2-3.6}{3.0} = 100\,\frac{0.6}{3.0}$$

$$= 20 \text{ percent}$$

b. The ***value*** of cathode-load resistor fo, the video mixer is changed to 150 ohms. Again, assume two positive input signals of 4.8 and 4.1 volts amplitude and corresponding output signals of 2.0 and 1.8 volts amplitude. When the input signals are in coincidence, the measured output-signal amplitude is 2.8 volts. Using the formula given above to determine the additive factor:

Given:

$$E_R = 2.8$$
$$E_H = 2.0$$
$$E_L = 1.8$$

Therefore:

$$\text{Additive factor} = 100\,\frac{2.8-2.0}{1.8} = 100\,\frac{0.8}{1.8}$$

$$= 44 \text{ percent}$$

In the two preceding examples, when the cathode-load resistor is decreased in value, the gain is also decreased; however, as the gain is decreased the additive factor increases. Conversely, as the cathode-load resistor is increased in vahre, the gain approaches unity; however, as the gain is increased, the additive factor decreases.

The following waveforms illustrate the signal-combining characteristics of a typical basic common-cathode video mixer for four different signal-input conditions. In part A of the illustration, a 4-volt positive input pulse is applied to one input only, and the resulting output is a 3-volt signal. In part B, a 4-volt input pulse is applied to each input, and the resulting output is a 3.6-volt signal. This output signal results from the additive mixing effect when the two input signals of equal amplitude and pulse width combine to produce an output pulse which is greater than the 3-volt output signal of part A (resulting from only one input signal) but which is less than either input signal. In part C, two equal-amplitude input signals of unequal puke width are applied to the video mixer circuit. This waveform group illustrates the effect of duty cycle on the mixing action. In this case, the additive mixing effect is readily apparent, since the combined signals produce a stepped output waveform which is 3.6 volts at maximum amplitude for the duration of the short pulse, and 3.0 volts amplitude for the remainder of the long pulse. For all practical purposes, upon termination of the short pulse, the output can be assumed to be the result of a single input signal. In part D, two equal-amplitude input signals which are not time-coincident combine to produce a series of 3-volt output pulses. This condition is representative of time-delayed or random pulses (neither input signal in coincidence) and, therefore, each signal produces an output voltage similar to that obtained in part A with one input signal.

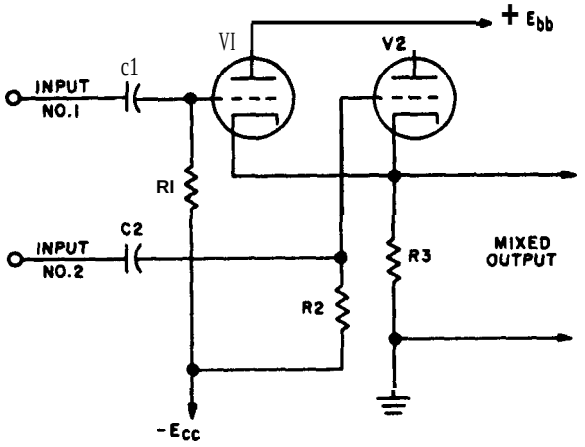
Modified Common-Cathode Video Mixer, Nonadditive Circuit

In some radar applications, especially where the output pulse information is displayed on a cathode-ray tube indicator as video or range marks, it is desirable to provide some form of limiting for time-coincident pulses so that the output voltage will be the result of the largest signal only. The process of combining two signals so that only the larger of the two signais is present in the output is called *non-additive* mixing.



Theoretical Signal-Combining Characteristics of Basic Common-Cathode Video Mixer

Modification to the basic common-cathode video mixer to achieve nonadditive mixing consists of biasing the tubes, VI and V2, approximately to plate-current cutoff. This is accomplished by returning grid resistors R1 and R2 to a source of negative voltage, as illustrated in the accompanying circuit schematic. Then, if the common cathode-load resistance, R3, is made relatively large so that the voltage gain of each cathode-follower stage approaches unity, a signal applied to one grid in excess of the value of fixed bias will produce in the common cathode circuit sufficient cathode bias to prevent the other tube from conducting. For example, assume that the fixed negative bias has been adjusted to provide a quiescent condition at or near plate-current cutoff for both tubes. If a positive video pulse of approximately 10 volts is applied to the grid of V1, the resulting signal appearing across cathode-load resistor R3 will produce approximately 8.5 volts output, which is applied as additional (cathode) bias to the grid of V2. Thus, a signal of less than 10 volts amplitude at the input of V2 cannot overcome the total effective instantaneous grid bias, and the signal does not appear in the output developed across cathode-load resistor R3. As can be seen from this example, the largest input signal at any instant of time effectively takes over the circuit and masks input signals of lesser amplitude. This is true provided that the time-coincident signals have the same pulse width (duty cycle); however, if the signals are of different pulse widths and of sufficient amplitude to overcome the fixed bias, the signal with the longest pulse width will always appear in the output.

Failure Analysis.

No Output The common-cathode video mixer circuit is similar in many respects to a cathode-follower circuit insofar as failures are concerned. Failure of the plate voltage supply will disrupt operation of the circuit, as will an open circuit in the cathode. The filament and plate voltages should be measured, as well as the dc voltage developed across the cathode-load resistance, to determine whether the applied voltages are within tolerance and whether the cathode resistor, R3, is open. Each input should be checked with an oscilloscope to determine whether signals are applied to the circuit and whether they are of the proper amplitude. Lack of signals at the grid of VI or V2 can be due to an open coupling capacitor (Cl or C2) or to failure of the external input-signal source. The output circuit should be checked to determine whether the load impedance has decreased or whether the output is shorted. Such a condition would effectively place the cathode at ground potential, resulting in very low or no output; for example, a low value of terminating resistance or a shorted coaxial cable could cause this effect. Also, if the output is taken through an output coupling capacitor, an open in the capacitor would prevent signals from reaching the stage following the mixer.

No **Mixed or Combined Output** Assuming that applied voltages are within tolerance and the tube is

known to be good, each input signal should be checked with an oscilloscope to determine whether both signals are of correct amplitude and are present at the respective grid of VI and V2. Lack of a signal at the grid of VI or V2 can be due to an open coupling capacitor (Cl or C2) or failure of the external input-signal source. If the circuit uses fixed grid bias to place each tube at or near plate-current cutoff, the applied bias should be measured at each grid to determine whether the bias voltage is excessive, thus preventing signals from combining in the cathode circuit.

Low or Distorted Output. If capacitor Cl or C2 is leaky or shorted, any value of dc voltage present at the input from the previous stage will be applied to the grid of V1 or V2. If the grid is made positive as a result, the tube will conduct additional plate current and cause the cathode voltage to be higher than normal. Thus, positive pulses on the grid will be severly limited in the cathode circuit. Where fixed bias is applied to the grid of V1 and V2, a leaky or shorted coupling capacitor C 1 or C2 will cause voltage-divider action to change the value of bias at the grid. This will cause the tube to shift its operating point on the $E_g - 1_p$ characteristic curve. Depending upon the previous stage and the input circuit configuration, the bias may be shifted to place the tube in either the cutoff or saturated region.

If the cathode-load resistor (R3) is paralleled with a terminating or impedance-matching resistor, a decrease in the value of either resistance will affect the output voltage. Also, if the output is taken through an output coupling capacitor, a shorted capacitor will affect the output voltage, since the impedance in the cathode circuit will be decreased and a dc path will be provided in parallel with the cathode-load resistance.

COMMON-PLATE VIDEO MIXER

Application.

The common-plate video mixer circuit is used to combine two (or more) input video or pulse signals. The mixer circuit normally has some gain. When two positive input signals are in time-coincidence, the circuit performs algebraic addition to produce a combined output signal which is of greater amplitude than the output produced by either input signal alone.

Characteristics.

Produces inverted signal in output; input signals of positive polarity produce output signals of negative polarity. The circuit is capable of combining small negative input signals to produce positive output signals.

Gain of normal video mixer (as designed) is slightly greater than unity for single input signal; gain is always greater than unity for time-coincident input signals.

When more than two input signals are to be combined, additional common-plate video-mixer circuits may be connected in parallel with little change in operating characteristics.

Output impedance is approximately equal to the value of plate-load resistance at low and medium frequencies, but decreases at high frequencies unless compensation is used.

High-frequency compensation, if required, is accomplished by the addition of a series plate-load inductance or a cathode bypass capacitor of relatively small value.

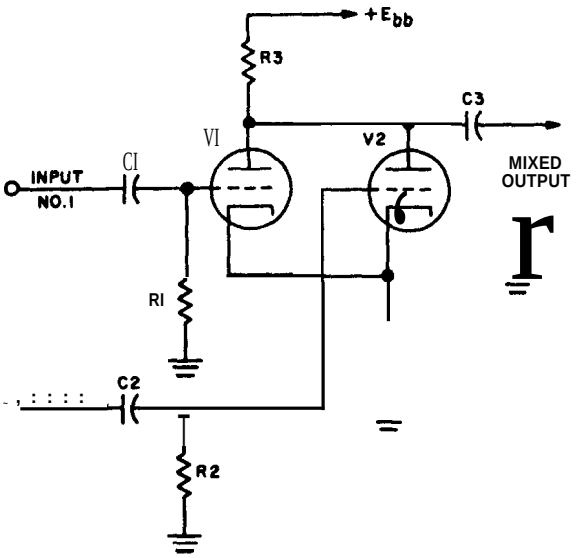
Circuit Analysis.

General. The basic common-plate video mixer combines two positive input signals. The circuit is fundamentally two video amplifiers in parallel with a common plate-load resistance. The output polarity is negative, and the combined signal is taken from the plate circuit.

The common-plate video mixer has good adding characteristics for signals in time-coincidence. For this reason, when the input signals are time-coincident, the circuit may not be satisfactory for certain radar applications unless modifications are made to reduce the adding effect and prevent overloading of subsequent video amplifier stages. In some applications the video mixer circuit is followed by a limiter or cathode follower, or each input is preceded by a limiter. The circuit described here purposely has a very low plate-load resistance and an unbypassed cathode resistance, to keep the gain as low as possible. Also, the use of a low value of plate-load resistance makes frequency compensation unnecessary.

Circuit Operation. The accompanying circuit schematic illustrates two triode electron tubes in a common-plate video mixer circuit. Electron tubes V1 and V2 are identical-type triode tubes; although the

accompanying schematic illustrates two separate triodes, a twin-triode is commonly used in this circuit. Capacitor Cl couples one input signal to the grid of V1; capacitor C2 couples the other input signal to the grid of V2. Resistors RI and R2 are the grid resistors for V1 and V2, respectively. Resistor R3 is the common plate-load resistor for VI and V2 and is generally a low-value resistance. Capacitor C3 is the output-coupling capacitor. Resistor R4 is the common cathode-bias resistor. The circuit utilizes a low value of plate-load resistance to achieve an extremely short rise time; no high-frequency compensation @ate-load inductance or cathode bypass) is used. The unbypassed cathode resistor makes the circuit degenerative, and also keeps the stage gain stabilized throughout the life of the tube to compensate for tube aging. The tolerance of component values in this circuit is not critical; 10-percent-tolerance parts are normally used.



Basic Common-Plate Video Mixer Circuit

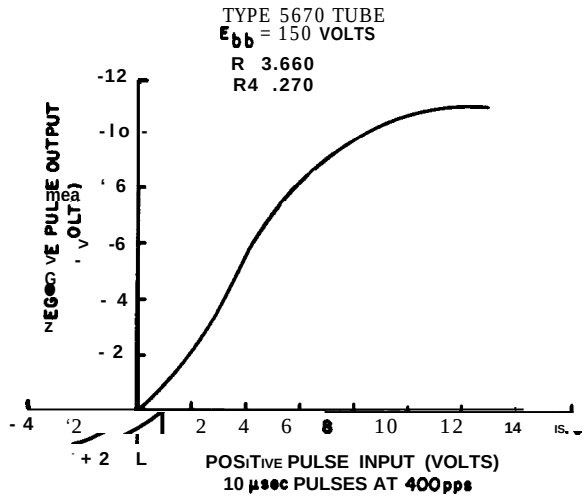
When voltage is first applied to the circuit, the grids (of V1 and V2) are at zero bias, and the combined plate current of both tubes passes through common-cathode resistor R4 to quickly establish the no-signal, or quiescent, bias. The electron tubes, VI and V2, are assumed to be identical-type tubes, or a single-envelope twin-triode with identical characteristics; however, a small unbalance in tube characteristics will not greatly affect the circuit operation.

The operation of each tube in the common-plate video mixer circuit is similar to the operation of the triode video amplifier, described in the Amplifier Section of this Handbook, when the input signals are *not* in time-coincidence. For example, assume a condition where a positive pulse is applied to the input of V1 but no signal is applied to the input of V2. In this instance, as the input signal to VI increases in a positive direction, the plate current of V1 increases, causing an increased voltage drop across plate-load resistor R3; therefore, the voltage at the plate of VI falls. As the input signal to V1 falls, the plate current decreases to its former value, causing a decrease in the voltage drop across plate-load resistor R3, and the plate voltage at V1 returns to its former value. Thus, a positive-going pulse applied to the grid has produced a negative-going pulse at the plate, resulting in signal inversion. However, since the cathode resistor, R4, is not bypassed, degeneration is introduced in the circuit, and the signal developed across cathode resistor R4 resulting from the change in VI plate current is in phase with the input signal; therefore, the amplitude of the instantaneous grid-to-cathode signal voltage of VI is reduced. The stage gain is also reduced, and, as a result, the amplitude of the negative signal developed in the plate circuit is effectively limited. The plate-load resistor, R3, is purposely a low value of resistance, and because of degeneration in the cathode circuit (resistor R4 is not bypassed) the gain of the stage is practically reduced to unity for a single input signal.

Note that as the plate current of VI increases with signal, the voltage developed across cathode resistor R4 also increases, and that this instantaneous voltage, in turn, changes the no-signal bias for the grid of V2. Thus, the instantaneous voltage increase, developed across cathode resistor R4 by the signal applied to Vl, appears as additional bias to the grid of V2 and effectively decreases the plate current of V2 through the common plate-load resistor, R3, and the common cathode resistor, R4. The net result is a limiting of the maximum instantaneous signal current through R3 and R4 because of the cathode-follower action of VI and the degenerative action of V2. Thus, the negative output-signal amplitude at the plate for one input signal is only slightly greater than the original input-signal amplitude.

The operation of the common-plate video mixer when two positive input signals are in time-coincidence produces addition of the signals, to give a combined negative out-put signal which is always greater than either of the two coincident input signals and greater than the output signal that results when only one input signal is present. The common cathode resistor, R4, is purposely left unbypassed to obtain degeneration and "cross-biasing" of the tubes; therefore, the amplitude addition of time-coincident signals is somewhat limited.

The accompanying graph illustrates the gain characteristic of a common-plate video mixer for one input signal In practice, the circuit is normally sup plied positive input pulses, Since the gain characteristic is nonlinear, a small positive input pulse will produce a negative output pulse which is only slightly greater than the input (gain approximately unity); whereas input pukes from approximately 3 to 9 volts result in a gain greater than unity, and input pulse greater than 9 volts result in a gain less than unity. Note that if small negative pulses are applied to an input, a small positive output pulse. will be obtained.



Gain Characteristic of Common-Plate Mixer

Two additional tubes can be paralleled with the mixer circuit, if desired, to provide four inputs. If the values of the plate and cathode resistors (R3 and R4) are not changed, the gain of each stage will be reduced to half the gain obtained for two tubes; however, if cathode resistor R4 is reduced accordingly to keep the bias approximately the same as for two tubes, the gain of each of the four tubes will be slightly greater than unit y.

An indication of the amount of addition of two signals in time coincidence is given by the ***additive factor.*** The additive factor (in percent) is expressed as:

$$\text{Additive factor} = 100\,\frac{E_R - E_H}{E_L}$$

where:

E_R = resultant (combined) output voltage for inputs in coincidence
E_H = output voltage for highest input level
E_L = output voltage for lowest input level

The signal addition occurring at the plate as a result of combining two time-coincident input sigmls compared to the output obtained for a single input can be seen from the measured results obtained from a typical common-plate video mixer. The mixer in this example used a plate-load resistor (R3) of 680 ohms, a cathode resistor (R4) of 270 ohms, and a supply voltage (E_{bb}) of 150 volts. Two equal positive input signals of 3.5 volts amplitude produced equal corresponding negative output signals of 4.0 volts amplitude. When the two input signals were applied to the mixer input circuit in time-coincidence, the measured output-sigml amplitude at the plate was 6.2 volts. Using the formula given above to determine the additive factor:

Given:

$E_R = 6.2$
$E_H = E_L = 4.0$

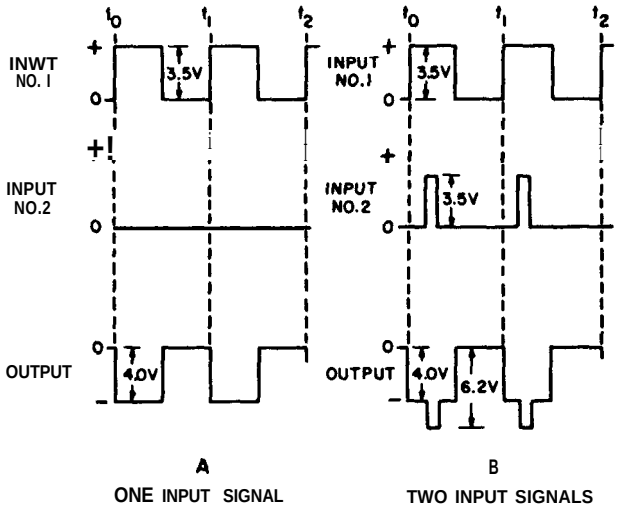
Therefore: Additive factor =

$$100\frac{6.2 - 4.0}{4.0} = 100\frac{2.2}{4.0} = 55 \text{ percent}$$

From the example it is seen that the common-plate video mixer combines time-coincident input signals in an additive manner.

491-044 0 73 63

The following waveforms illustrate the signal-combing characteristics of a typical basic commonplace video mixer for two different signal-input conditions. In part A of the illustration, a 3.5-volt positive input pulse is applied to one input only, and the resulting negative output is a 4-volt signal. In part B, a 3.5-volt input pulse is applied to each input; the pulses are of equal amplitude but are of unequal pulse width (duty cycle). The resulting combined output signal is a negative pulse which is 6.2 volts maximum amplitude when the two signals are time-coincident. Note that the longer input pulse produces a 4-volt output signal and that, when the short input pulse is applied to the circuit, the combined output signal is increased to 6.2 volts for the duration of the short pulse.



Thaoretieel Signal-Combining Charaetaristics of Basic Common-Plate Video Mixar

This type of mixer cannot prevent overloading of subsequent video amplifier stages by time-coincident input sigmls; therefore, the mixer is usually followed by a limiter stage to limit the output signal applied to the video amplifier chain. The limiting level is determined by the highest output-sigml amplitude resulting from one input signal; any additional output-signal amplitude resulting from two input signals in time-coincidence will result in clipping at the limiter stage.

Failure Analysis.

No Output. The common-plate video mixer circuit is similar in many respects to a video-amplifier circuit insofar as failures are concerned. Failure of the plate-voltage supply will disrupt operation of the circuit, as will an open circuit in the cathode. With a tube known to be good installed in the circuit, the filament and plate voltages should be measured, as well as the dc voltage developed across the cathode resistance, to determine whether the applied voltages are within tolerance and whether the plate-load resistor (R3) or cathode resistor (R4) is open. Each input should be checked with an oscilloscope to determine whether signals are applied to the circuit and whether they are of the proper amplitude. Lack of signals at the grid of VI or V2 can be due to an open coupling capacitor (Cl or C2) or to failure of the external input-signal source. An open output coupling capacitor (C3) will prevent signals from reaching the stage following the mixer; a leaky or shorted output coupling capacitor will form a voltage divider with the input resistor of the following stage. Thus if the input resistor of the following stage is returned to ground or to a negative supply, the voltage at the plates of VI and V2 will be reduced, and the operation of the following stage will be upset by the change in voltage applied to the grid.

No **mixad or Combined Output.** Assuming that the applied voltages are within tolerance and the tube is known to be good, each input sigml should be checked with an oscilloscope to determine whether it is of correct amplitude and is present at the respective grid of VI and V2. Lack of a sigml at the grid of V1 or v2 can be due to an open coupling capacitor (C1 or C2), an open grid resistor (RI or R2), or failure of the external input-sigml source.

Low or Distortad Output. If one input coupling capacitor (Cl or C2) is leaky or shorted, any value of dc voltage present at the input from the previous stage will be applied to the grid (V1 or V2) by voltage-divider action of the capacitor and grid resistor (R1 or R2). If the grid is made positive, the tube will conduct additional plate current and cause the cathode voltage developed across R4 to be higher than normal. Thus, the bias of one tube is shifted because of a change in voltage at the grid, and the bias of the other tube is changed as a result of a change in cathode voltage. Since the input pulses are positive, it is possible that plate-current saturation

will occur for the fust tube and that the second tube will provide an output pulse of reduced amplitude when tirnecoincident signals are applied to the circuit. The output, therefore, will be low or distorted and will not be representative of a normal mixed or combined output.

PART 11-2. HETERODYNING CIRCUITS

MIXERS

General.

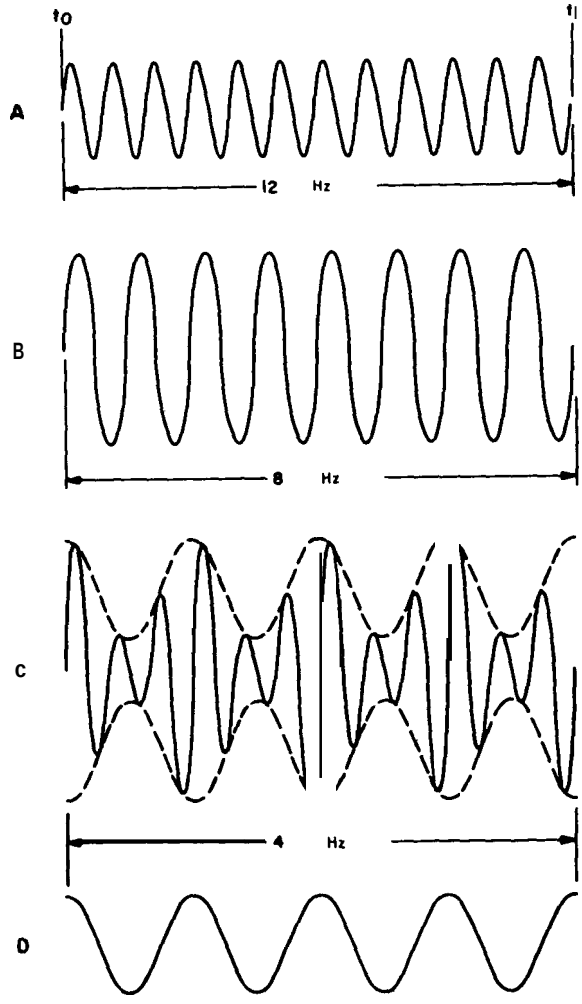
The frequency-mnversion function in a superheterodyne receiver is accomplished either by a mixer circuit with a separate local oscillator or by a pentagrid converter circuit (described later in this section).

The term ***mixer*** used in this section should be confused with the term ***audio mixer,*** which designates the linear circuit used to combine audio signals. The term ***mixer,*** as used in this section, designates a nonlinear circuit that heterodynes radio-frequency and local-oscillator signals in a superheterodyne receiver to produce an intermediate-frequency signal.

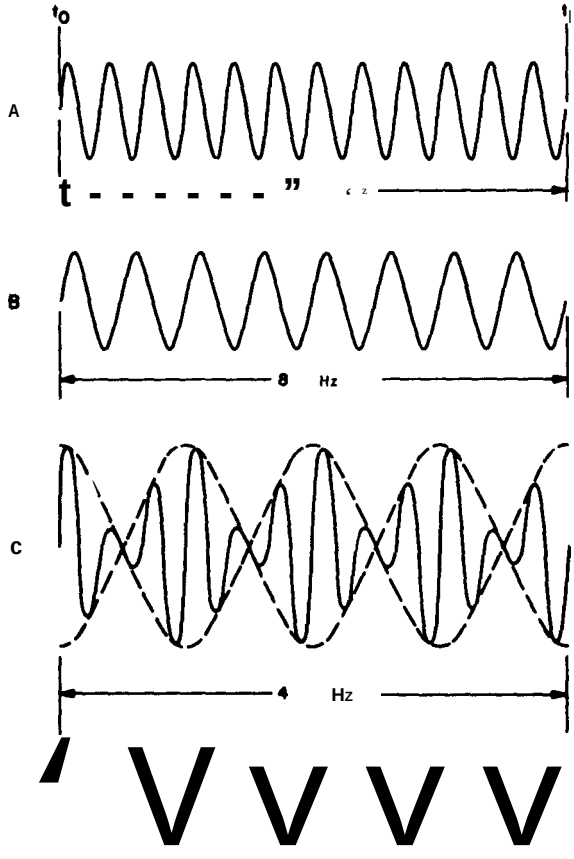
In receiver design practice, it is desirable to convert the receiver r-f signal to an intermediate frequency before further amplification takes place. The principle of frequency conversion and subsequent amplification at an intermediate frequency results in excellent selectivity and over-all gain characteristics for the receiver. The frequency conversion is obtained by the ***heterodyne*** process, which is the combining of an incoming radio-frequency signal with a locally generated sigml in a nonlinear device, to produce frequencies equal to the sum and difference of the two combining frequencies. The mixer stage sometimes referred to as the ***first detector in*** the superheterodyne receiver, performs only the frequency conversion function, and must be supplied a heterodyning r-f voltage generated by a separate local-oscillator circuit. The output frequencies of the mixer stage, in addition to the frequencies of the input voltages, are primarily the sum and difference of the signal-input frequency and an integral multiple of the local-oscillator frequency. The output circuit of the mixer stage is tuned to select only one frequency, which is usually a beat frequency equal to the difference between the signal-input frequency and the local-oscillator frequency. This difference, or beat, frequency is known as the ***intermediate frequency.***

At this time a brief discussion of the heterodyne principle is helpful in order to better understand the production of beats in a superheterodyne receiver. The accompanying illustration shows graphically how a beat (intermediate) frequency is produced when two different signal frequencies of ***unequal*** amplitude are combined. If the two waveforms, parts A and B, are superimposed, the waveform given in part C results; this waveform shows amplitude fluctuations with respect to the time axis. At each instant, the two signal frequencies (A and B) combine to produce a resultant amplitude which is equal in value to the algebraic sum (A + B) of the individual sigml values. The amplitude variations, represented in part C as the dotted lines forming an envelope for the resultant, are called ***beats,,*** and vary in amplitude at a frequency that is equal to the difference between the frequencies of the two signals being combined. Thus, from a study of the combined waveform given in part C, it can be seen that during the time interval between t. and t_1 the number of beats per second is equal to the ***difference*** between the two frequencies given in parts A and B.

For simplicity, frequencies of 12 and 8 Hz are given in parts A and B, respectively. The evelope of the resulting waveform in part C is shown as 4 cycles per second. The output signal which results after the combined signals are acted upon by a nonlinear device in the mixer stage is shown in part D as the intermediate (beat) frequency. Although the frequencies (12, 8, and 4 Hz) used in the following illustration are extremely low, the heterodyne principle would be the same for other corresponding frequencies, such as 1200, 800, and 400 kHz, or 12, 8, and 4 MHz. Thus part A can be thought of as the received r-f signal, part B as the local-oscillator signal, and part D as the intermediate-frequency (beat-frequency) output of the mixer stage after demodulation.



Heterodyning of Two Signals of Unequal Amplitude



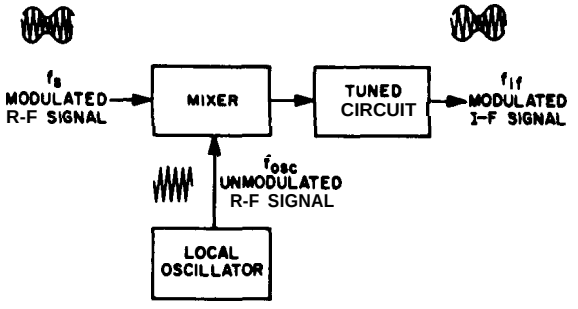
Heterodyning of Two Signals of Equal Amplitude With Resulting Distortion

To produce an output which has very little distortion, the amplitude of the locally generated signal must be larger (usually at least ten times larger) than that of the received r-f signal. This principle is shown by the previous illustration representing the heterodyning of two signals of ***unequal*** amplitude. The following illustration shows the heterodyning of two signals of ***equal*** amplitude, and the distortion which results. Note that the envelope of the waveform shown in part C drops to zero, and that there is resulting distortion in the demodulated waveform shown in part D.

If one of the two frequencies (A or B) being heterodyned is modulated, the same action as previously described will occur, except that the resultant waveform shown in part D will vary in amplitude according to the modulation component of the original input frequency (A or B).

The accompanying block diagram illustrates the heterodyne principle of a frequency converter consisting of a mixer and local oscillator. Two voltages of different frequency are each fed to the input of the mixer; one voltage is the r-f signal voltage, and the other is the voltage generated by the local oscillator. These two voltages beat, or heterodyne, within the mixer to produce an output having, in addition to the frequencies of the two input voltages, many sum-and-difference frequencies. The output of the mixer

includes a tuned circuit to select the desired beat frequency. The beat frequency is generally chosen to be a frequency which is the difference between the two mixer-input frequencies.



Block Diagram of Mixer and Looal Oscillator

In the block diagram, a modulated r-f sigml is applied to the mixer stage; an unmodulated r-f signal of constant amplitude from the local-oscillator circuit is aJso applied to the mixer stage. The heterodyning, or mixing, of these two signals produces, in the mixer output, an intermediate-frequency sigml which contains all of the modulation characteristics of the origiml modulated r-f signal. The undesired sum-and-difference frequencies and the two mixer-input frequencies (r-f and oscillator signals) are rejected by the tuned circuit in the output of the mixer; only the desired intermediate (difference or beat) frequency is permitted to pass through the tuned circuit. This intermediate-frequency sigml is then amplified and detected in succeeding stages of the receiver.

The local-oscillator frequency differs from the frequency of the received r-f signal by an amount equal to the intermediate frequency; therefore, the local-oscillator frequency can be either ***above*** or ***below*** the received r-f sigml and, in either case, produce the desired intermediate frequency. Depending upon the design requirements of the receiver and the frequencies involved, the local oscillator is tuned to a frequency either higher or lower than the r-f signal frequency. When the local-oscillator frequency is ***below*** the received r-f signal, the following formula applies:

$$f_{if} = f_s - f_{osc}$$

where:

f_{if} = intermediate frequency
f_s = received r-f signal frequency
f_{osc} = local-oscillator frequency

When the local-oscillator frequence is ***above*** the received r-f signal, the following formula applies:

$$f_{if} = f_{osc} - f_s$$

The mixer circuit includes a nonlinear element, consisting of either an electron-tube or semiconductor device; if an electron tube is used, the nonlinear element can be a simple rectifier (diode), a triode, or a multigrid tube. When a triode, tetrode, or pentode electron tube is used as the nonlinear circuit element, the tube is biased at or near cutoff, or otherwise operated on a nonlinear portion of its characteristic curve. Triode and multigrid electron tubes used as the mixer in superheterodyne receivers generally produce some signal amplification (conversion gain), in addition to the desired frequency conversion. A discussion of similar nonlinear elements is given in the Detector (Demodulator) Circuits Section of this Handbook.

Mixer-local oscillator combination circuits can provide reasonable frequency stability in superheterodyne receivers up to approximately 500 MHz. The mixer circuits described in this section are representative of typical electron.tube mixers found in many communication-electronic equipments.

DIODE MIXER (ELECTRON TUBE)

Application.

The diode mixer is used in superheterodyne receiver circuits to combine, or "mix", the r-f sigml from a local oscillator with the incoming r-f signal, in order to produce the desired i-f (intermediate-frequency) output signal. The electron-tube diode

mixer is generally used in applications where signal-to-noise ratio is an important consideration or where the transit time at very high frequencies becomes critical for other types of electron-tube mixers.

Characteristics.

Requires a separate local-oscillator circuit to supply the heterodyning voltage.

Utilizes the principle of rectification by a non-linear device.

Output circuit is tuned to the difference frequency, or intermediate frequency.

Conversion gain is less than unity.

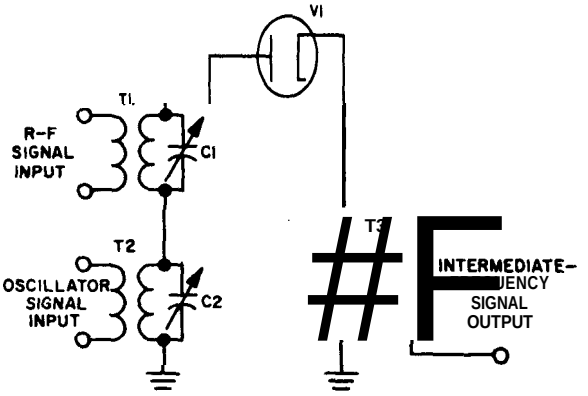
Signal-to-noise ratio is good.

Circuit Analysis.

General. The diode mixer is one of the simplest types of mixer circuits employed as a frequency converter. In this application, voltages of the two input frequencies to be heterodyned are applied in series to the diode, and the mixer-output voltage is obtained from a tuned transformer or impedance-coupling arrangement. The output circuit is tuned to the difference frequency (intermediate frequency) so that it will pass this frequency on to the succeeding intermediate-frequency amplifier stages but will attenuate (reject) all other frequencies.

The electron-tube diode used as a mixer is subject to transit-time effects; therefore, its use as a mixer at very high frequencies is somewhat limited. When transit-time effects are important, the crystal diode is frequently used as a mixer in preference to the electron-tube diode.

Circuit Operation. A simple diode mixer circuit is illustrated in the following circuit schematic. Transformer T1 consists of an untuned primary winding and a tuned secondary winding; capacitor Cl and the secondary winding of T1 form a resonant circuit at the frequency of the r-f sigml to be received. Transformer T2 is similar to TI, except that capacitor C2 and the secondary winding T2 form a resonant circuit at the frequency of the local-oscillator signal. The resomnt circuits, shown in the schematic as Tl, Cl and T2, C2, are actual L-C circuits composed of inductors and capacitors at alI radio frequencies up to the ultra high frequencies. At the ultra high frequencies and above, the tuned circuits may be in the form of tuned lines or resonant cavities.



Diode Mixer Circuit

Electron tube V1 is a cathode-type diode; the filament (heater) circuit is not shown on the schematic.

Transformer T3 is a double-tuned transformer, with the primary and secondary circuits resonant to the output (intermediate) frequency. This transformer exhibits a bandpass characteristic and thereby discriminates against frequencies above and below the desired output frequency.

When no r-f signal is applied to the input of transformer Tl, but the local-oscillator signal is applied to the input (primary) of transformer T2, diode V1 acts only as a rectifier. For this input condition, the current pulsations passing through the primary winding of the double-tuned transformer, T3, are those of the local-oscillator frequency; however, the tuning of transformer T3 does not permit the local-oscillator frequency to reach the output because of the bandpass characteristic of the transformer.

When the r-f sigml and the local-oscillator signal are simultaneously applied to their respective tuned circuits (T1 and T2), the two signal voltages are ap plied in series to the mixer diode, V1.

Since the two applied signals differ in frequency, the voltages are not always in phase with each other. Periodically these two voltages algebraically add or subtract to produce an amplitude variation at regular intervals; it is this periodic amplitude variation in the form of a beat-frequency voltage which is of greatest importance. The beat frequency is actually the difference frequency produced by the instantaneous

signal voltages as they combine to increase amplitude when approaching an in-phase relationship and to decrease amplitude when approaching an out-of-phase relationship.

Because the two sine-wave frequencies are superimposed, the mixer diode rectifies, or detects, both frequencies. As a result, pulsating currents which vary in amplitude at the beat-frequency rate are produced in the primary of transformer T3. Thus, a carrier envelope is formed which varies in accordance with the difference frequency. The pulsating currents forming the carrier envelope flow through the primary winding of transformer T3. Since the primary circuit is tuned, it presents a high impedance to the difference (intermediate) frequency. Consequently, this frequency is passed by transformer T3, and a voltage is induced in the secondary winding which varies is amplitude in accordance with the amplitude of the origiml r-f sigml.

If the received r-f sigml contains amplitude-modulation components, the beat difference will also contain amplitude-modulation components, which vary in accordance with the audio frequencies modulating the original r-f signal. If the received r-f sigml is frequency-modulated, the beat difference will deviate at the same rates as the original r-f sigml. Thus, it is seen that the characteristics of the intermediate-frequency sigml are the same as those of the original received signal, except that the frequency of the received signal has been "converted" to a lower frequency.

The output signal voltage developed across the secondary tuned circuit of transformer T3 is applied to succeeding intermediate-frequency amplifier stages and is subsequently detected, or demodulated.

Failure Analysis.

General. Since the circuit of the diode mixer is relatively simple, failure of the circuit to operate can be resolved to one of several possibilities. The diode, VI, should be checked to determine whether it is in satisfacary condition and whether the correct filament (heater) voltage is applied to the tube.

The presence of an r-f signal (or a test signal) and the local-oscillator signal must be determined, since no output can be obtained from the mixer circuit unless both sigmls are applied to the mixer input. Resonant circuits T1, C1 and T2, C2 must be properly aligned, each to its specified frequency. The double-tuned output transformer, T3, must also be correctly tuned to the desired intermediate frequency. Since one or more open windings in the tuned circuits (TI, T2, and T3) can cause a lack of output, these windings should be checked with an ohmmeter to determine whether continuity exists.

DIODE MIXER (SEMICONDUCTOR)

Application.

The semiconductor diode mixer is used in transistorized superheterodyne receivers in heterodyne frequency converter circuit arrangements to provide the intermediate frequency; and in electron tube high-frequency receivers to provide a low-noise r-f to i-f mixer. Special purpose applications include test equipment, microwave repeaters, and single-sideband transmitters, in which mixers are used for frequency conversion.

Characteristics

Requires a separate source of heterodyning voltage (local oscillator).

Uses nonlinear transfer characteristic of a diode to provide mixing action.

Conversion gain is less than one, and efficiency is high.

Signal-to-noise ratio is high (better than that of an electron tube).

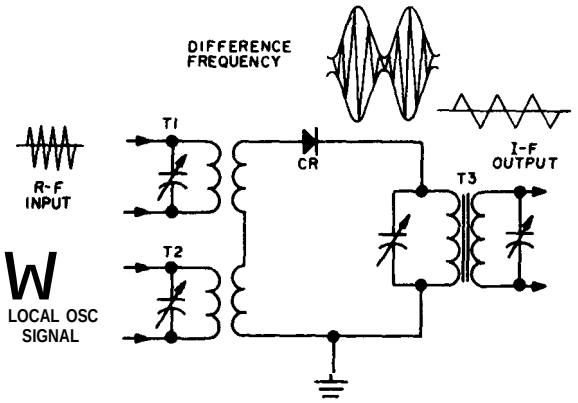
Heterodyne-signal (local oscillator) amplitude must be larger than received-signal amplitude for minimum distortion and best efficiency.

Circuit Analysis.

General. The semiconductor diode mixer is one of the simplest types of mixer circuits employed in frequency conversion. In this application, the two signal voltages to be heterodyned are supplied in series to the diode, and the mixer output voltage is obtained from a tuned-transformer arrangement. The output circuit is tuned to the intermediate frequency, which is usually the difference frequency between the two signals. Thus all other unwanted frequencies are rejected, and the i-f signal (which also contains the modulation components of the input signal) is sup plied to the i-f amplifier for further amplification. The preceding discussion concerns the use of the mixer in receivers where the input signal is converted

to a lower frequency. In very low frequency receivers, or in a sideband generator where the signal in generated at a low frequency and heterodyned to a higher frequency, the opposite condition exists, and the sum frequency is the output frequency. In each case, the circuit actions are the same, but the frequencies of interest are different.

Circuit Operation. The accompanying circuit schematic shows a simple diode type mixer.



Diode Mixer

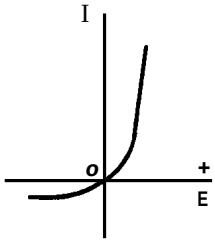
In **this** circuit, T1 is tuned to the high frequency input sigml, and T2 is tuned to the lower-frequency local-oscillator signal. The secondaries of T1 and T2 are connected in series, and the r-f input is superimposed on the local oscillator signal. The combined sigmls are effectively rectified by crystal diode CR, producing a difference frequency current in the primary of output transformer T3, comected in series between the cathode of the crystal and ground. Since T3 is tuned to the desired intermediate frequency, it offers a high impedance at that frequency, and thus serves as the load across which the output voltage is developed. The secondary of T3 is also tuned to the i-f signal, and together with the tuned primary, it provides a highly selective circuit with bandpass characteristics.

When the signal voltages in the secondary of T1 and T2 are in phase, they add and the voltage applied to the crystal is increased. When they are out of phase, the voltages subtract and the crystal input voltage is reduced. Since the two voltages are sinusoidal, the resultant sigml will also be sinusoidal, and vary similarly. Because the new signal is a composite signal, its maximum and minimum amplitudes will occur at different times from those of the other signals. Thus the frequency of the new signal will be different from the original frequencies. Any intelligence existing as modulation (either AM or FM) on these carriers will be transferred to the new signal. Since the local-oscillator signal is unmodulated, the new sigml will contain the modulation of the high-frequency received signal, together with an unwanted hum or noise components present on the local-oscillator signal.

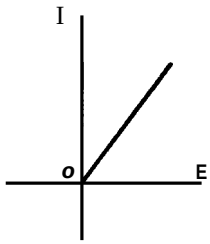
Since the crystal conducts only when its anode is positive with respect to the cathode, only the positive alterations are effective. Pulses of current are produced at the rate of the original sigmls plus the composite signal. This current flows through the primary of T3 and induces a voltage in the secondary of T3. Since both the primary and secondary of T3 are tuned, the greatest output voltage will occur at the frequency or over a range of frequencies for which the highest impedance is offered. Frequencies outside this band will be offered a low impedance, and little or no output voltage will be developed. Thus only the selected output frequency is obtained.

The basic principle of mixer operation is the use of the noniinear transfer characteristic of the crystal diode to produce signal voltages in the output which did not exist in the input signaL At the same time, all modulation components present on the original signal must be effectively transferred to the new signals. The desired output frequency is then selected by a tuned circuit and separated from all the other unwanted frequencies. The manner in which this is accomplished is shown in the accompanying illustrations.

First, let us examine the transfer characteristic of a crystal diode and compare it with a linear characteristic, as shown in the accompanying illustrations.

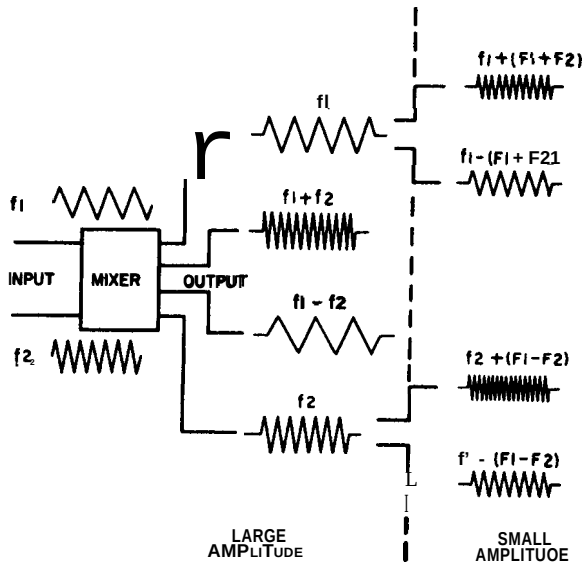


Crystal Diode Characteristic



Linear Characteristic

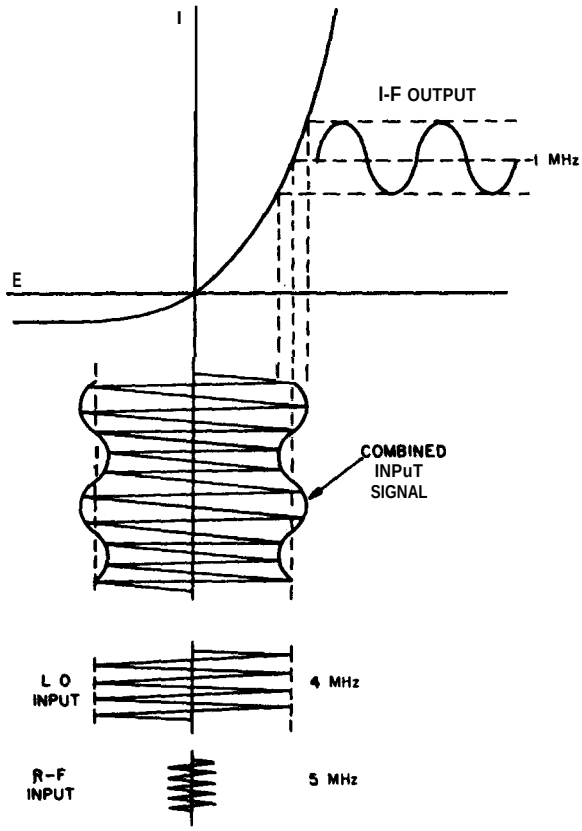
As the input voltage to the crystal varies the current also varies, but not equally for all increments of input voltage. On the other hand, the ideal linear curve will result in equal current increments for equal voltage increments. If the diode voltage-current characteristic were linear, the input voltage would produce a current which, when passed through a resistor or load impedance, would produce an output voltage identical to the input voltage. Therefore, if two different voltages were applied as inputs, exactly the same voltages would be obtained in the output (except for a slight loss due to the resistance in the crystal). Thus, frequency conversion could not occur if the diode transfer characteristic were linear. On the other hand, when an input voltage is applied to the nonlinear diode, a distorted output is obtained. The distortion consists of signals which differ in frequency from the original sigml. If two different signals are applied to the nonlinear diode, the output circuit contains distortion products for both sigmls. These extraneous signals are the sum and difference frequencies of the original sigmls, plus beats between the origiml signals and the distortion products (which are beat signals themselves), as illustrated in the following figure.



Mixer Output Wavaforms

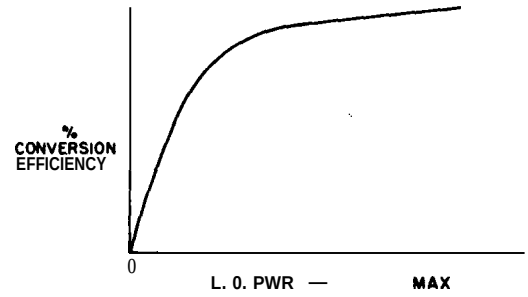
To produce the desired conversion with fidelity, one input (usually the input supplied by the local oscillator) must be larger than the other. This is easily accomplished by using the weak high-frequency input signal as the small signal, and the strong local-oscillator signal as the large signal. When the input voltage is large enough to appear at the point of greatest inflection on the diode characteristic curve, the best efficiency is obtained. The following figure illustrates the conversion transfer graphicrdly. In effect, the small input signal of 5 MHz modulates the large local-oscillator signal of 4 MHz and produces a l-MHz beat signal, which rides on the local-oscillator carrier somewhat like a ripple voltage. The output

circuit contains pulses for each positive cycle of the two input frequencies, plus the beat signal. Selection of the desired output frequency is obtained by using a tuned circuit as the load. The greatest output is developed, of course, at the beat frequency to which the load is tuned, and the other frequencies are effectively rejected.



Development of Beat Signal

The manner in which the conversion efficiency varies with local-oscillator signal amplitude is shown graphically in the following figure. As can be seen the best efficiency is obtained for the strongest local-oscillator signal that can be handled by the diode. Since the detector output increases very slowly after the maximum inflection point of the characteristic curve is reached, the efficiency changes very little beyond this point. Thus there is a limit beyond which not much change of efficiency occurs if the local-oscillator power is increased. Note, however, that for very small sigmls the efficiency is low. In addition to low conversion efficiency when the input signal is of the same amplitude as the local-oscillator sigml, extreme distortion is produced, because the beat signal varies from zero to a maximum of twice normal (in effect 100% modulation). In this case the circuit acts somewhat like a square-law detector. Little use is made of this circuit characteristic. Normally, the local-oscillator signal amplitude is fixed at about ten times the amplitude of the received signal.



Conversion Efficiency Variation

It is interesting to observe that the local-oscillator signal is always unmodulated; if both signals were modulated, the linear transfer of modulation would be annulled because of phase cancellation between modulation components. The normal transfer of modulation occurs linearly even through the beat is produced by deliberately distorting the r-f signal. This deviation from the normal rule of avoiding distortion is due to the large separation in frequency between the modulation (usually an audio-frequency signal) and the input and local-oscillator signals (which are always radio-frequency signals). The audio modulation varies at such a relatively slow rate that many r-f cycles can be lost without a noticeable change in fidelity; that is, any change in the amplitude of a single r-f cycle has little effect on the over-all operation.

Since the semiconductor diode will conduct in a reverse direction, it represents a lower-impedance load than the conventional electron tube diode, and it aIso has a lower forward resistance. Neither parameter, however, has any great effect on the operation of the diode as a mixer.

Failure Analysis.

No Output. If the local-oscillator signal or the r-f input is missing, no i-f output will be produced. Both signals must be present to obtain frequency conversion. An open circuit in the input transformer (Tl) or the local-oscillator transformer (T2)–either primary or secondary-will also render the circuit inoperative. A defective crystal may be checked by making forward- and reverse-resistance checks of the diode. The reverse resistance should be very much larger than the forward resistance. Since the proper functioning of transformer T3 is necessary to select the output signal, an open circuit in this transformer could also result in no output. Moreover, it is possible that mistuning of the input circuits could cause absence of one of the signals and produce a no-output indication. A resistance or continuity check of the transformers should be made to insure that the circuit is complete, and a test signal should be applied to the input to heterodyne with the local-oscillator signal while checks are made for an output signal in T3. It will be necessary to use a VTVM with an r-f probe to determine whether the i-f voltage is present. With a modulated input to the mixer, an oscilloscope with an r-f probe can be used to observe whether the modulation appears in the output.

Low **Output.** A low-output condition can occur if the local-oscillator signal is equal to or less than that of the input signal. Such a condition could be caused by mistuning of T1 or T2. Substituting a test signal in place of the local-oscillator signal will quickly determine whether the oscillator output is low (if the proper value is known, the oscillator voltage can be measured with a VTVM and r-f probe). A similar result could be produced by the local-oscillator being tuned off frequency as a result of improper padding or alinement.

Other Conditions. Defective shielding or lack of proper lead dress after repair may permit the local-oscillator signal to leak into the preceding stages of the receiver and reduce the receiver sensitivity by producing a high avc voltage. Or it may allow the local-oscillator signal to feed through the i-f and detector stages and cause birdies and unwanted signals. Such troubles will disappear when the local oscillator is temporarily disabled and a well shielded test-sigml source is substituted in its place.

MICROWAVE DIODE MIXER (SEMICONDUCTOR)

Application.

The microwave diode mixer is used in superheterodyne radar receivers to combine, or "mix", the incoming r-f microwave signal with the local oscillator signal to produce the desired intermediate frequency (i-f) output signal. The microwave diode mixer is generally used applications where signal-to-noise ratio is an important consideration or where transit time at very high frequencies becomes critical for other types of semiconductor mixers.

Characteristics,

I-f voltage is linearly dependent upon signal amplitude, for sigmls small compared with the local oscillator power.

Transit time effects are minimized.

Overall noise figure is as low as 7 dB at frequencies Up to 25,000 MHz.

Requires a separate local oscillator to supply the heterodyning voltage.

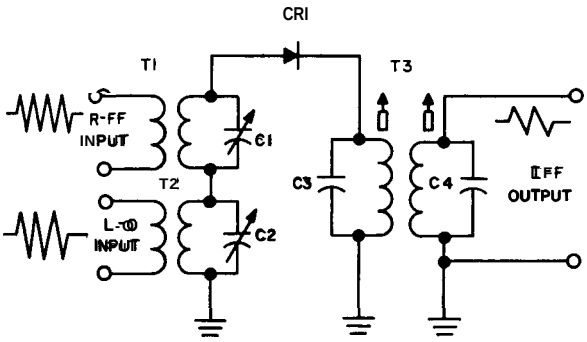
Output circuit is tuned to the i-f frequency.

Conversion gain is less than unity.

Circuit Analysis.

General. The crystal is the most effective element for the superheterodyne receiver at microwave frequencies. The operation of a crystal as a mixer is similar to that of the diode electron tube. Since a crystal is not an amplifier, there can be no conversion gain. The conversion loss is taken as the ratio of the available i-f sigml power to the available r-f signal power. It varies with the circuit impedance but is normally about 6 to 10 dB. Crystals are easily damaged, and voltages should not be applied which are greater than about 5 volts in the blocking (anode to cathode) direction or which result in more than about l-vdc in a resistive load. In application, the desired r-f input signal and the local oscillator signal are applied in series to the microwave diode, and the mixer output voltage is obtained from a transformer tuned to the desired i-f signal so that it will pass this frequency and reject all other frequencies.

Circuit Operation. A simplified microwave diode mixer circuit is shown in the accompanying illustration.



Microwave Diode Mixer Equivalent Circuit

Transformer TI consists of an untuned primary winding and a tuned secondary winding; Capacitor Cl and the secondary winding of T1 form a resomnt circuit at the frequency of the received r-f signal. Transformer T2 is similar to Tl, except that capacitor C2 and the secondary winding of T2 form a resonant circuit at the frequency of the local oscillator. This resonant circuits, shown in the schematic as Tl, Cl and T2, C2, are actual LC circuits composed of inductors and capacitors at radio frequencies.

Semiconductor CR1 is a point contact crystal diode used at microwave frequencies. Transformer T3 is a doubletuned transformer, with the primary and secon&ry circuits resonant to the intermediate frequency. This transformer has a bandpass characteristic which discriminates against frequencies above and below the desired output frequency.

When no r-f signal is applied to the input of transformer Tl, but the local oscillator signal is applied to the input (primary) of transformer T2, semiconductor CR1 acts only as a rectifier. For this input condition, the current pulsations passing through the primary winding of the double-tuned transformer, T3, are those of the local oscillator frequency; however, the tuning of transformer T3 does not permit the local oscillator frequency to reach the output because of the bandpass characteristic of the transformer.

When the r-f and local oscillator signals are applied simultaneously to their respective tuned circuits, the two signal voltages are applied in series to semiconductor mixer diode CR1.

Since the two applied signals differ in frequency, the voltages are not always in phase which each other. Periodically these two voltages algebraically add or subtact to produce an amplitude variation at regular intervals; it is this periodic amplitude variation in the form of a beat frequency voltage which is of greatest importance. The beat frequency is actually the difference frequency produced by the instantaneous signal voltages as they combine to increase amplitude when approaching an in-phase relationship and to decrease amplitude when approaching an out-of-phase relationship.

Because the two sine-wave frequencies are superimposed, the mixer CR I rectifies, or detects, both frequencies. As a result, pulsating currents which vary in amplitude at the beat frequency rate are produced in the primary winding of transformer T3. Thus a carrier envelope is formed which varies in accordance with the difference frequency. The pulsating currents forming the carrier envelope flow through the primary winding of transformer T3. Since the primary circuit is tuned, it presents a high impedance to the difference (i-f) frequency. Consequently, this frequency is passed by transformer T3, and the output voltage is induced in the secondary winding which varies in amplitude in accordance with the amplitude of the original r-f signal.

If the received r-f signal contains amplitude-modulation components, the beat difference will deviate at the same rates as the original r-f signal. Thus, the characteristics of the intermediate fre quency signal are the same as that of the original r-f signal, except that the received sigml has been changed to a lower frequency.

The output (i-f signal) voltage developed across the secondary tuned circuit of transformer T3 is applied to the succeeding stages where it is amplified and demodulated.

Failure Analysis.

General. When making voltage checks use a VTVM to avoid the low values of shunting resistance employed on the low range of conventional volt-ohmmeters. Be careful to observe the proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the diode junctions will cause a false low resistance reading.

No Output Since the circuit of the microwave diode mixer is relatively simple, failure of the circuit to provide an output can be resolved to one of several possibilities, The resonant circuits Tl, Cl and T2, C2 must be properly aligned to their respective frequencies. The double-tuned output transformer T3, must also be correctly aligned to the desired intermediate frequency. The presence of the desired r-f and local oscillator frequencies must be determined, since no output can be obtained from the mixer circuit unless both signals are applied to the mixer input circuits. One or more open windings in the transform"ers Tl, T2, or T3 can cause a no-output condition, so these windings should be checked with an ohmmeter to determine whether continuity exists. Capacitors Cl, C2, C3, and C4 can be checked with an in-circuit capacitor checker.

Low Output. If the tank circuits are not tuned to the proper frequencies, or if one of the capacitors should become leakly, a low output condition could occur. Check to see if the r-f, local oscillator, and i-f tank circuits are tuned properly, and check all capacitors for a leaky condition.

TRIODE MIXER (ELECTRON TUBE)

Application.

The triode mixer is used in receiver circuits to combine or "mix" the r-f signal from the local oscillator with the incoming r-f signal, to produce the desired intermediate frequency (I-F) output.

Characteristics.

Requires a separate local oscillator circuit to supply the heterodyning voltage.

I-F frequency remains the same for any selected input frequency.

Operates on the non-linear portion of the E_g-I_p curve.

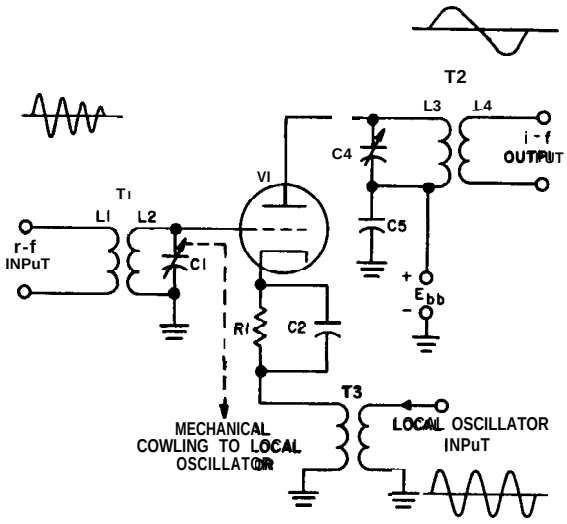
Has an amplification factor, which is referred to as conversion gain.

Circuit Analysis.

General. The purpose of the mixer stage is to convert the incoming r-f frequency, usually into a lower frequency, which contains the same characteristics (modulation) as the original r-f frequency. This lower output frequency, called the intermediate or i-f frequency, remains the same, regardless of the frequency of the r-f signal received.

By operating over the non-linear portion of the tube's characteristic E_g-I_p curve, harmonic distortion is produced in the plate circuit, and as a result of this harmonic distortion, new frequencies, which are harmonics of the input, are introduced. By proper selection of the local oscillator frequency, specific output frequencies can be obtained. This mixing of frequencies is called heterodyning, and the result at the plate is the presence of four basic frequencies: Namely, the sum and the difference of the two inputs, and the two original inputs (various other beats are also produced but are not often used particularly because of the small amplitude remaining as compared with the basic outputs). A resonant tank in the plate circuit is tuned to the selected difference frequency, so that it will pass only this frequency on to the succeeding i-f amplifier stages and thus effectively attenuate all of the other beat frequencies.

Circuit Operation. The accompanying circuit diagram illustrates a typical triode mixer.



Typical Triode Mixer

L2, the secondary of T1, together with Cl, forms a tank circuit tuned to the desired r-f frequency, and

this selected r-f signal is applied directly to the control grid of tube VI. The tube is biased class "C" by the use of C2 and R1, which form a cathode bias circuit, and it is for this reason that the tube operates on the non-linear portion of the E_g-I_p curve. The signal from the local oscillator is coupled through transformer T3 to the cathode circuit of the tube, and because the tube operates on the non-linear portion of the characteristic curve, the two input signals are mixed. The result at the plate is a signal containing the sum and difference of the two inputs, plus each of the two originally applied signals. The primary, L3, of T2, together with C4, forms a tank circuit tuned to the difference, or i-f frequency, and capacitor C5 bypassed the unwanted r-f frequencies to ground.

With no r-f signal applied, and with the signal from the local oscillator applied to the cathode circuit, tube VI conducts. The current through the cathode starts charging capacitor C2, but because of its long time constant, the cycle ends before the capacitor can charge to the peak value of the input. The charge is slow to leak off, however, because of the value of R1, and within a few cycles, the cathode circuit stabilizes at a voltage which determines the operating bias of the tube. For additional information on cathode bias, refer to the introduction to the Amplifier Section of this Handbook. Because of the large cathode bias, the tube operates class "C", and thus over the nonlinear portion of the E_g-I_p curve.

Capacitor Cl and the tuning capacitor in the local oscillator are mechanically connected. so that whenever the value of Cl is changed to operate the r-f tank at a particular frequency, the local oscillator tank is also changed automatically by the same amount. This results in the local oscillator frequency and the r-f frequency always being separated by the same amount of any frequency which may be selected at the input. The amplitude of the local oscillator voltage is approximately ten times as great as the r-f signal amplitude, for efficient mixing and the frequency is selected either above or below the r-f frequency, depending upon the application of the circuit, by an amount which is equal to the i-f frequency.

Under actual operating conditions, the following action takes place. The input r-f frequency and the local oscillator frequency are simultaneously applied to the grid and cathode circuits, respectively. As previously mentioned, these two inputs are of different frequencies, and consequently, they periodically vary in their phase relationships with each other. For this reason, they add or subtract algebraically at regular intervals, and the result at the plate is a new signal whose amplitude varies at a steady rate. This variation in amplitude is of primary importance, and is known as the "beat-frequency". This "beat-frequency" is in reality, the difference frequency which results from the algebraic addition of the two inputs as they approach an in-phase relationship, and their subtraction as the,y approach an out-of-phase relationship. This beat frequency is equal to the desired i-f frequency.

The resulting plate current pulses, whose amplitudes vary at the beat-frequency rate, arrive at the primary of transformer T2, and a carrier envelope which varies at the beat (i-f) frequency is developed. Since the primary of T2 is tuned to this i-f frequency by the use of C4, it presents a maximum load to the plate of the i-f frequency and the changing field that is developed around the primary winding induces an output in the secondary. All other beat frequencies present in the primary are not developed, because the impedance to these frequencies is of a minimum. For a detailed description of the heterodyning action, refer to the introduction to this section of the Handbook.

If the received r-f signal contains amplitude modulated components, the beat frequency also contains similar amplitude modulated components, which vary in accordance with the audio frequencies modulating the original r-f signal. If the received r-f signal is frequency modulated, the beat difference will deviate in frequency at the same rate as the original r-f signal. Thus, the characteristics of the i-f signal are the same as those of the original received signal, except that the frequency of the received signal is converted to a lower frequency.

A commonly used circuit variation of the triode mixer applies both the local oscillator and r-f signals to the grid of the tube. There is little operational difference, but cathode injection provides better oscillator stability, since the load impedance presented to the oscillator is lower.

The advantage of the triode mixer lies in its relative simplicity and relatively high signal to noise ratio. The conversion gain is about one third of that of the same tube used as an amplifier.

The use of the triode mixer, however, is limited to the VHF spectrum or lower. Above these frequencies,

the effect of the interelectrode capacitance of the tube elements becomes to great, and the low output is not practical.

Failure Analysis.

No Output. A defective tube, an open or shorted Cl, C4, or C5, or a defective T1 or T2 can cause a no-output condition to exist. If no output exists, check the plate of V1 with a voltmeter for the presence of plate voltage. If plate voltage is not present, check L3 for a possible open and C5 for a short, with an ohmmeter. If no output still exists check C2, C4, and C5 with an ohmmeter for shorts or opens, also check T1 and T2 for continuity or possible shorts. Check the secondary of T3 also for a possible open circuit. If the above checks fail to locate the trouble, check all capacitors for value with an in-circuit capacitor checker.

Low or Distorted Output. A defective tube, or low plate supply voltage can cause a low output condition to exist, Check the plate supply voltage with a voltmeter for the proper voltage. Check the output of the local oscillator with an oscilloscope to make sure that it is of proper amplitude.

A distorted output can be caused by a defect in nearly any component in the circuit. Check for the presence of the r-f signal on the grid of V1 with an oscilloscope. If no signal is present, check for a signal on the primary of T1. If the signal is present on the primary, check the transformer windings with an ohmmeter for an open or short, and capacitor Cl for a possible short. If no signal is present on the primary, the trouble lies in the preceding r-f amplifier stages, and the mixer is probably not defective. Check for presence of the local oscillator signal on the cathode. If not present, check for its presence on the primary of transformer T3. If not on the primary, the trouble lies in the oscillator circuit, and the mixer is probably not at fault. If the signal is present on the primary, check the secondary of the transformer for a short or an open, and check RI and C2 for proper value. If both the local oscillator and the input r-f signals are present at the grid and cathode of the tube, the trouble is in the plate circuit. Make certain that the plate tank circuit is tuned to the proper i-f frequency. Check C5 with an in-circuit capacitor checker to determine if it has changed in value. Check the windings of T2 for a partial short, as this can change the resonant frequency of the tank.

COMMON EMITTER MIXER (SEMICONDUCTOR)

Application.

The common emitter mixer is used in transistor iz ed superheterod$_{yne}$ receivers to combine the incoming r-f signal with the local oscillator signal to produce the desired i-f frequency.

Characteristics.

Provides conversion gain.

Requires a separate local oscillator to provide the heterodyning signal.

Utilizes the nonlinear transfer characteristics of the transistor to provide heterodyning action.

The transistor is biased in the low current region where nonlinearity is high.

A relatively high signal to noise ratio is obtained.

Operates better at higher frequencies because of reduced transit time effects.

Circuit Analysis,

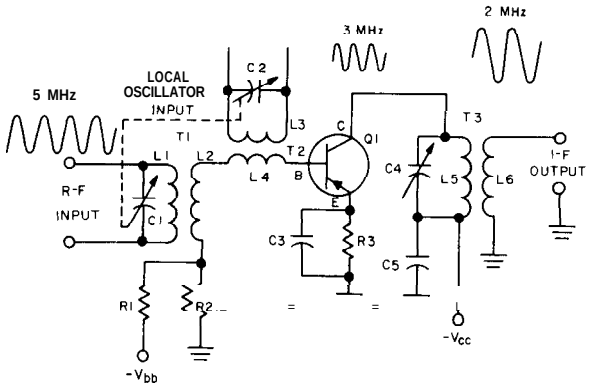
General. The purpose of the mixer stage is to convert the incoming r-f frequency usually into a lower frequency which contains the same characteristics (modulation) as the original r-f frequency. This lower output frequency, called the intermediate frequency, or the i-f frequency, must remain the same for any r-f signal received within the range of the receiver for proper operation. The radio frequency is converted to an intermediate frequency by a process called heterodyning. When the input signal, along with another specific frequency referred to as the “local oscillator signal,” is injected into the base (or emitter) of a transistor, four basic frequencies are obtained at the collector (although many other beat frequencies are also generated they are seldom used). These are the original two frequencies and the sum and difference of these inputs. A resonant tank in the collector circuit is tuned to the difference frequency, so that it will accept and pass this frequency on to the ‘following stages and effectively attenuate all the other unwanted frequencies present.

There are also applications where an incoming signal is converted to a higher frequency, as in Very Low Frequency receivers and in Single Side Band generators, where the sum frequency instead of the difference frequency is used as the intermediate frequency. Circuit operation is the same for this

application, the important change is that the output tank is tuned to the desired (sum) frequency.

The efficiency of frequency conversion in the transistor at lower frequencies is strongly dependent on the alpha rating or maximum usable gain capability of the transistor. Over the medium frequency range conversion output depends primarily on base resistance, and in the high frequency range conversion efficiency is limited by the amount of emitter reverse shunting capacitance, the less the capacitance the better is the performance. Conversion gain also influences the noise factor. At low frequencies the transistor is equal to a crystal diode with a transistor amplifier, while at vhf some gain may still be obtained, the noise is usually higher than that produced by the diode and transistor amplifier combination.

Circuit Operation. The accompanying diagram illustrated a typical common-emitter mixer.



Common-Emitter Mixer

As can be seen from a study of the schematic, resistors R1 and R2 form a voltage divider to provide base bias for Q1. Resistor R3, bypassed by capacitor C3, is a conventional emitter swamping resistor used to prevent temperature changes from altering transistor performance.

Winding L1 is the primary of Tl, and, together with capacitor C 1, forms a parallel resonant tank circuit tuned to the selected r-f signal frequency. This signal is inductively coupled to secondary L2 of TI. Transformer T2 injects the local oscillator signal on the base of Q1. Transistor Q1 is the nonlinear device used for heterodyning. The primary, L5, of transformer T3 together with C4 forms a parallel resonant tank circuit tuned to the difference (i-f) frequency, and capacitor C5 also shunts the unwanted frequencies remaining in the collector circuit to ground.

The bias voltage divider formed by RI and R2 together with emitter resistor R3 biases transistor Ql in the low current region of its dynamic transfer curve. Operation in this region provides good heterodyning action since considerable nonlinearity occurs here.

The received r-f signal is coupled through T1 in series with the local oscillator signal injected through T2, to the base of Q1. Since these two frequencies are different the phase relationship between them is constantly changing. This causes these two signals to constantly add or subtract algebraically so that amplitude variations appear on the collector at regular intervals in the form of a newly developed beat frequency. This beat frequency is the desired product of heterodyning the two signals and is called the intermediate frequency. If the received r-f signal is amplitude modulated the resultant i-f signal will have the same amplitude modulation characteristics (the modulation is transferred linearly from one signal to the other). Likewise, if the received r-f frequency deviates around a center frequency at the same rate as the original r-f signal deviated. See the introduction to this Section for a detailed discussion of frequency conversion. C 1 and the tuning capacitor of the local oscillator are mechanically connected so that whenever Cl is turned to tune the r-f tank to a different frequency, the local oscillator frequency is, likewise, changed a corresponding amount. This results in a constant difference frequency being produced as the receiver is tuned over the entire range. The local oscillator signal amplitude is made approximately ten times that of the incoming r-f signal for efficient mixing. The resonant tank formed by the primary of T3, and consisting of L5 and C4 is tuned to the difference frequency or i-f. This resonant tank presents a high impedance only to the intermediate frequency and a maximum amplitude output signal is developed and inductively coupled to the secondary, (L6), of T3. Capacitor C4 which tunes the output tank circuit also presents a low impedance to the unwanted frequencies in the collector circuit, and they are shunted around L5 and bypassed to ground by C5. Normally this bypassing is sufficient.

It has been noted, however, that in strong signal areas, and especially in all-wave types of superheterodyne receivers, that sometimes strong beat harmonic frequencies are "generated which are of sufficient amplitude to appear somewhere in the tuning range. Since these signals seem to appear at nonharmonic frequency points on the dial they cause the operator to infer that this station is operating off-frequency. This effect depends upon the choice of the i-f, whether or not it is single or double conversion, and it also depends upon how well the shielding is effective, and varies from model to model. This effect is mentioned here to indicate the importance of selecting only desired frequencies.

Failure Analysis.

General. When making voltage checks, use a vacuum tube voltmeter to avoid low value of multiplier resistance employed on the low voltage ranges of the standard 20,000 ohm-per-volt meter. Be careful to observe proper polarity when checking continuity with an ohmmeter. Since a forward bias through any of the transistor junctions will cause a false low resistance reading.

No Output. A no-output condition is usually indicative of a defective transistor, or an open base, emitter, or collector circuit. In the common-emitter circuit a shorted base or collector would also cause no output. These conditions can easily be found by resistance and continuity checks with an ohmmeter. To prevent false readings, be careful to observe proper polarity when checking resistance or continuity. Check the power supply voltage to make certain that loss of output is not due to a blown fuse or a defective power supply.

It should be noted that an i-f frequency could not be produced by the mixer if the local oscillator signal can not reach the base of Q1. Presence of this signal can be determined by simulating this signal with a signal of proper frequency from a signal generator and injecting it into the base of Q1. An output then would indicate a fault in either the local oscillator, or local oscillator coupling transformer T2. Trouble could then be localized to either the local oscillator or T2 by injecting the simulated local oscillator signal in the primary of T2. If this causes an output it would be safe to assume that the local oscillator is at fault. If signal injection into the base of QI produced an i-f output and injection into the primary of T2 did not, T2 can be assumed to be at fault. It should also be noted that failure to the local oscillator will cause very little noise to be present at the output of the receiver. In contrast, failure of the r-f stages would not greatly affect the noise present at the receiver output, but would prevent or greatly diminish radio reception.

Presence of the r-f input signal can be determined by utilizing the procedure described above and applying it to transformer T1.

If resistance and continuity checks reveal that all components are good but an output cannot be produced even when injecting frequencies from a signal generator it is possible that the output tank, the primary of T3 is badly mistuned or the trouble probably exists in the secondary of T3. Check the resistance of the secondary of T3 with an ohmmeter. If the trouble persists the defect could possibly be in the input circuits to the following stage.

Low Output. Low output could be caused by a change in bias oi a defective transistor. Check DC bias levels with a vacuum tube voltmeter. With power removed, indications of improper bias should be followed up with resistance checks to determine the component at fault.

It should be noted that deterioration with age causing lack of gain may result under high temperature conditions. Unlike vacuum tubes, however, transistors have operated for years without noticeable deterioration under proper operating conditions.

Another possible cause of decreased output would be insufficient local oscillator signal reaching the base of Q1. This condition could be checked by tracing the local oscillator signal through transformer T2 to the base of Q1, with an oscilloscope, noting that the amplitude is sufficient on the primary of T2 and that there is not excessive attenuation through T2. Less likely though a still possible cause of low output would be insufficient r-f signal reaching the base of Q1. This condition could be isolated to the proceeding r-f stages or transformer T1 by using the procedure described above for checing the local oscillator signal. Should all the conditions necessary for proper operation be met, i.e., proper operating bias, good transistor and sufficient amplitude input and local oscillation signals, poor performance could be the result of mistuning of output tank T3. With an r-f input into the receiver try tuning T3 for a peak receiver output.

AUTODYNE CONVERTER (SEMICONDUCTOR)

Application.

The autodyne converter is generally used in transistorized radio receivers to convert the incoming r-f signal to an intermediate frequency (i-f), and amplify the i-f, for application to succeeding stages.

Characteristics.

Uses a single transistor to provide the functions of these stages.

Acts as a local oscillator.

Acts as an i-f amplifier.

Acts as a self-contained mixer.

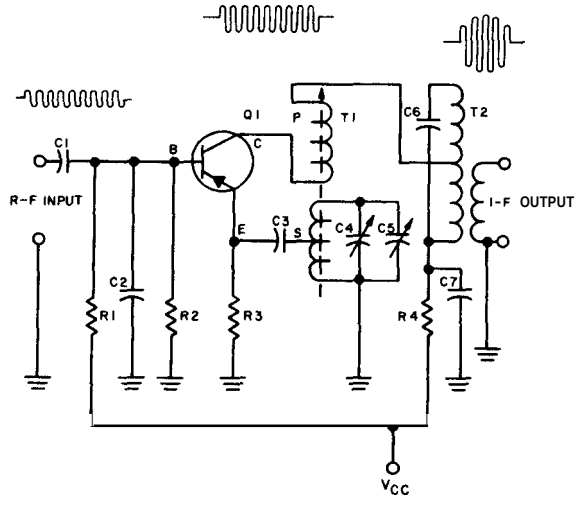
Has lower conversion gain than circuit using a separate oscillator.

Circuit Analysis.

General. The autodyne converter is used as a combination local oscillator, mixer, and i-f amplifier in transistorized radio receivers. In operation, random noise in the oscillator section produces a slight variation of collector current. This signal is induced into the secondary winding of a transformer tuned to the oscillator frequency, and is then fed back to the emitter circuit. With the feedback winding of the transformer properly phased, the feedback is positive (regenerative) and of suficient amplitude to cause sustained oscillations.

In the mixer section, the transistor is biased in a relatively low current region, thus operating on quite non-linear characteristics. As the desired incoming r-f signal is tuned, it mixes with the local oscillator signal and provides at the output the following four signals; the original r-f signrd, the local oscillator signal, the sum of the two, and the difference of the two. Because the i-f tank circuit is tuned to the difference of the two signals, it is this signal which is selected, amplified, and applied to the following stage.

Circuit Operation. The schematic of a typical autodyne converter is shown in the accompanying illustration.



Typical Autodyne Converter Circuit

Q1 is a PNP type transistor whose base is capacitively coupled to the r-f input by Cl. Fixed base bias is supplied by the voltage divider consisting of RI and R2 bypassed for r-f by C2 (see the introduction to the Amplifier Section of this Handbook for a detailed explanation of biasing). Capacitor C3 couples the local oscillator tank circuit to the emitter of Q1, and also bypasses emitter swamping resistor R3 to prevent degeneration. The swamping resistor stabilized the transistor against theramal current changes (see the introduction to the Amplifier Section of this Handbook for a detailed explanation of emitter swamping action). The secondary winding of T1 together with tuning capacitors C4 and C5 form the oscillator tank circuit, which is inductively coupled to the collector by the primary winding. Thus, feedback is obtained from collector to emitter to sustain oscillation. Another tuned tank circuit resonated at the i-f is formed by the primary of T2 and capacitor C6. Collector voltage is obtained from the supply through dropping resistor R4, bypassed by C7 for undesired r-f and i-f signals. The secondary winding of T2 is inductively coupled to the primary to furnish the i-f output.

In operation, current flows through the transistor as determined by the biasing circuit. Internal noise or thermal variations initially produce a feedback voltage between the collector and the emitter which is in-phase with the input circuit. As the emitter current increases, the collector current also increases, and additonal feedback between the windings of Tl further increases the emitter current until it reaches the saturation region, where the emitter current no longer increases. When the current stops increasing, the induced feedback voltage is reduced until there is no longer any voltage fed back to the emitter circuit. At this time, the field around the tank and tickler coils collapses and induces a reverse voltage into the emitter circuit, which causes a decrease in the emitter current, and hence a decrease in the collector current. The decreasing current then induces a larger reverse voltage in the feedback loop, driving the emitter current in the opposite direction, that is, to zero or cutoff. Although the emitter current is cutoff, a small reverse saturation current (I_{ceo}) flows; this current has essentially no effect on the operation of the circuit, but it does represent a loss which lowers the overall efficiency. In this respect, the transistor differs from the electron tube, which has zero current flow at cutoff.

The discharge of the tank capacitor through the primary winding of the transformer causes the voltage applied to the emitter to rise from a reverse-bias value through zero to a forward bias value. Emitter and collector current again flows, and the previous described action repeats itself, resulting in sustained oscillations.

The tuning capacitors in the r-f and local oscillator tank circuits are mechanically connected, so that whenever one is varied, the other is varied by the same amount. This results in the local oscillator frequency and the r-f frequency always being separated by the same amount at any frequency which may be selected at the input. The amplitude of the local oscillator voltage is approximately ten times as great as the amplitude of the r-f signal, for efficient mixing, and the frequency is selected either above or below the r-f frequency, depending upon the application of the circuit, by an amount which is equal to the i-f frequency.

Since the two applied signals differ in frequency, their voltages are not always in phas with each other. Periodically, these two voltages algebraically add or subtract to produce an amplitude variation at regular intervals; it is this periodic amplitude variation in the form of a beat frequency voltage which is of importance. The beat frequency is actually the difference frequency produced by the instantaneous signal voltage as they combine to increase amplitude when approaching an in-phase relationship, and to decrease amplitude when approaching an out-of-phase relationship. When the incoming r-f signal contains amplitude modulated information, the resulting beat frequency also contains the same amplitude modulated information, and varies in accordance with the audio frequency modulating the incoming r-f signal. If the received r-f signal contains frequency modulated information, the beat frequency difference deviates at the same rate as the incoming r-f signal frequency. Thus the characteristics of the resulting i-f are the same as those of the original r-f signal, except that the frequency of the received signal is converted to a lower or higher frequency, depending upon the application.

As a result of the heterodyning action taking place within the elements of the transistor, the output signals present at the collector of Q1 are as follows: the r-f signal, the local oscillator signal, the sum of the two, and the difference of the two. Since the i-f transformer T2 is freed tuned to the difference frequency, it is this frequency which is inducted into the secondary winding and applied to the succeeding stages. All other signals are bypassed to ground through capacitor C7. The output signal present on the secondary winding of T2 contains all of the information that was present sent on the original r-f signal.

Failure Analysis.

General. When making voltage checks use a vaccum tube voltmeter to avoid the low values of shunting resistance employed on the lower ranges of conventional voltmeters. **Be** careful also to observe the proper polarity when checking continuity with an ohmmeter, since a forward bias through any of the transistor junctions will cause a false low-resistance reading.

No **Output. A no-output** condition can occur from one of the following faults; a defective Q 1, an open Cl, R4, or R3, open windings on T1 or T2, or if capacitors C2 or C7 are shorted. Be sure that the supply voltage is correct before performing any checks. If V_{cc} is not correct, the trouble is probably not in the autodyne but in the power supply.

If an r-f signal is present at the input to the circuit, check for the r-f signal at the base of Q1, if the signal is not present, Cl is defective. If the signal is present on the base of Q1, check for the signal on the collector of Q1; if it is not present, Q1 is defective, R3 is open, C3 is shorted, or T1 or T2 has an open winding. Check R3 and T1 and T2 with an ohmmeter. Check C3 with an incircuit capacitor checker. If the signal is still not present on the collector of Q1, Q1 is probably defective.

Low Output. A low output condition may arise from the components in the circuit changing value, the oscillator not being tuned properly, shorted turns on the transformers, a change in bias voltages, a defective Q1, or mismatched impedances.

Check for the proper oscillator frequency on the emitter of Q1. If the oscillator frequency is not present, C3 is defective. If the oscillator frequency is incorrect, tune the tank circuit to the proper frequency. Check for the proper bias voltages on Q1. If the bias voltages are incorrect, check the components in the circuit which have an inproper bias.

PENTODE MIXER

Application.

The pentode electron tube is used as a mixer in superheterodyne receivers to combine, or "mix", the r-f signal, in order to produce the desired intermediate frequency (i-f) output signal.

Characteristics.

Requires a separate local oscillator circuit to suppiy the heterodyning voltage.

Output circuit is tuned to resonate at i-f frequency.

Plate resistance and transconductance are fairly high.

Operates on non-linear portion of E_g-I_p curve.

Output frequency (i-f) remains constant under normal operating conditions.

Has a relatively high conversion gain and signal to noise ratio.

Circuit Analysis.

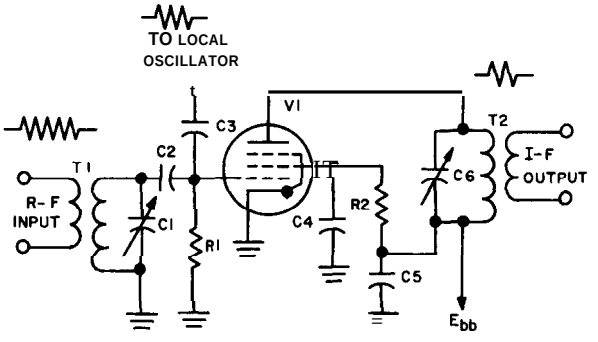
General. The pentode mixer is frequently used in f-m equipment for the vhf band. At frequencies where the screen grid is effective, the pentode mixer provides good isolation between the input and output circuits. This means reduced input loading and elimination of possible instability as compared with a triode mixer. The oscillator and signal voltages are usually applied to the control grid simultaneously. In this way, a noise figure is obtained which exceeds that of a normal pentode amplifier, but which is much lower than in any of the multigrid mixers.

The pentode has an extremely high conversion transconductance and permits high voltage gain in the mixer stage. The equivalent noise voltage produced by the tube is twice that of a triode mixer of the same transconductance. Because of the high obtainable transconductance of pentodes, the overall performance can exceed that of most triodes. Since the triode has a certain amount of stray coupling between grid and plate circuits, it is at a disadvantage in this respect when compared with the pentode. At the signal frequency, the i-f circuit is capacitive, and this, because of ***Miller effect,*** results in a reflected low resistance in the grid circuit. The screen in a pentode effectively stops this loading. With a pentode, cathode injection of the oscillator signal is possible, but this mode of injection increases the effective cathode inductance. Since the input load is proportional to the cathode inductance, cathode injection lowers the voltage gain of the input circuit and also the noise performance. The stability of the oscillator, however, is improved at very-high frequencies, where a low-impedance oscillator load is needed. Unless the oscillator and mixer are loosely coupled, interaction and pulling becomes severs. Interaction of the oscillator and the signal is greatest when they are both applied to the same grid. Similarly, oscillator radiation becomes a greater problem; however, the high transconductance of the pentode permits the ***use*** of small oscillator voltages, and radiation is not as great a problem as in a triode.

In operation, the use of a pentode as a mixer is similar to the use of a triode as a mixer. However, the use of a single grid for both the carrier and local oscillator signals sometimes gives rise to difficulties resulting from coupling between the carrier input circuit and the local oscillator circuit. Using the pentode as a mixer, one signal may be applied to the suppressor grid and the other signal to the control grid. By applying the input signals to separate grids, it provides some isolation between the local-oscillator and r-f signals. The value of the cathode resistor is chosen so that it will cause the tube to operate on the nonlinear portion of the E_g-I_p curve (the lower bend of

the response curve). The plate current of the tube then contains the two original input frequencies as well as the sum and difference frequencies of the two original signals. The signal from the local oscillator is normally made much stronger than the r-f input signal so that the percentage of modulation is kept low. The low percentage of modulation required for frequency conversion can be produced in several ways. The method most frequently used depends on the transfer characteristic of a tube or other circuit element. The transfer characteristic expresses the relationship between the signal applied to the input of a device and the signal obtained from its output. The transfer characteristic of a vacuum tube is not a straight line, since the relationship of E_g to I_p usually is curved at low values of plate current. Therefore, the vacuum tube is a non-linear device. When the voltage on the grid of a vacuum tube becomes more negative and reaches the plate current cut-off value, no current flows in the plate circuit. Consequently, for an entire range of voltages no current flows in the input circuit. Therefore, the vacuum tube is non-linear, even if its transfer characteristic is perfectly straight.

Circuit Operation. The schematic of a typical pentode mixer circuit is shown in the accompanying illustration.



Typical Pentode Mixer Circuit

Transformer T1 consists of an untuned primary winding and a tuned secondary winding; capacitor Cl and the secondary winding of T1 form a resonant circuit at the frequency of the r-f signal to be received. Electron tube V1 is a pentode; the filament (heater) circuit is not shown on the schematic.

After being amplified in the step-up transformer T1, the r-f signal is applied to the grid of mixer tube V1 along with the local oscillator signal which is applied through coupling capacitor C3. Blocking capacitor C2 isolates the contact bias resistor R1 from the signal source. Screen bypass capacitor C4 has a low enough reactance to place the screen at ground potential. Dropping resistor R2 determines the screen voltage on the screen grid of V1. An r-f bypass to ground is provided by capacitor C5; and the primary winding of transformer T2 in parallel with tuning capacitor C6 provides a resonant tank circuit for tuning the desired i-f output signal.

With no r-f input, the control grid of V1 has only contact bias. That is, some of the electrons in the space charge have enough velocity to reach the grid. This flow of electrons from cathode to grid causes a small grid current to flow. By making the value of R1 a high resistance (approximately 1 megohm) the resulting voltage drop across it provides a negative bias on the tube, which is called contact-potential bias. Capacitor C2 charges to the voltage developed across RI, holding the tube near cutoff.

Varying capacitor Cl tunes the tank circuit to the desired incoming r-f signal. This signal is amplified in step-up transformer T1, and is applied to the control grid of Vl, along with the local oscillator signal, The amplitude of the local oscillator voltage is approximately 10 times the value of the incoming r-f signal voltage. The local oscillator frequency is either above or below the desired i-f frequency (depending on the circuit application), by an amount which is equal to the desired i-f frequency.

Since the two applied signals differ in frequency, their voltages are not always in phase with each other. Periodically these two voltages algebraically add or subtract to produce an amplitude variation at regular intervals; it is this periodic amplitude variation in the form of a beat frequency voltage which is of greatest importance. The beat frequency is actually the difference frequency produced by the instantaneous signal voltages as they combine to increase amplitude when approaching an in-phase relationship, and to decrease when approaching an out-of-phase relationship.

If the incoming r-f signal contains amplitude modulated information, the resulting beat frequency will also contain the same amplitude modulated information. This information varies in accordance with the audio frequency modulating the incoming r-f signal. If the receiver r-f signal contains frequency

modulated information, the beat frequency difference will deviate at the same rate as the incoming r-f signal frequency. Thus the characteristics of the resulting i-f are the same as those of the orignal r-f signal, except that the frequency of the received signal has been converted to a lower or higher fequency depending upon the application.

As a result of the heterodyning action taking place within the elements of the tube, the output signals present at the plate of VI are: the sum of the two input signrds, the difference of the two input signals, and the two input signals themselves. Since the primary winding of transformer T2 is tuned, it will present a high impedance to the desired i-f frequency. This frequency is passed by the tank circuit consisting of the primary winding of T2 and variable capacitor C6, and a voltage is induced in the secondary winding which varies in amplitude in accordance with the amplitude of the orignrd r-f signal. All other signals are bypassed to ground through capacitor C5. The output signal voltage developed across the secondary windings of T2 then contains all of the information present on the desired r-f input signal.

One variation of the pentode mixer circuit is to use cathode injection of the local oscillator signal, but using this mode will increase the effective cathode inductance. Because the input is proportional to the cathode inductance, cathode injection will lower the voltage gain of the input circuit and also the noise performance. Another variation of the pentode mixer circuit uses the suppressor grid for one of the inputs and the control grid for the other. This provides a slight amount of isolation between the two inputs.

Failure Analysis.

No Output. A defective tube, an open or shorted Cl, C5, or C6, or a defective T1 or T2 can cause a no-output condition. Check the plate of V1 with a high resistance voltmeter. If plate voltage is not present, use an ohmmeter to check the continuity of the primary winding of T2 and to check Cl, C5, and C6 for a shorted or open condition. If the previous checks fail to locate the trouble, the circuit supplying the plate voltage is probably at fault.

Low Output. A low output would normally be caused by a defective or weak VI, or a low filament or plate voltage, or if the i-f and r-f tank circuits are not tuned to the proper frequencies. A weak local oscillator voltage can cause a low output. Check the filament and plate voltages with a VTVM. If they are not normal, refer to the procedure in the previous paragraph. If they are normal, check the amplitude of the local oscillator signal. If it is low, check C3 with an in-circuit capacitor checker. If the output is still low, the trouble is probably in the local oscillator circuit.

Distorted Output. A distorted output can be caused by a defect in nearly any component in the circuit. With an oscilloscope, check for an r-f signal on the secondary winding to TI. If the r-f signal is not present, check the windings of TI with an ohmmeter for continuity. Should the windings not be defective, the trouble lies in the preceding stages and the mixer is probably not defective. If the signal is present on the secondary winding of T1, check for the presence of the local oscillator signal on the high side of C3. If it is not present, the local oscillator is at fault. If it is present, both the r-f and local oscillator signals should be present on the control grid of VI. If the local oscillator signal is not present, C3 is defective. If the r-f signal is not present, C2 is defective. If both the r-f and local oscillator signals are present on the control grid of V1, Tube VI is probably defective. If the output is still distorted, check the plate and screen voltages with a VTVM, If both voltages are low, check the output of the plate voltage supply. If it is low, the trouble lies in the plate supply. If it is normal, and the screen voltage is low, check R2 with an ohmmeter, and C4 and C5 with an in-circuit capacitor checker and the primary winding of T2 with an ohmmeter. If the output is still not present, check the secondary winding of T2 with an ohmmeter.

BALANCED MIXER (ELECTRON TUBE)

Application.

The balanced mixer is used in receiver circuits to combine or "mix" the r-f signal from the local oscillator with the incoming r-f signal, to produce the desired intermediate frequency (i-f) output.

Characteristics.

Uses two triodes connected in push-pull.

Fixed, class "C" bias is used.

Requires a separate local oscillator circuit to supply the heterodyning voltage.

Provides amplification, which is referred to as conversion gain.

I-F frequency remains the same for any selected input frequency.

Circuit Analysis.

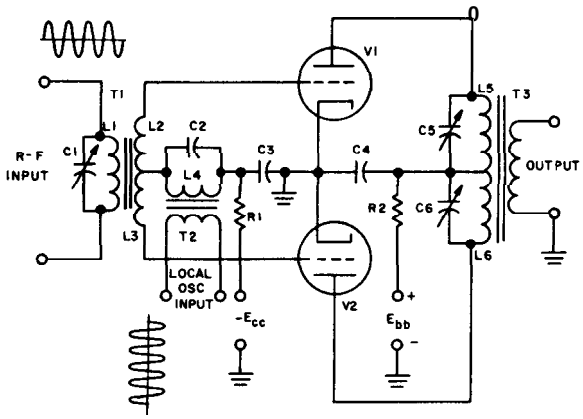
General. The purpose of the mixer stage is to convert the incoming r-f frequency, usually into a lower frequency, which contains the same characteristics (modulation) as the original r-f frequency. This lower output frequency, called the intermediate, or i-f frequency, remains the same, regardless of the frequency of the r-f signal received.

The local oscillator signal is applied in parallel to the grids of tubes VI and V2 while the r-f signal input is applied in series with the local oscillator input so that the r-f input alternately aids and opposes the local oscillator signal.

By operating both the tubes class "C", and by applying two different frequencies to the input of the tubes, a mixing, or heterodyning action occurs, and the result at the plates is a number of different frequencies, which consist primarily of the sum and the difference of the two inputs, and the two originally applied signals.

Since the tubes are connected for push-pull operation, the outputs aid each other at the output transformer, which is usually tuned to the difference frequency, and for this reason, a higher amplification factor is obtained.

Circuit Operation. This accompanying circuit diagram illustrates a typical balanced mixer.



Typical Balanced Mixer

The input r-f signal, applied to the primary of Tl, is selected with tuning capacitor Cl, which is mechanically connected to the tuning capacitor in the 10CSI oscillator. The secondary of T1 is split, and the local oscillator signal is applied through transformer T2 to the center tap of the split secondary. Capacitor C2 provides an effective ground for the center tap of the split secondary, and C3 provides a ground return for the secondary of T2 and keeps r-f out of the bias supply. Resistor RI establishes Class C bias on tubes V1 and V2, and capacitor C4 is an r-f bypass to ground. Resistor R2 is a plate voltage dropping resistor which establishes the plate voltage for the tubes. Capacitors C5 end C6 in the output circuit are used to tune the primary of the output transformer, T3, to the desired difference frequency.

With no r-f signal applied at transformer T1, and the signrd from the local oscillator applied at transformer T2, the voltages applied to the grids of V1 and V2 are in phase with each other.

By applying a signal at the input transformer Tl, voltages are developed in the secondary windings L2 end L3, which are equal and opposite with respect to each other, because of the grounded center tap arrangement. Thus, when the grid of V1 is positive with respect to its cathode, the grid of V2 is negative with respect to its cathode, and conversely.

Capacitor Cl and the tuning capacitor in the local oscillator are mechanically connected, so that whenever the value of Cl is changed to operate the r-f tank at a particular frequency, the local oscillator tank is also changed automatically by the same amount. This results in the local oscillator frequency and the r-f frequency always being separated by the same amount at any frequency which may be selected at the input. The amplitude of the local oscillator voltage is approximately ten times as great as the r-f signal amplitude, for efficient mixing, and the frequency is selected either above or below the r-f frequency, depending upon the application of the circuit, by en amount which is equal to the i-f frequency.

When both the local oscillator and the r-f inputs are applied simultaneously, the following action results.

Assume that the local oscillator signal end the r-f input signals on the grid of V1 are positive and in phase. A voltage is developed in the plate circuit which is the algebraic sum of the two applied signals. At the same instant, a positive local oscillator signal and a negative r-f input signal is applied to the grid of V2. The result in the plate circuit of V2, therefore, is

also a signal which is the algebraic sum of the two inputs. Since the two inputs are 180 degrees out of phase with each other, they subtract, and the signal at the plate of V2 is smaller in amplitude than the signal at the plate of VI. Because the tubes are connected in push-pull, the two out-of-phase r-f signal inputs add in the primary of T3, and the two in-phase local oscillator components subtract. The local oscillator components are of equal amplitude, and of opposite polarity at the plate, so their algebraic difference is O volts. The two r-f signals are in phase, and they add in the plate circuit, the result being a positive going signal.

Let us consider the opposite set of circumstances. As the polarities of the local oscillator and the r-f signals at the grids of the tubes change, the signal in the plate circuit also changes. When the signal from the local oscillator becomes negative on the grids of the tubes, and the r-f signal input is such that it applies a negative signal on the grid of Vl, and a positive signal on the grid of V2, the following results occur. Because both of the signals on the grid of V1 are in phase, they add algebraically, and the result at the plate of V1 is a negative going signal which is the sum of the two input signals. The two signals on the grid of V2, however, are out of phase, and the result at the plate is the algebraic difference. Because the local oscillator component is cancelled out in the plate tank circuits, the resultant output is a negative going signal which is the algebraic sum of the two r-f inputs.

The local oscillator signal is of a different frequency than. the r-f input, so their phase relationship with each other is constantly varying. The closer they are in phase with each other, the greater is the output, and the further out of phase they are, the smaller the output. These variations in the amplitude of the plate current occurs at the desired difference frequency, and it is this difference frequency or i-f to which the plate tank circuits are tuned. Since the tanks present a high impedance to the i-f, a changing field is developed around the primary winding, which induces an output in the secondary winding.

The local oscillator component is eliminated in the plate circuit because they are of opposite polarity, and since they always are equal in amplitude and opposite in polarity, they cancel. All other frequencies in the plate circuit are bypassed to ground through capacitor C4 without being developed. For a detailed description of heterodyning action, refer to the introduction to this section of the Handbook.

If the received r-f signal contains amplitude modulated components, the beat frequency also contains similar amplitude modulated components, which vary in accordance with the audio frequencies modulating the original r-f signal. If the received r-f signal is frequency modulated, the beat difference will deviate in frequency at the same rate as the original r-f signal. Thus, the characteristics of the i-f signaf are the same as those of the original received signal, except that the frequency of the received signal is converted to a lower frequency.

Failure Analysis.

No Output. The only components which will cause a no output condition to exist is an open R2, a shorted C4, or a defective T3. Check the value of R2 with an ohmmeter, and check C4 for an open or a short with an ohmmeter. Check the windings of T3 for continuity. Note that one defective tube will not cause a no-output condition to exist. Both tubes must be defective.

Low Output and Other Conditions, If the output appears to be low when observed on an oscilloscope, it could be simply a heterodyned signal of insufficient amplitude, or an output which is the result of one or the other of the input signals being coupled through the mixer stage without being mixed, and thus useless. Determine first of all whether or not the mixer is at fault by checking for the r-f input and the local oscillator input on their respective transformer primaries. Remember to disable the r-f amplifier when checking the local oscillator input, and the local oscillator input when checking the r-f input. If either one of them are not present, the mixer stage is probably not faulty, and the output will most likely be restored with the renewal of the missing input signal. If each signal is present on its respective primary, check the continuity from the grid of VI to the grid of V2 with an ohmmeter. If it is an open circuit, the secondary of T1 is probably open. Also check the secondary of T2 for continuity with an ohmmeter. Check C2 for a possible short, as this would place a short across the secondary of T2. Check C3 for an open, and RI for proper value with an ohmmeter. If the above components check good, and the proper signals are applied to their respective primaries, these signals should be present on the grids

of the tubes. If the trouble still exists, one of the transformers is probably defective.

If both signals are present on each grid, and the output is low, the tubes are probably defective. Do not overlook the possibility of the tuned circuits being misaligned. If the low output still exists, check the bias supply and the plate voltage supply to be certain that voltages are normal. Check R1 and R2 with an ohmmeter for proper value. Check C4, C5, and C6 for an open or a short with an ohmmeter, and the primary and secondary of transformer T3 for continuity. If above checks fail to locate the trouble, check all capacitors with an in-circuit capacitor checker, and double check all transformers.

PENTAGRID MIXER

Application.

The pentagrid mixer is used in modern superheterodyne receivers as a frequency converter. Incoming r-f signals are combined with signals from a local oscillator to produce an intermediate frequency (i-f).

Characteristics.

Offers good selectivity.

Serves both as a frequency converter and a high gain amplifier.

Signal-to-noise ratio is poor.

Requires a separate local oscillator to supply the heterodyning voltage.

Uses two input control grids to provide electron coupling.

Operates with either cathode-self, fixed, or avc bias voltage.

Circuit Analysis.

General. The functional operation of the pentagrid mixer is very similar to that of other mixer circuits discussed previously in this handbook. R-f and oscillator voltages are injected into the tube and added algebraically. The fundamental frequencies, along with their sum and difference frequencies, appear across the output circuit. The output circuit is a parallel resonant tank, tuned to the i-f. The desired i-f signal is transformer coupled into the next stage.

The primary difference between the pentagrid mixer circuit and other mixer circuits is the input arrangement. In the diode, triode, and pentode mixer the r-f and oscillator voltages are inserted on the same tube element, allowing for greater interaction between input signals. In the pentagrid mixer, r-f and oscillator signals are inserted on separate control grids, isolated from each other and the plate by screen grids. Consequently, the frequency pulling effects and signal interaction, common to other mixer circuits, is virtually eliminated.

Circuit Operation. Before discussing operation of the pentagrid mixer it will be helpful to review the operation of the pentagrid tube.

The pentagrid tube consists of a plate, cathode, filaments and five grids, hence the name pentagrid. Two of the grids are used as control grids (C1 and G3), two are used as screen grids (G2 and G4), and the fifth is used as a suppressor grid. For all practical purposes the gain of the pentagrid tube is comparable to that of the pentode, however the introduction of an extra screen grid increases the partition noise, and consequently, the circuit noise.

The screen grids are operated at a positive voltage and serve as the accelerating anodes for electrons leaving the cathode. However, the electrons strike the plate of the tube with such force that they bounce off (secondary emission) and form a space charge around the positive screen grid (G4).

The space charge greatly limits the plate voltage swing, so a negative grid (G5) is placed between screen and plate, and its negative charge diverts electrons back to the plate,

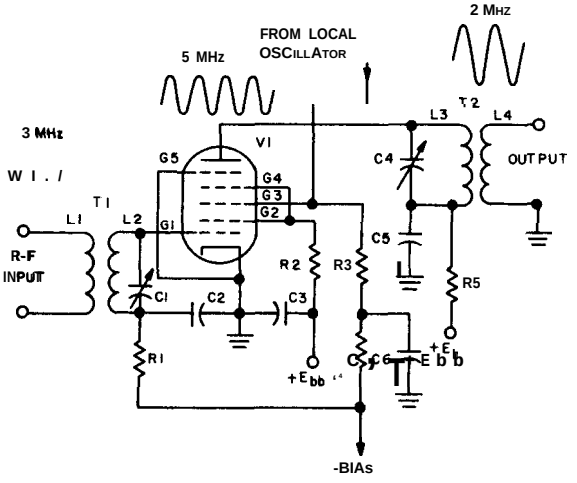
By following the above discussion it can be seen that the pentagrid tube plate current is made independent of plate voltage. In fact, the plate voltage may swing as low as, or lower than, the screen voltage without serious loss of amplifier gain capabilities. In mixer circuits gain (gin) is referred to as “conversion transconductance” and represents the quotient of i-f output current divided by r-f input voltage; or, conversion transconductance = Iif/Erf. In pentagrid tubes conversion transconductance may run as high as 500 micromhos.

In the mixer circuits previously discussed, such as the triode and pentode mixer, the r-f and oscillator signals are injected on the same control grid. Thus the r-f input circuit is “seen” by both inputs and stray coupling induces oscillator detuning, or frequency pulling. In pentagrid mixers, r-f and oscillator signals are simultaneously injected on separate control grids (G1 and G3). As stated previously in this discussion, G2 acts as an electrostatic shield between the input

elements, and is effectively grounded at r-f frequencies by capacitor C3. Thus, the input circuits are shielded from each other, and interaction caused by stray capacitive coupling is virtually eliminated. Hence the instability of operation and frequency pulling effects common to other mixers is not experienced in the pentagrid circuit.

Thus, in the pentagrid mixer the gain is high, and the input grids are also isolated creating a stable circuit free from pulling effects.

A typical pentagrid mixer circuit is illustrated in the accompanying schematic diagram.



Pentagrid Mixer

Fixed bias from an external bias supply is applied to the control grid Cl through decoupling resistors R1 and coil L2 and to G3 grid via R3 and R4. The tube is biased below cutoff with no input from the r-f and local oscillator, so that in the absence of a signal the tube will not conduct. Capacitors C2 and C6 are r-f bypass capacitors which prevent r-f signals from entering the bias supply.

Dc voltage is applied to the plate and screen through plate decoupling resistor R5 and coil L3, and through screen resistor R2. Capacitors C3 and C5 are also r-f bypass capacitors to prevent r-f from entering the power supply.

With no r-f signal applied to G1, and oscillator voltage applied to G3 the tube begins to conduct, with the plate current varying at the oscillator frequency; however, due to the highly selective tuning of the output tank comprised of L3 and C4, the current variations are by-passed through the tank to ground via C5 and no output is realized at L4.

As the receiver is tuned to the desired r-f frequency the r-f signal is impressed across coil L1. Transformer action takes place and the signal is transferred inductively from the primary to secondary winding L2. Coil L2 and capacitor C 1 form a parallel resonant tank between the control grid (Gl) and cathode, tuned to the selected r-f frequency. Capacitor C2 by-passes extraneous frequencies to ground and prevents their entering the bias supply.

As r-f and oscillator signals appear simultaneously on G1 and G3, respectively, plate current increases and the tube operates just above cutoff on the non-linear portion of the Eg-Ip curve (the lower bend in the response curve).

Harmonic distortion, caused by operating the tube nonlinearly, results in mixing action within the tube. The two original frequencies, plus their sum and difference frequencies, appear between the plate and ground across L3, and C4. The parallel resonant tank, formed by L3 and C4, selects the difference frequency and transformer action occurs between the primary or secondary of T2, resulting in the i-f appearing across L4. The unwanted frequencies (the two originals and their sum) are bypassed through C5 to ground. Capacitor C5 is of a circuit value which will bypass the high frequency components in the plate, but not the relatively low frequency i-f. Since the i-f tank offers a high primary load impedance, only the i-f signal is developed across it and is inductively coupled to the secondary or output winding. The output then consists of a signal at the intermediate frequency which contains all the original signal modulation and any hum modulation from the local oscillator, if not adequately plate faltered.

Failure Analysis.

No Output. Before troubleshooting the mixer stage it is necessary to ascertain that r-f and local oscillator signals of proper amplitude and frequency are present at the inputs to the mixer circuit. The operation of the mixer circuit depends upon the heterodyning of these two signals and if either is absent an i-f output will not appear across L4. An oscilloscope, equipped with a high frequency–high impedance probe, must be used to check the presence of r-f and oscillator signals on L1 and G3 respectively.

After assuring the presence of input signals, check the dc and bias supply output voltage for nominal

output and ripple as directed in the equipment handbook.

If power supply voltages are present and of correct amplitude, check each component visually for signs of overheating. Also check connections for good electrical and mechanical contact.

Use a vacuum tube voltmeter to check each tube element on the base of the socket. If plate, filament, or screen voltage is absent the tube will not conduct, resulting in no output. Remove power and check power supply plate decoupling resistors R2 and R5 and coil L3 for correct dc resistance. Also check capacitors C3 and C5 with a in-circuit capacitor checker to determine if they are shorted or leaky. If bias voltage is appreciably off value the tube will either be cutoff (increased bias) or saturated (decreased bias). Check bias resistors R1, R3, and R4 and coil L2 for correct dc resistance. Use an in-circuit capacitor checker to check capacitors C2 and C6 for a shorted or leaky condition.

If all circuit components are within tolerance and the presence of both r-f and oscillator signals is verified, the tube is most likely at fault.

If still no output is obtained, check the tuning of the input and output circuits as directed in the equipment handbook. If either tank will not tune, carefully check the "capacitor and coil associated with the tank. Remove power and use an ohmmeter to check the primary and secondary windings of T1 and T2 for the correct dc resistance. If the resistance has increased the Q of the circuit will be decreased and output of the desired frequency may be impossible to obtain.

Low or Distorted Output. Check the r-f oscillator input circuits for proper amplitude and frequency with an oscilloscope. Be especially watchful for distorted input waveforms caused by noise, hum, defective coupling, etc. If input waveforms are correct and free from distortion, check the waveform at the plate of V1 (use a 30-100 pf, 250 v dc blocking capacitor in series with the probe).

If the waveform appearing on the plate is clipped or small in amplitude, check for correct dc operating voltages on the tube elements. Check bias voltage first, as increased bias will cause abnormal plate voltage due to decrease conduction. If bias voltage is incorrect check resistors R1, R3 and R4 and coil L2 for correct dc resistance. Check r-f by-pass capacitors, C2 and C6, for shorts using an in-circuit capacitor checker.

If bias voltage is correct and plate voltage is low check the dc resistance of R5 and L3. Also check C5 for a shorted or leaky condition.

If all voltages are correct and the output of the tube is still weak, the tube is probably defective.

If the output of V1 appears normal and the output of the mixer stage is still weak or distorted, check the tuning of the output tank circuit. If the tuning of capacitor C4 has shifted appreciably the band pass of the tank circuit will be greatly reduced and the i-f frequency will be suppressed.

PENTAGRID CONVERTER

Application.

The pentagrid converter is used in modern superheterodyne receivers to convert radio frequencies (r-f) to intermediate frequencies (i-f) by heterodyning (mixing) the received r-f signal with a locally generated signal.

Characteristics,

One tube functions as both oscillator and mixer.

Output is stable up to and including the h-f band.

Signal-to-noise ratio is poor.

Offers high gain (conversion transconductance).

Oscillator section is electron-coupled and isolated from input sigmls to minimize "pulling effects".

Circuit Operation.

General. The pentagrid converter is a low cost, high gain, frequency converter with excellent stability, commonly used for frequencies up to and including the h-f band. Perhaps the most frequent application of the pentagrid converter is in the standard acdc house-hold receiver where, due to the high gain characteristics of the pentagrid tube, an r-f amplification stage is not required. By combining the r-f amplifier, local oscillator and mixer into one tube the over-all cost of the receiver is greatly reduced without sacrificing quality; however, in more sophisticated receivers where greater sensitivity and selectivity are desired, the pentagrid converter is usually preceded by at least one stage of amplification.

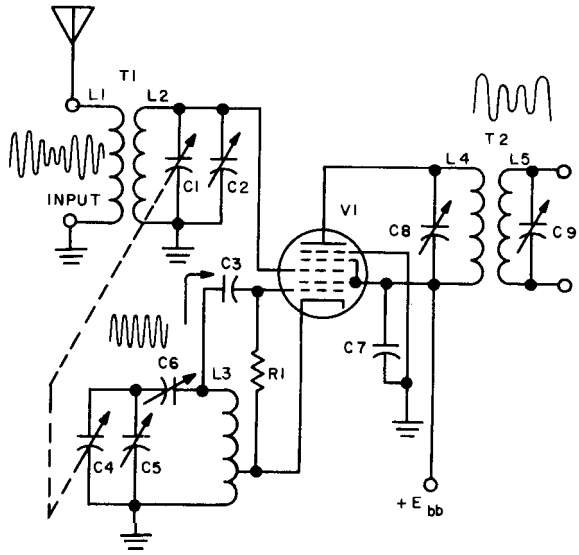
Basically, the pentagrid converter can be divided into two separate circuits; an electron-coupled oscillator (formed by the cathode, inner control grid, and screen grid) and a conventional pentagrid mixer with separate grid injection.

The tube is biased below cutout by a shunt grid leak bias network, and plate current only flows when the oscillator signal is large enough to overcome the heavy negative bias. Thus, conduction takes place for the small amount of time that the oscillator signal is at its peak amplitude. This breaks the plate current into pulses varying at the oscillator frequency. As the receiver is tuned to the desired r-f frequency, the r-f voltage injected on the outer control grid is added algebraically with the oscillator signal so that plate current now follows their combined sum voltage.

Operating the tube just above cutoff on the non-linear portion of the Eg-lp curve causes harmonic distortion. Consequently, in addition to the two original frequencies, their sum and difference frequencies are now present in the plate circuit.

A parallel resonant tank circuit is placed in the plate circuit and is tuned to the desired i-f, which can be either the sum or difference of the two original frequencies. Transformer action transfers the selected i-f to the input of the next stage. The two original frequencies and their sum or difference (depending upon which frequency was selected for the r-f) are by-passed to ground through the relatively low impedance offered by the screen bypass capacitor.

Circuit Operation. A typical pentagrid coverter circuit is illustrated in the following schematic diagram. Pentagrid converters are occasiomlly modified to function in special circuits, consequently, circuit arrangements which vary from the accompanying schematic may be incorporated in different receivers; however, the functional operation remains basically the same.



Pentagrid Converter

R-f signals arriving at the antenna are impressed across L1 and coupled across transformer T1 to the secondary tuned tank formed by inductor L2 and capacitor Cl. C2 is a trimmer capacitor used to track the high frequency end of Cl during alignment. The selected r-f frequency is inserted into the converter tube on the outer control grid, G3.

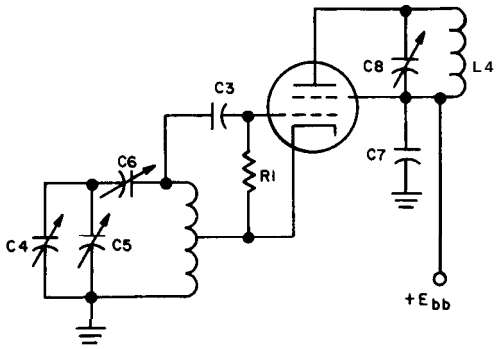
Oscillator signals are developed in the grid tuned tank formed by inductor L3 and capacitor C4. C5 is a

trimmer capacitor used for tracking the high frequency end of the main tuning capacitor C4, and C6 is a padder capacitor used to track the low end of C4. The oscillator signals are coupled to inner control grid G1 through coupling capacitor C3 which, working id conduction with RI, develops the shunt grid leak bias voltage for the tube.

Conduction takes place when the positive peaks of oscillator signal overcome the class C bias, causing plate current to flow in pulses at oscillator frequency. The pulsed electron stream is further modulated by the r-f signal and both frequencies, plus their sum and difference frequencies appear in the plate circuit. The parallel resonant tuned tank formed by inductor L4 and capacitor C8 acts as a plate load, and is tuned to the desired i-f frequency. Capacitor C7 prevents r-f from entering the power supply.

The output is taken across the parallel tuned tank formed by inductor L5 and capacitor C9 which further selects the desired i-f frequency.

The schematic diagram shown incorporates an electron-coupled Hartley oscillator as the frequency generating section. For illustrative purposes the oscillator portion of the pentagrid converter has been re-drawn in the following schematic diagram. Notice that the screen grids (G2 and G4) form a composite oscillator anode. A detailed operational description of the oscillator section is included in the following paragraphs.

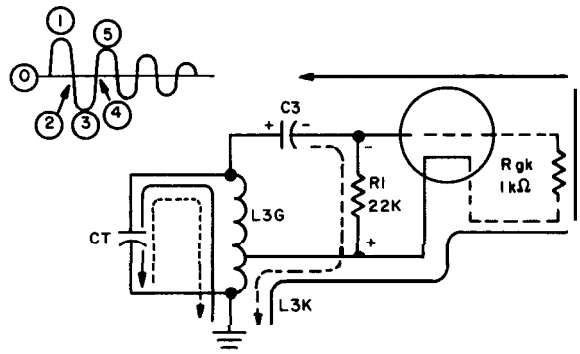


Oscillator Section

In frequency converter circuits it is desirable to have as nearly a stable oscillator injection signal as possible with little variation in frequency or amplitude. In the pentagrid converter this need was intensified by combining two separate functions into one tube envelope. It is known that variation in the plate load of conventional oscillator circuits causes considerable variation of oscillator frequency. Hence, the need for an oscillator whose output circuit is completely isolated from the tuned grid circuit.

In the electron coupled Hartley oscillator, the internally connected screen grids are supplied with a dc potential and act as a composite anode for the oscillator section of the pentagrid converter. Electrons are attracted from the cathode and flow towards the screen grids (anode); however, because of the relatively large spacing between the wires of the screen grid, most of the electrons pass on through to the plate element of the pentagrid tube. Consequently, only a small amount of screen current flows and the screen voltage remains comparatively constant. It can be seen then that electrons leaving the cathode "see" a relatively constant load because of the stable anode potential on the screen grid, but the actual output circuit of the oscillator is in the pentagrid tube plate. The screen grids are held at r-f ground potential by r-f by-pass capacitor C7 whose impedance is very low at r-f. Thus the only coupling which exists between the input and output circuit is the electron stream, hence the name "electron-coupled" oscillator.

To sustain oscillations in the grid circuit it is necessary to "feedback" an in-phase portion of the output signal. In the electron coupled Hartley the tapped inductor acts as an autotransformer to accomplish this purpose. For illustrative purposes the grid and cathode circuit has been redrawn in the accompanying schematic diagram.



Simplified Oscillator Circuit

The inductor L3 is divided into two sections which will be designated L3k (cathode winding) and L3g , (grid winding). It can be seen that the total inductance former by L3, in parallel with the total capacitance of C4, C5 and C6, forms the frequency determining tank circuit. The solid lines represent the initial flow of current (charge path) and the broken lines represent the reverse of current (discharge path).

At the instant power is applied to the tube, zero bias exists on the control grid and the tube readily conducts. For the following discussion it will be helpful to remember that cathode current "follows" plate current. Increased cathode current develops a voltage potential across inductor L3 and capacitors C4, C5 and C6, represented by CT, begin to charge (O to 1 on the sine wave). At point 1, the capacitors have charged to approximately the applied voltage and begin to discharge back through inductor L3, (point 1 to 2) setting up a magnetic field, (point 3). The magnetic field begins to collaspe, (point 3 to 4) recharge capacitor CT (point 5) and the cycle repeats itself; however, notice that the voltage at point 5 is less then that at point 1. This is due to inherent circuit losses (coil resistance, etc.) and eventually, after a few more cycles, the oscillations will dampen out entirely. Thus, it can be seen that an in-phase signal of sufficient amplitude to cancel out circuit losses is necessary to sustain oscillations.

For simplification, bias voltages are disregarded in this discussion and will be discussed later in the text.

The positive going grid (O to point 1) causes an increase in plate (and cathode) current, resulting in an increased voltage across inductor L3k, 180° out of phase with the grid signal. The mutual inductive action of the autotransformer L3g and L3k produces another 180° phase shift, so that regenerative (in-phase) feedback is accomplished. The feedback voltage will be relatively small due to the turns ratio of the transformer but it is of sufficient amplitude to reinsert and compensate for any circuit losses. Thus, the flywheel effect of the tuned tank circuit, aided by the mutually induced voltage from L3k, impresses a linear sine wave on capacitor C3, which is part of the shunt grid leak bias circuit.

As has been previously mentioned, it is required that a mixer operate over the nonlinear portion of the Eg-Ip curve, thus the tube must be biased below cutoff. The grid leak bias circuit comprised of resistor RI and capacitor C3 performs this function and will be discussed in detail in the following paragraphs.

The oscillator input signal arriving from the grid tank circuit is impressed on the tank side of capacitor C3. On the positive swing of the oscillator input signal the grid is driven positive, causing current to flow from cathode to grid through the internal grid-cathode resistance, Rgk (The value of Rgk is considerably lower than that of the parallel resistance R1 so the major portion of the current will flow through Rgk) and C3 charges rapidly, placing a negative voltage on the control grid. As the oscillator signal swings negative, grid current ceases to flow and capacitor C3 begins to slowly discharge through resistor R1. The value of R1 is considerably larger than Rgk, so discharge time is longer than charge time. Before C3 can become fully discharged the oscillator signal begins to swing positive and grid current flows again, charging C3 to a higher potential and placing more bias voltage on the control grid. Eventually, after a few more cycles of oscillator signal, the charge on C3 becomes stabilized and grid voltage remains at a constant level.

If the time constant of the R-C bias network is too long, capacitor C3 will eventually become fully charged, placing the tube in absolute cutoff and no current will flow, consequently, oscillations will cease. Hence, the value of grid leak resistor R1 is critical. It must be large enough to develop a sufficient negative voltage for cutting the tube off and small enough to allow a partial discharge of C3 before the next oscillator cycle begins. Thus, by using the correct value of grid leak resistance the circuit may be designed to cut off for 9070 of the time only 10% (the positive peak) of the signal causing tube conduction.

The positive peaks of the oscillator signal brings the tube out of cutoff and modulates the electron stream in pulses. R-f signals arriving at the antenna are impressed across inductor LI, the primary winding of T1. The signals are transformer coupled to the secondary winding, inductor L2. Capacitor Cl and L2 make up a parallel resonant tank tuned to the selected r-f frequency. Notice that Cl in the r-f section and C4 in the oscillator section are mechanically ganged, and varying one will cause the other to vary by an equal amount, hence the oscillator and r-f stage are always, theoretically, separated by the intermediate frequency. However, on the extreme ends of the tuning range the variable capacitors become somewhat non-linear and if proper tracking is to be acquired it is necessary to insert trimmer and

padder capacitors to "fine tune" the local oscillator and r-f sections. Capacitors C2 and C5 are "trimmer" capacitors used to track the low frequency end of Cl and C4 respectively and C6 is a "padder" capacitor used to track the high frequency end of capacitor C4.

The frequency selected by Cl and L2 is applied to the outer control grid, G3. The r-f signal grid is electrostatically shielded from the oscillator grid by screen grid G2 which is at ground potential. Consequently, very little electron coupling exists between the r-f and oscillator circuits and frequency pulling effects are virtually eliminated,

The electron stream, varying at oscillator frequency, is further modulated by the r-f signal and plate current begins flowing at a rate, as determined by the algebraic sum of the two signals. Harmonic distortion, caused by operating the tube non-linearly, produces various frequencies (the origiml rf and oscillator signals and their sum and different frequencies) in the plate circuit. The fixed tuned output tank comprised of L4 and C8 is tuned to the desired i-f, which is usually the difference frequency, and inductively couples the selected i-f to the secondary winding tuned circuit comprised of L5 and C9.

The unwanted original frequencies and their sum frequency are shunted to ground through r-f by-pass capacitor C7.

Failura Analysis.

No Output. Before troubleshooting the converter stage check each component visually for signs of overheating. Also, check all component connections for good electrical and mechanical contact. Check the mechanical coupling between the ganged capacitors C4 and Cl. If the coupler has loosened the oscillator and r-f signals will not be separated by the desired i-f frequency and no output will be obtained from the converter circuit.

The output tuned tank comprised of L4 and C8 is tuned to the desired i-f which is a mixture of the locally generated oscillator signal and the received r-f signal. Thus, if both input signals are not present on their respective control grids the tube will not operate properly, resulting in no output. Before further troubleshooting is accomplished the presence of both input signals must be ascertained. It is important to remember that oscillator signals are dependent upon tube conduction.

To check the r-f signal, connect an oscilloscope (equipped with a high impedance-high frequency probe) between the outer control grid and ground. If receivers where the converter is not preceded by an r-f amplifier the r-f signal may not be of sufficient amplitude to produce an indication on the oscilloscope. If this is the case a signal generator, adjusted to the selected r-f and loosely coupled to the antenm loop, should produce an indication on the oscilloscope. If no signal is obtained after performing the preceding checks, use an ohmmeter to check inductors L1 and L2 for the correct dc resistance. Also, check capacitors Cl and C2 for a shorted condition using an in-circuit capacitor checker. In receivers where an externa. antenna is used the antenna transmission line must be checked for a short or open.

Since grid leak bias voltage depends upon the applied oscillator input signal, both the bias voltage and oscillator signal may be checked simultaneously by connecting a vacuum tube voltmeter between the inner control grid and ground. If no voltage is present on the control grid, remove power and check the dc resistance of inductor L3 using an ohmmeter. Also check capacitors C4, C5 and C6 for a shorted condition. If the components forming the oscillator tank appear normal, use an in-circuit capacitor checker to check capacitor C3 for a shorted or leaky condition. If C3 is defective the bias on VI will decrease and the tube will be saturated. Also check resistor RI using an ohmmeter. If R1 has increased in value the bias on V1 will increase, cutting the tube off.

If both signals are present on the control grids, check the plate and screen elements for the correct dc potential. If plate or screen voltage is abnormal check inductor L4 for nominal dc resistance using an ohmmeter. Also check capacitor C7 using an in-circuit capacitor checker.

If all the circuit components are found to be within tolerance check inductors L4 and L5 for the exact d-c resistance as specified in the equipment handbook. Also, use an in-circuit capacitor checker to check C8 and C9 for a shorted condition.

If it is verified that the circuit components are within tolerance and the correct voltages are applied to the tube elements and a no-output condition still exists, tune the primary and secondary of the output transformer T2 as directed in the equipment handbook.

Low or Distorted Output. A low or distorted output in converter stages could be caused by

numerous defective components within the circuit; however, the two most likely causes would be either distorted input signals or improper bias voltage.

First, check the r-f oscillator signals for correct amplitude and frequency using an oscilloscope equipped with a high impedance-high frequency probe. Be especially watchful for distorted waveforms caused by noise, hum, clipping, etc.

If the quality of the received r-f signal from the antenna (or r-f amplifier) is questionable, disconnect the antenna and inject the signal from an r-f signal generator and recheck the signal applied to the control grid. If the sigml is distorted, check the tuning of the grid tank. Also, carefully inspect the grid tank ground connections for good electrical contact. A loose or intermittent ground comection would introduce hum and distort the signal.

If the oscillator signal shows signs of distortion, check the d-c resistance of tapped inductor L3 and resistor RI. Use an in-circuit capacitor checker to check capacitor C3 for a shorted or leaky condition.

If the input waveforms present on the control grids appear to be normal, check the output waveform in the plate circuit. (Use a d-c blocking capacitor in series with the oscilloscope probe). If the output waveform is clipped or small in amplitude, check the cathode and inner control grid for proper operating voltages. A noticeable 60 Hz hum in the output waveform could be caused by a cathode to heater short or high grid leakage.

If the waveform at the plate appears normal, but the output of the converter remains distorted, tune the output transformer T2 as specified in the equipment handbook.

PART 11-3. AGC CIRCUITS

AGC (AVC) CIRCUITS

General.

AGC (automatic gain control), frequently referred to as *AVC* (automatic volume control), is a control circuit that automatically changes the over-all gain of a receiving system in a manner which is inversely related to the strength of the received carrier signal. The terms AGC and.4 *VC* have been used interchangeably, and some confusion has resulted from this practice. The exact use of one or the other term is determined principally by the type of circuit(s) being controlled or by the type of useful output obtained from the controlled system.

Originally, the circuit was used extensively in radio and communications equipments where the useful output obtained was an audible signal heard in headphones or from a loud speaker; the circuit was therefore called ***automah"c volume control.*** However, basically the same circuit has also been employed to provide automatic control of amplification, or gain, in other electronic equipments. Since these similarly controlled equipments produce a useful output that does not necessarily result in an audible output signal, the term ***volume*** does not apply; in this case the term ***gain*** is technically correct. For example, if the basic circuit is used to control the amplification (gain) of the r-f and i-f amplifier stages in a communications or broadcast receiver, it is frequently still referred to as an ***A VC circuit;*** on the other hand, if it is used to control the amplification (gain) of the i-f amplifier stages in a radar receiver, or the r-f and i-f stages in a television receiver, it is called an ***AGC circuit.*** In either example the electronic function is the same-to control an output signal in accordance with the strength of the input carrier signal.

In the paragraphs to follow and throughout this section, the distinction between AGC and AVC will not be made. The term AGC (automatic gain control) will be used to designate the circuit that controls useful output, regardless of whether it is in the form of a visual (video) display or similar indication, or an audible signal.

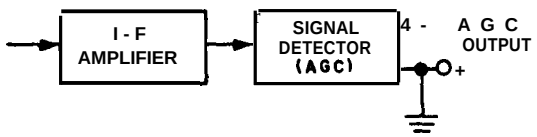
The basic AGC circuit is intended to maintain the output of a receiving system nearly constant within relatively narrow limits, and must do so as the input carrier signal level varies over a considerable range. AGC action is normally accomplished by developing a dc control voltage which is proportional to the amplitude of the received carrier signal, and then applying this voltage in the form of bias to regulate the gain of one or more remote cutoff amplifier stages within the receiving system.

Types of AGC Circuits (Electron Tube).

AGC circuits vary somewhat because of the overall gain characteristics required of the receiving system. However, most electron tube AGC circuit configurations fall into one of three general classifications: simple AGC, delayed AGC, and amplified and delayed AGC. These three classifications of AGC circuits are described briefly in the paragraphs which follow.

4

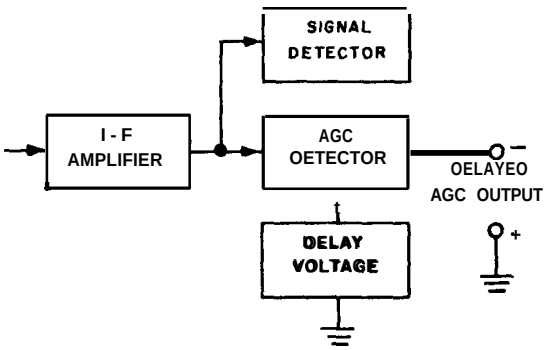
Simple AGC. A simple AGC circuit and a diode-detector circuit (described in the Detector Section of this Handbook) are very similar in many respects. For this reason, the AGC circuit and the signal detector circuit of a receiving system are frequently combined within a single stage. The accompanying block diagram illustrates a simple AGC system; this AGC system makes use of a negative dc control voltage obtained directly from the signal detector output, since the rectified voltage produced by the detector is proportional to the amplitude of the received carrier.



Simple AGC System

The resulting d-c voltage obtained from the detector circuit is filtered by an R-C circuit to remove any amplitude modulation components present in the detector output, and is then applied as bias to the control grid of each stage to be controlled in the receiving system. The time constant of the R-C filter is long enough to remove the lowest modulation frequencies from the dc voltage, but short enough that a change in dc bias level will respond to moderately rapid changes in received signal strength due to signal fluctuations, fading, etc. The simple AGC circuit is employed in many typical AM superheterodyne receivers which use a diode-type detector; it is also employed in some FM receivers which use a ratio-type detector.

Delayed AGC. The term delayed AGC is used to denote a voltage delay, and should not be confused with a time delay. The simple AGC system just described is effective on all received signals, from the weakest to the strongest. It has the disadvantage of developing an AGC voltage even for very weak received signals and, as a result, the sensitivity of the receiver to weak signals is reduced considerably. Therefore, in order to increase sensitivity and enable the receiver to respond to weak signals, it is desirable to provide a means of delaying the application of AGC voltage until the received signal reaches a predetermined value, sometimes called the *threshold* level of AGC. The accompanying block diagram illustrates a typical delayed AGC system.



Simple Delayed AGC System

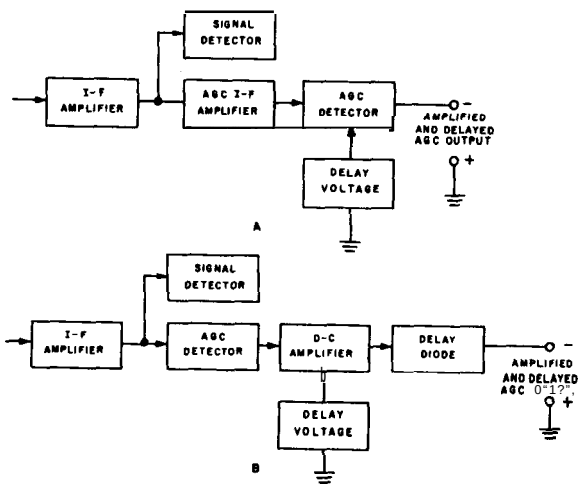
The delayed AGC system makes use of a fixed delay voltage applied to a separate AGC detector. The delayed AGC detector must be a separate diode, independent of the signal detector (demodulator) diode, because the fixed delay voltage prevents the AGC detector diode from rectifying an r-f signal until the signal level exceeds the value of the delay voltage. Thus, if separate diodes were not used, the delay voltage would prevent the detector (demodulator) diode from rectifying weak signals which are below the threshold level established by the value of the delay voltage. Once the signal level rises and exceeds the value of the delay voltage, the AGC detector begins to rectify and produce a dc output voltage which is applied as bias to the controlled stages. The requirement for filtering of the dc output voltage to remove amplitude modulation components and the R-C time-constant considerations are essentially the same as the simple AGC system. The delayed AGC circuit is employed in many AM boradcast, communications, and dual-diversity super-heterodyne receivers, as well as in similar microwave and radar receiving systems.

Amplified and Delayed AGC. There are many variations in amplified and delayed AGC systems. However, these various AGC systems can be classified according to two categories: systems which amplify a signal ***before*** rectification, to obtain the AGC voltage, and systems which amplify the AGC voltage ***after*** signal rectification. In either case, a form of delay Voltage is incorporated so that the maximum sensitivity

491-044 0 7365

of the receiver can be realized for weak-signal reception. When amplified and delayed AGC is used to control a receiving system, the over-aU output versus signal input characteristics can be made to approach an almost ideal condition.

The accompanying illustration shows block diagrams for two basic types of amplified and delayed AGC systems.



Amplified and Delayed AGC Systems

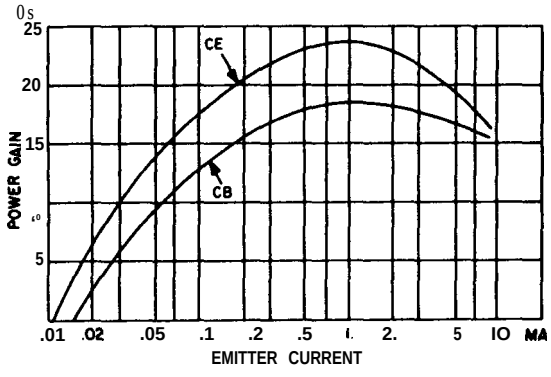
Part A of the illustration shows a system in which the signal is amplified by an AGC i-f amplifier ***before*** rectification by the AGC diode. Part B shows a system in which the signal voltage is amplified by a dc amplifier ***after*** rectification by the AGC diode. The dc amplifier stage is followed by a delay diode which supplies AGC voltage to the controlled stages only when its cathode is negative with respect to its plate, and the diode conducts; when the delay diode is not conducting, the AGC output voltage is zero and the receiver gain is at maximum for all signals below the threshold of AGC operation.

Note that both AGC systems illustrated incorporate a form of delay voltage. [n the amplified and delayed AGC system illustrated in part A, the delay voltage is applied to the AGC detector, which follows a separate amplifier; the separate amplifier receives its signal from the last i-f amplifier of the receiving system. Another variation of this AGC system employs an independent AGC amplifier channel consisting of several stages and having a greater over-all amplification (gain) than does the signal i-f amplifier channel. In the AGC system illustrated in part B, the delay voltage is shown applied to the d-c amplifier stage. One possible variation of this circuit applies a delay voltage to the AGC detector as in the circuit for the delayed AGC system shown in Part A. In practice, however, almost all AGC circuits using a dc amplifier to control the AGC voltage employ a delay diode in the output to prevent the dc output voltage from ever becoming positive with respect to ground.

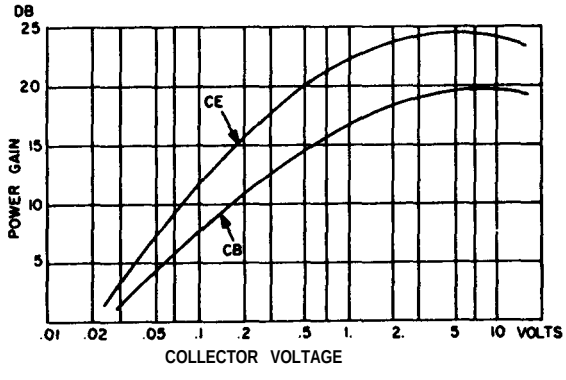
Types of AGC Circuits (Semiconductor)

AGC circuitry in the semiconductor field falls into two general classes. One class uses the variation of dc bias on one or more elements of a transistor amplifier stage to control its gain. The other class employs a diode or another transistor to shunt the input signal to ground (or around the controlled stage) and thereby reduce the over-all gain. The output of the second detector in a superheterodyne receiver provides, in addition to the desired signal, a dc component which is proportional to the carrier strength of the received signal. This dc component offers a convenient method of controlling the bias on a preceding r-f or i-f amplifier and thus controlling the stage gain.

Variation of transistor bias to control the gain may be accomplished either by changing the emitter current (I_E) while the collector voltage is held substantially constant, or by changing the collector voltage (V_C) by means of the collector current. These two methods are sometimes called ***reverse AGC and fir-ward AGC,*** respectively. The following illustrations show a comparison of the two methods. In the figures, curves are shown for both the common-emitter and common-base circuit configurations. Upon examination of the figures, it is evident that the two configurations perform similarly, with the



Emitter Current Control



Collector Voltage Control

Comparison of Bias Control Methods

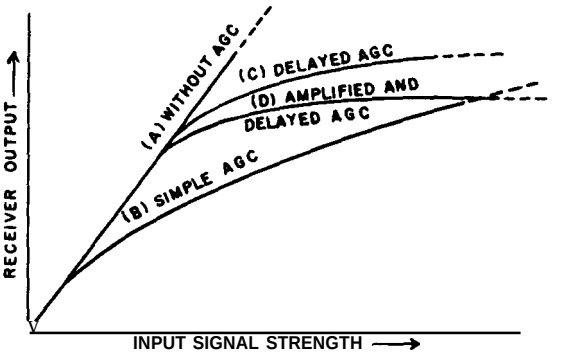
common-emitter circuit providing a somewhat greater control range. The emitter current control circuit is more generally used than the collector voltage control circuit, mainly because of the very low collector voltage provided. At low collector voltages the collector capacitance is increased (an inherent disadvantage in the transistor); consequently, the alpha cutoff frequency is reduced, making the transistor a poor r-for i-f amplifier. The illustrations also indicate an important difference between the semiconductor AGC circuit and the electron tube AGC circuit; namely, the transistor AGC unit operates at very much lower power and voltage levels. For example, over the first decade (between .01 and 0.1 ma), the CE emitter-control circuit provides a range of from approximately O to 18 dB gain variation with a current variation of only 100 microampere. In the collector-voltage control circuit a similar range is covered with a variation of only 0.28 volt. Over the second decade, this performance is halved with the curve reaching its zenith and then declining.

When the bias of the transistor is changed by AGC control, the input and output impedances also change and produce a shift in the bandwidth and center frequency to which the circuit is tuned. For example, when the emitter current of a CE stage is reduced to decrease the gain, it causes an increase in input impedance and capacitance. As a result, the bandwidth of a parallel resonant circuit used with it is decreased (because of the increased Q), and its center frequency is shifted higher. This is a basic disadvantage of this type of circuit and presents a design problem. In addition, at the very low currents and voltages given in the examples the stage cannot handle much power, particularly since the reduction is usually in a downward direction. The usual practice is to apply AGC control to a single stage (either the 1st r-f or i-f), rather than a number of stages as is common in electron tube practice. In those cases where substantial power is required to drive and control the emitter current of the transistor gain-controlled stage, a dc amplifier may be provided. Usually, however, amplification is obtained by applying the control voltage to the base of the transistor amplifier and allowing it to act as its own dc amplifier. Delayed AGC action can also be provided by adjusting the bias to be effective only above or below the desired operating level.

Typical AGC Characteristics. One of the purposes of the AGC system is to hold the i-f (or r-f) signal input to the detector (demodulator) relatively constant over a considerable range of received signal strength at the input terminals to the receiving system. It was previously stated that a simple AGC system accomplishes control of receiver gain by varying a negative dc bias voltage applied to the control grids of remote cutoff tuhes in the r-f and i-f stages of the receiver. Thus, as the received signal increases, the signal at the detector also increases, resulting in a greater negative dc voltage available for control purposes. The control (bias) voltage is applied to the early stages of the receiver to reduce the overall gain. The reduction in receiver gain lowers the

input to the detector and, within limits, tends to keep the detector output from rising too rapidly as the input signal increases. However, it is virtually impossible to hold the input to the detector (demodulator) constant, because the AGC voltage is dependent upon the strength of the received signal, which is amplified by the controlled stages of the receiver and rectified by the detector. Thus, an increase in the strength of the received signal means that the rectified output of the detector also increases, and this voltage (or a corresponding voltage) is, in turn, fed back as a control voltage. Therefore, it is reasonable to assume that there must always be some increase in the receiver-output voltage. The rate of increase, however, is determined by the individual circuit design, and desirable characteristics can be attained which approach the ideal characteristic.

The following illustration graphically compares the receiver-output characteristics of typical AGC systems with the characteristic of a receiver using a conventional diode detector without AGC. The plot of receiver output versus input signrd strength for a receiver without AGC (curve A) shows that the output rises rapidly for an increase in signal strength; however, the receiver output soon becomes distorted because of overloading which occurs with large input signals. The plot of receiver output for a receiver with simple AGC (curve B) shows that even small input signals are acted upon by the AGC voltage, and, as a result, the output obtained from weak signals is reduced. The plot of receiver output when delayed AGC is used (curve C) shows that the output for small input signals closely follows the output obtained when no AGC is used and that, when the input signal reaches some predetermined strength, the output is prevented from rising too rapidly as the input signal is further increased. The plot of receiver output when amplified and delayed AGC is used (curve D) approaches an ideal condition wherein the receiver is sensitive to weak signals and the output is held relatively constant once the input signal exceeds some predetermined strength.



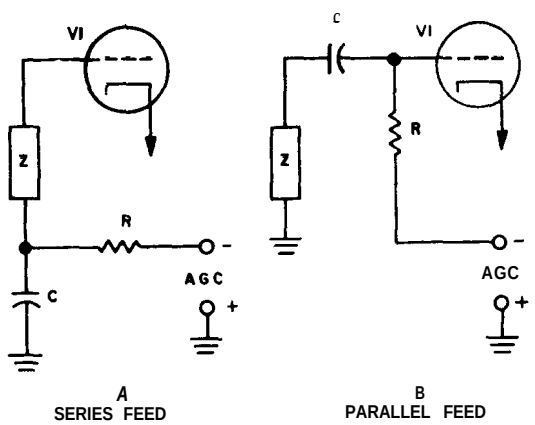
Reeeiver Output Versus input Signal Strength

Methods of Feeding AGC-Controlled Stages. Two methods are used to feed AGC voltage to the input of a controlled amplifier. These two methods are commonly called ***series feed*** and ***parallel*** (or ***shunt) feed.*** In either method, the AGC voltage is actually in "series" between the control grid and the cathode of the controlled tube. The terms ***series feed*** and ***parallel feed*** are used for convenience to identify the circuit arrangement which enables the AGC voltage to be applied to the control grid. AGC systems utilize one method or the other in feeding the control voltage to an individual tube. Sometimes, because of resonant circuit design or interstage coupling arrangements, one method is used to feed one stage of the receiver and the other method is used to feed another stage. For example, in a typical VHF superheterodyne receiver, the single r-f amplifier is a parallel-fed stage while the i-f amplifier channel incorporates several series-fed stages.

The series-feed arrangement is illustrated in part A of the accompanying simplified schematic diagram. Impedance Z is normally a tuned circuit, transformer, or other coupling impedance. Resistor R and capacitor C form a decoupling network; in addition, capacitor C must also be considered as a d-c blocking

and r-f bypass capacitor for the grid-circuit impedance, Z. The d-c path for the application of control voltage to the grid of the tube is through impedance Z; in other words, the impedance is in "series" with the control voltage.

The parallel-feed arrangement is illustrated in part B of the accompanying simplified schematic diagram. In this circuit, resistor R is effectively in parallel with impedance Z, and provides a "parallel" (or "shunt") dc path for the application of control voltage to the grid of the tube. The value of the resistor is usually made high so as not to "swamp" or "load" the impedance; however, the actual value of resistor R together with the other resistors in the series circuit between the control grid and cathode must not exceed the rated maximum grid-circuit resistance recommended for use with the particular type of tube. Capacitor C is a d-c blocking capacitor, and is used to prevent impedance Z from acting as a voltage divider in conduction with resistor R.



Methods of Feeding AGC-Controlled Stages

AGC Time-Constant Considerations. In a previous paragraph it was mentioned that a dc control voltage obtained from a detector must be filtered to remove any modulation or alternating component of the rectified pulsating voltage; otherwise, if not removed, the modulation or alternating component would be applied to the controlled stages, along with the dc voltage. If any modulation component is fed back to the inputs of the controlled stages, a degenerative effect occurs and, as a result, the percentage of modulation on the carrier signal being amplified by the controlled stages will be reduced accordingly. Also, this effect may introduce considerable amplitude distortion in the output (demodulated) signal.

An R-C circuit is normally used to filter the dc control voltage. The design of a suitable R-C falter, of necessity, may be a compromise; the time constant must be sufficiently long to effectively filter out the lowest modulation-frequency component from the control voltage, and the time constant must be short enough to permit a change in dc control voltage when rapid fluctuations in signal level occur. (Time constants are discussed earlier in this section under Wave-shaping Circuits). Thus, the R-C networks of the AGC circuit influence the ability of the control voltage to follow rapid changes in the strength of the received signal.

A simple AGC system is illustrated in the following simplified schematic diagram. The r-f amplifier, mixer, and first i-f amplifier stages are series-fed and controlled by AGC voltage taken from the detector (demodulator) diode. (The second i-f amplifier stage is self-biased and is not controlled by AGC voltage.) RI is the detector load resistor and capacitor Cl is the r-f bypass capacitor for R1. Resistor R2 and capacitor C2 form an R-C network to filter the AGC voltage obtained from the detector. Resistor R3 and capacitor C3 form a decoupling network for the mixer stage; similarly, resistor R4 and capacitor C4 form a decoupling network for the r-f amplifier stage.

The time constant of an AGC system will depend largely upon the design of the receiving system and the type of transmissions to be received. Typical values of time constants used in communications work range from 0.1 second to 0.5 second. The time constant of an R-C circuit is given as:

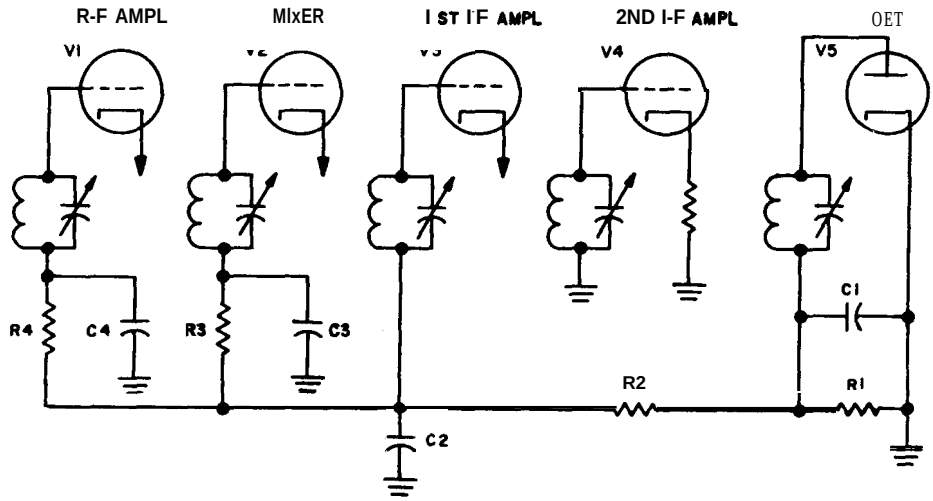
$$TC = RC$$

where:

TC = time in seconds
R = resistance in megohoms
C = capacitance in microforads

However, the typical AGC circuit is usually a complex network, and, because of the action of the detector diode in the circuit, the charge time constant and the discharge time constant of the circuit are not the same. The charge time constant for the AGC system shown in the illustration when the detector diode is conducting and rectified dc output is developed across load resistor R1 can be expressed as follows:

Charge TC = R2 (C2 + C3 + C4) + R3C3 + R4C4



Simple AGC System

The discharge time constant for the system when the detector diode is not conducting (or is conducting less) can be expressed as follows:

Discharge TC = (R4 + R2 + R1)C4 + (R3 + R2 + R1)C3 + (R2 + R1)C2 + RIC1

Note that the discharge path for the network is not the same as the charge path. Furthermore, because detector-load r-f bypass capacitor C1 is usually a small value, the term R1 Cl in the discharge time-constant expression can be neglected because its effect on the over-all constant is small.

Occasionally, the detector load resistor, Rl, is used as a manual volume control for the receiver; the variable contact of the volume control is coupled by means of a capacitor to an audio amplifier stage. When this is the case, the audio coupling capacitor, together with the grid resistor for the succeeding amplifier stage, may have an effect upon the AGC time constant, especially when the volume control is adjusted for maximum volume. Although the effect upon AGC action by the audio coupling capacitor and the grid circuit of the amplifier stage is a design consideration, the effect is usually neglected when making time-constant calculations.

The following example illustrates the difference between the charge and discharge time constants in a typical AGC system. The resistors and capacitors in the simplified schematic given earlier are assigned typical circuit values as follows:

R1 = 1 meg c l = 0.0001 μf
R2 = 1 meg C2 = 0.05 μ f
R3 = 0.1 meg (1OOK) C3 = 0.05 μf
R4 = 0.1 meg (1OOK) C4 = 0.01 μ f

To calculate the charge time constant in seconds:

Charge TC = R2(C2 + C3 + C4) + R3C3 + R4C4
= 1(0.05+ 0.05+ 0.01)+ (0.1 x 0.05) + (0.1 x 0.01)
= 0.11 + 0.005 + 0.001
= 0.116 second

To calculate the discharge time constant in seconds:

Discharge TC = (R4 + R2 + R1)C4 + (R3 + R2 + R1)C3 + (R2 + R1)C2 + RIC1
= (2.1)0.01 + (2.1)0.05+ (2)0.05 + (1)0.0001
= 0.021 + 0.105 + 0.1 + 0.0001
= 0.2261 second

Thus, from the calculations made above, the charge time constant is found to be 0.116 second and the discharge time constant 0.2261 second. From this example it can be seen that if the discharge time constant is too long and the received signal fades rapidly, the output of the receiver will be reduced until the R-C networks have discharged sufficiently to permit the receiver gain to increase and compensate for the drop in input signal level. This inability of AGC voltage to respond and follow rapid changes in input signal level is called ***time delay*** (or ***time kg)*** in the AGC response. The greater the values of R and C, the longer the AGC time constant and the time delay of the AGC system; the smaller the value of R and C,

the shorter the time constant and the time delay. However, if the charge time constant is too short, modulation components which are present on the dc control voltage may cause degenerative effects, (These effects were mentioned earlier in this discussion.) Thus, reducing the values of R and C below some practical minimum for a particular AGC system results in a reduction of filter efficiency; therefore, it is usually necessary to reach some compromise between filter efficiency and time delay in the design of an AGC system.

SIMPLE AGC CIRCUIT (ELECTRON TUBE)

Application.

The basic AGC circuit is used in many communications and broadcast receivers and in certain radar and television receivers, to obtain a dc control voltage which is supplied as an automatic bias for the r-f and i-f stages of the receiver.

Characteristics.

D-C control voltage is obrained directly from a detector (demodulator) diode or from an additional diode used as a half-wave rectifier,

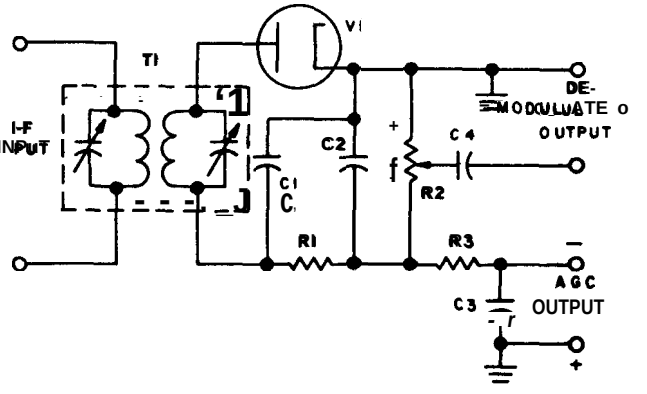
Uses an R-C network as an output filter.

Dc output voltage varies in proportion to r-f input voltage. This circuit has a disadvantage in that weak input signals produce a small output voltage which, in turn, tends to lower over-all receiver sensitivity to weak signals.

Circuit Analysis.

General. The diode detector circuit, described in the Detector Section of this Handbook, and the diode detector with AGC circuit, described in this section, are very similar. Because of this similarity and because it is a simple matter to add a few components and make use of the detector output as a source of control voltage, the functions of the detector and AGC circuit are frequently combined in a single stage. The rectified voltage produced by the detector (demodulator) diode across its load resistance is proportional to the amplitude of the received carrier; therefore, the resulting rectified dc output voltage can be used to control the over-all gain of the receiving system. An R-C network is used to filter the pulsating dc output of the detector and rdso to remove any modulation component which might be present.

Circuit Operation. A combined detector and AGC circuit is illustrated in the accompanying circuit schematic.



Combined Detector (Demodulator) and AGC Circuit

A comparison of this circuit with the typical diode detector given in the Detector Section of this Handbook will show that the circuits are basically the same except for the addition of resistor R3 and capacitor C3.) Transformer T1 consists of tuned primary and secondary windings which are resonant at the frequency of the i-f amplifier; T1 is the output transformer of the i-f amplifier channel in a conventional receiving system.

Electron tube V1 is an indirectly heated cathode-type diode, and may be included within the envelope of a multi-purpose tube; the filament (heater) circuit is not shown on the schematic.
